Foreword

Ernesto L. Schiffrin, CM, MD, PhD, FRSC, FRCPC, FACP

Physician-in-Chief, Sir Mortimer B. Davis-Jewish General Hospital, Director, Hypertension and Vascular Research, Lady Davis Institute of Medical Research, Distinguished James McGill Professor and Associate Chair, Department of Medicine, McGill University, Montreal, Canada; Editor-in-Chief, The American Journal of Hypertension

Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease, edited by Julio A. Chirinos, MD, PhD, arrives to us at a time when the field of arterial stiffness has come full circle from experimental to clinical and therapeutic implications, including its potential applications to patients in the clinic. It is not an easy area of research and clinical understanding for most physicians, because of the physical and mathematical aspects that tend to be beyond their knowledge and typical clinical training curricula. Therefore, a text that fills the gap between biophysics, biology, physiology, clinical application, epidemiology, and therapeutics applied to a range of vessels throughout the body and different clinical conditions is certainly very welcome. In particular, it is important that the text is accessible to experts in different fields at all these levels, thanks to the ability to explain difficult concepts in detail but with clarity and some degree of simplicity, and that is what *Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease* does throughout its two volumes, with homogenous prose despite being multiauthored. Dr. Chirinos has managed to summon a group of writers for all chapters that comprises the "who's who" of the field of arterial stiffness and pulsatile hemodynamics from North America, Europe, Asia, and Australia.

The book is organized in sections that deal with successive aspects of vascular stiffness and its consequences. The first section addresses biophysical principles of pressure, flow, pulsatile hemodynamics, aortic structure, wall stiffness, and hemodynamic function. This is followed by a section on pulsatile hemodynamics of the arterial vasculature and its impact on the left ventricular function, and the microcirculation. The following section deals with the biology of arterial stiffening including associated effects on elastin, inflammation and calcification, and mechanisms of cellular aging, and dysfunction of smooth muscle and the endothelium. The clinical and epidemiological aspects of arterial stiffness and its role in cardiovascular prevention and different disease conditions, including hypertension, obesity, diabetes, heart failure, coronary artery disease, chronic kidney disease, cognitive decline, and pregnancy among others, follow in the next section. The primary aortopathies and conditions associated with low pulsatility such as use of left ventricular assist devices are described next. The following section addresses therapeutic implications of large artery stiffness and effects of exercise, weight control, and drugs, both presently in use and potential new drugs for the future. The last section addresses stiffening of the pulmonary circulation, including pulmonary hypertension.

Throughout this book the different authors manage to present complex concepts in a way that can be understood by the uninitiated, who could be expert in other aspects of this subject matter. Undoubtedly this is an authoritative textbook that will familiarize the biomedical community with the field, and facilitate the use of the knowledge acquired so far on arterial stiffness to improve patient outcomes.

This page intentionally left blank

Preface

The field of arterial stiffness and pulsatile hemodynamics has significantly expanded over the last few decades. Increasingly, epidemiologists, clinicians, engineers, and biologists recognize the importance of large artery stiffening in various disease states. The role of large artery stiffness and pulsatile hemodynamics in cardiovascular aging is also widely recognized. However, there remains a gap between the biophysical and theoretical concepts and clinical practice. The aim of this textbook is to provide a comprehensive reference on arterial stiffness and pulsatile hemodynamics, covering the intersection of clinical, biologic, epidemiologic, and biophysical concepts.

We intend for the audience of this book to be composed of clinical and basic science investigators interested in arterial stiffness, physicians and other healthcare providers, epidemiologists and biomedical engineers. Whereas excellent books are already available covering various aspects of this field, in many cases, these are highly specialized, are mathematically-oriented, are restricted to specific knowledge areas, or deal exclusively with clinical or biologic aspects without discussing hemodynamic mechanisms linking arterial stiffness and pulsatile hemodynamics with disease pathophysiology. Therefore, we intended to produce a book that introduces the interested reader to this field in relatively simple terms but at the same time covers, with reasonable depth, a broad range of relevant topics in biophysics, biology, epidemiology, and clinical medicine.

Despite the increasing recognition of this field, studies on arterial stiffness and pulsatile hemodynamics are often misinterpreted or underappreciated from a clinical standpoint. I believe that a proper interpretation of the field is nevertheless essential for a better understanding of multiple clinical conditions and disease states. One of the barriers to a better integration and data interpretation is that clinicians and biologists tend to be less familiar with the biophysical aspects of this field, whereas engineers naturally tend to be less familiar with the clinical and biologic aspects. Yet, a basic understanding of both is essential to drive the field forward and to adequately interpret available data. There is a need for a reference that: (a) presents complex engineering concepts in a readable format for individuals trained in clinical medicine, biology, or epidemiology rather than engineering; (b) clearly discusses the clinical implications of pulsatile hemodynamics

and arterial stiffness; and (c) provides a comprehensive review of key biologic pathways involved in arterial stiffening. This textbook intends to fill this gap.

Throughout the textbook, we utilize stand-alone basic concept boxes to deal with: (1) biophysics concepts that clinicians would be either be unlikely to be familiar with, but that would be very useful for understanding the topic; (2) clinical or biologic concepts that nonclinicians or non-biologists (i.e., bioengineers) are unlikely to be familiar but that are essential to understand the topic. We also utilize stand-alone "in-depth" boxes to develop more advanced concepts that clinicians or biologists are unlikely to be eager to study in depth due to relatively complex math or biophysics, even though a mathematically oriented person (such as a bioengineer) would find very useful. Stand-alone boxes are mentioned and are useful to understand the main text in the chapters, but should in general not be absolutely necessary to follow its flow. To the extent possible, mathematical principles are explained in the main text without complicated formulas, in a conceptual manner.

The book is organized into six sections. Section I deals with the biophysical and technical principles involved in the measurements and interpretation of pressure, flow, pulsatile hemodynamics, aortic structure, wall stiffness, and hemodynamic function, and is not considered optional but rather essential to better understand the rest of the book. Most of the content in this section deals with *in vivo* assessments, particularly in humans, but a dedicated chapter in this section deals with animal models and *ex vivo* methods to study arterial stiffness. Section II deals with basic anatomic and physiologic considerations, including the hemodynamic role of the aorta, pulsatile hemodynamics in the arterial tree, ventricular physiology, ventricular–arterial interactions (as they relate to both load and myocardial oxygen supply), and the microcirculation. Section III deals with the biologic pathways leading to arterial stiffening and dysfunctional pulsatile hemodynamics, including elastin breakdown and associated processes, inflammation, aortic wall calcification, smooth muscle dysfunction, endothelial dysfunction, autonomic dysfunction, and cellular mechanisms of aging. Section IV deals with clinical and epidemiologic aspects of arterial stiffness and pulsatile hemodynamics, including normal,

supernormal, and early vascular aging, ethnic differences, and the role of arterial stiffness in cardiovascular prevention strategies and in various disease states, such as hypertension, obesity, diabetes, exercise intolerance, heart failure, aortic valve disease, coronary artery disease, age-related cognitive dysfunction, chronic kidney disease, pregnancy related complications, congenital heart disease, and the cardiovascular complications of infectious diseases. Additional chapters deal with relevant aspects of primary arteriopathies and clinical situations associated with low arterial pulsatility (particularly, implanted left ventricular assist devices). Section V deals with therapeutic approaches to improve arterial stiffness and pulsatile hemodynamics, including discussions of standard vasoactive drugs in current use, as well as novel drugs, nonpharmacologic approaches (exercise training, diet), and personalized medicine strategies. Finally, Section VI deals with the pulmonary circulation, with an emphasis on pulmonary arterial stiffening, right ventricular−pulmonary arterial interactions, and pulmonary hypertension.

Throughout this book, we intend to discuss the relevant biophysics, presenting complex engineering concepts in a simplified format. Similarly, we intend to place the importance of arterial stiffness in the appropriate clinical context, ultimately keeping in mind how this field can aid in patient care and development of novel therapies. I have been extremely fortunate to have the support of a large number of internationally recognized experts, who have selflessly contributed their time, effort, and deep expertise to write the various chapters in this book, providing authoritative reviews about the state-of-the-art in their respective topics. I hope that this textbook will help advance the field, that it will be an aid to educators in this field, and that it will contribute to the training of the next generation of investigators dedicated to the study of arterial stiffness and pulsatile hemodynamics.

Acknowledgments

I want to thank the chapter authors for selflessly contributing their time and expertise for the success of this project. I am forever grateful to Melissa, Gabriella, and Daniel Chirinos for their support throughout this project, and to my parents, Julio Chirinos Pacheco and Josefina Medina, for being such inspirational role models. I also want to acknowledge my academic home, the Cardiovascular Medicine Division at the University of Pennsylvania, for strongly supporting my career and the various academic activities that led to the edition of this book. My very special thanks to my colleagues at the University of Ghent (particularly Ernst Rietzschel, Thierry Gillebert, Patrick Segers, and Marc De Buyzere) for many years of wonderful collaboration, and to the North American Artery, ARTERY, Pulse of Asia, and Latin American Artery societies for providing platforms for the advancement of this important field. I am also grateful to the National Institutes of Health (NIH) which supported my work through multiple awards throughout the years, particularly the National Institutes of Aging which provided me with a mid-career development award to study large artery stiffness and arterial aging (K24-AG070459). I am indebted to Dr. Patrick Segers for going above and beyond his chapter writing, providing critical feedback for several other sections of the book. I also want to acknowledge the essential contributions by the many senior investigators, who although did not participate in the book, inspired or motivated many of us, including but not limited to Wilmer Nichols, Nico Westerhof, Michael O'Rourke and Michel Safar, as well as John Cockcroft, who has worked relentlessly to promote the field in Europe and the US, and Alfonso Bryce, Pedro Forcada, Eduardo Barbosa and Enrique Melgarejo, who have done the same throughout Latin America. Last but not least, my gratitude goes to the editorial team at Elsevier for their guidance and help throughout this project.

Introduction

The pulsatile nature of blood flow in arteries has been known since antiquity through palpation of the arterial pulse for early diagnosis of disease.[1] However, the inherent function of arterial elasticity in determining the relationship of pulsatile blood pressure and flow was only able to be studied in recent decades following development of techniques for reliable measurement of hemodynamic parameters. Although it was possible to measure arterial pressure accurately under experimental conditions, flow measurement was much more challenging. Hence, biophysical relationships were initially explored by calculating flow from pressure measurements.[2]

The pivotal, and perhaps the most important, work in the application of the fundamental theory of fluid flow to blood flow in arteries was done in the 1950s by John Womersley, an English applied mathematician. The critical contribution of Womersley was to extend basic knowledge of fluid flow to blood flow in compliant tubes, such as arteries, under an oscillating pressure gradient. This then made it possible to compute blood flow from measured pressure (or more specifically, pressure gradient) and from knowledge of physical properties of blood vessels. He did much of this work in the United States (Wright−Patterson Airforce Base, Ohio) in the latter part of his career, and during the post-war period when there was great expansion of the novel machines (early digital computers) used in the war effort to perform rapid computations of missile trajectories. Womersley made use of these facilities to obtain solutions of the fundamental fluid flow (Navier−Stokes) equations with circular boundaries as applied to arteries. The derivation, theory, and tabulation of basic functions appeared in his in-depth technical report[3] (an officially classified document until recently), which has formed the theoretical basis of much of modern hemodynamics. This gave rise to a seminal monograph on *Blood Flow in Arteries* by his physiologist collaborator Donald McDonald in 1960, with a second edition in 1974, and six other subsequent editions of *McDonald's Blood Flow in Arteries* under the stewardship of Wilmer Nichols and Michael O'Rourke. The seventh edition is currently in press.[4]

This chapter addresses the fundamental concepts inherent in pulsatile hemodynamics, with the view that much has already been written for specialists in the field, but more needs to be done to promote the basic conceptual understanding to a wider audience of scientists, early career researchers, and clinicians. This textbook will contribute significantly to such a challenging task and will impact extensively on translation of the knowledge contained in the various chapters to inform and support scientific investigation and advance clinical practice. This chapter presents the underlying concepts inherent in pulsatile hemodynamics and arterial stiffness through a combination of qualitative description and formal mathematical relations. The field is vast, as is evident by the extensive

number of chapters in this book. Thus, this chapter is by necessity not exhaustive, and to avoid excessive repetition, reference is made to other relevant chapters where appropriate.

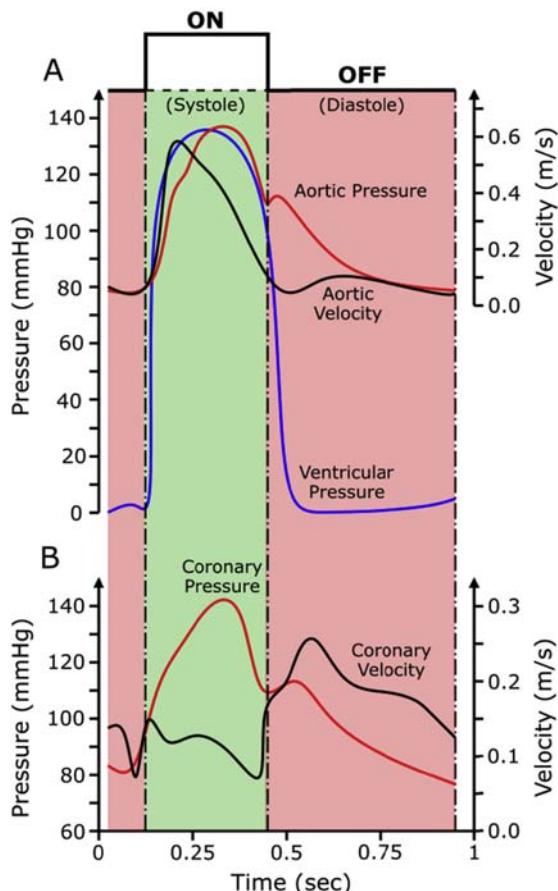
The relevance of arteries to cardiovascular disease is clear, insofar as the contribution of their function as blood conduits: any blockages in the vessel lumen will cause ischemic events. However, the role of arteries as closed elastic vessels which contain blood, and which are under circumferential wall tension and pulsatile load, is not as clear. It is obvious to physical scientists that arteries are more than just passive conduits for blood distribution. They are a key determinant of arterial blood pressure, the biomarker of the mechanical tension in the arterial wall. A healthy heart, in adapting to a stiffening arterial vasculature while preserving cardiac output, will generate increasingly higher pulse pressure, feeding back to a path of increasing degenerative changes in the heart and other target organs, and in the arteries themselves. The evolution of the recognition of the intrinsic role of arterial elasticity associated with hemodynamic pulsatility might be akin to the trajectory in the understanding of the role of the vascular endothelium. There was a time when the endothelium was thought to be a passive lining of blood vessels, until its role was recast to be the stuff of Nobel Prizes[5]!

The basic hemodynamic concepts described in this chapter will aim to support the large amount of material presented in the subsequent chapters to promote the relevance of pulsatility of arterial blood pressure and flow and the important role of arterial stiffness, with the overall translational goal to have measurement of arterial stiffness done alongside the conventional clinical measurement of blood pressure.

Pulsatile phenomena

Pulsatility as an evolutionary requirement for self-sustaining circulatory systems

Hemodynamic pulsatility and elasticity of blood vessels are fundamental phenomena in the intact circulation of self-sustaining organisms. Since the heart is the power source for motion of blood in the circulation, for a self-regulating and self-contained system, there will necessarily be a requirement for a time period when the heart obtains energy (as an "input" quantity) and a subsequent time period when it delivers energy (as an "output" quantity), that is, in machine parlance, a "duty cycle." The heart receives energy mainly from oxygenated blood in the coronary circulation during the time of ventricular relaxation (including the energy-dependent diastolic filling phase and the atrial kick) and transforms the input (chemical) energy into output (mechanical) work, where blood motion in the systemic arterial vasculature occurs due to ventricular contraction

and opening of the aortic valve. In general usage (ranging from machine operation to digital waveforms and neural circuits), the duty cycle is expressed as a percentage of the time for which the system is active. For the heart, this is the time of ventricular ejection, which constitutes approximately 30% of the cardiac cycle.


The "self-sustaining" concept requires a continuous repetition of the process of energy conversion and a general regularity of the duty cycle for optimization of mechanical efficiency. The principal function of the heart to operate as a pump is to convert the potential energy developed as tension in the myocardial fibers to kinetic energy, manifesting as movement of blood in the circulatory system. In terms of energy conversion for motion of blood, it is estimated that the heart is a rather inefficient pump, with an overall mechanical efficiency at rest of some 20%.[6] (Note: if there is no movement of blood in the aorta, the heart, while still being able to beat, will have a pump efficiency of 0%.) While this may appear to be a suboptimal design constraint, it could be considered to translate to an evolutionary advantage, enabling the heart to have a substantial "reserve capacity," allowing for a large operating range in terms of the ability to increase cardiac output through increased contractility and increased frequency of repetition of the duty cycle, that is, an increase in heart rate.

Fundamental association of pulsatility and vascular structure and function

The opening of the aortic valve establishes continuity between the contracting left ventricle as the power source and the aorta as the reservoir of blood, enabling blood distribution throughout the systemic vasculature. The branching structure of the aorta and major arteries constitutes a system of conduits distributing blood to the microcirculatory beds, where the large pulsatility of blood flow due to ventricular contraction becomes extremely low. Because of the essential design of the heart as a pump, the aorta and arterial tree as blood conduits, and the evolutionary requirement for organism self-sustainability, the operation of the duty cycle requires closure of the aortic valve, so that the (mammalian) heart can replenish its energy through oxygenated blood flow in the coronary circulation (most of which occurs in diastole for the left ventricle) and fill the ventricle for the subsequent ejection (Fig. 1.1).

The conduit function of the arterial vasculature enables blood distribution to all tissues of the body. The blood volume is compartmentalized by the branching tree structure in which vessel caliber gradually decreases with successive branching generation. The change in cross-sectional area and branch points generally follows principles of optimality to maximize energy transfer at junctions[7,8] (see Section The arterial vasculature as a distributed system of branching distensible tubes).

Cardiac "Duty Cycle"

FIGURE 1.1 Schematic representation of a cardiac "Duty Cycle" (energy in/energy out), with ventricular pressure, aortic pressure, and aortic flow velocity waveforms (panel A) and coronary pressure and coronary flow velocity waveforms (panel B). Pump energy output (stroke volume) mainly occurs during the ON period (systole) and energy input (oxygenated coronary blood flow) mainly occurs during the OFF period (diastole).

In addition to the conduit function, the aorta and major arteries expand during ventricular systole to store a portion of the ejected blood volume. The degree of expansion is determined by the elastic properties of the vessel wall; that is, the distensibility of the vessel wall will determine the storage capacity of an arterial segment, generally referred to as vessel compliance (C; units of mL/mmHg). This property, together with vessel size, determines the pressure pulse (ΔP; units of mmHg) that is generated by an increase in volume (ΔV; units of mL):

$$\Delta P = \frac{\Delta V}{C} \qquad (1.1)$$

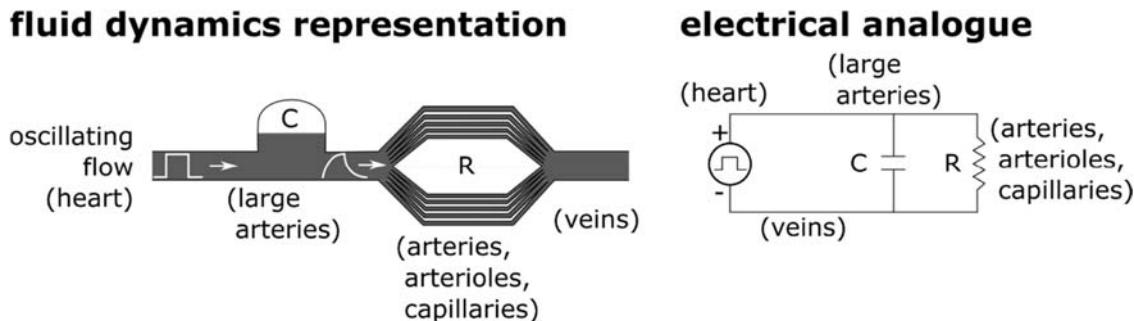
This relationship is fundamental to the interaction of hemodynamic pulsatility and arterial stiffness (when total arterial compliance (TAC) is substituted for C, and cardiac

stroke volume (SV) for ΔV, the resulting ΔP corresponds to the pulse pressure *(PP):* the diastolic-to-systolic pressure difference: *PP=SV/TAC).* Since the stiffness of the arterial wall determines the degree of expansion for accommodating the increase in blood volume, a stiffer arterial wall has a lower compliance, i.e.,

$$arterial\ stiffness \propto \frac{1}{C} \qquad (1.2)$$

Hence, from Eqs. (1.1) and (1.2),

$$\Delta P \propto arterial\ stiffness \qquad (1.3)$$

Eq. (1.3) essentially states that for a given stroke volume, the pulse pressure depends on arterial stiffness. Since stroke volume is reasonably well-regulated during normal healthy aging,[9] this association can explain the underlying mechanism of isolated systolic hypertension, the most common form of hypertension in the elderly, where systolic pressure is elevated in the presence of normal diastolic pressure, that is, an increase in *pulse* pressure.[10] The effect of volume on the distension of the arterial vasculature, and so increase in wall tension, which then manifests as arterial pressure, is partly mediated through modification of kidney function affecting plasma volume.[11] This broadly explains why hypertension has traditionally been the domain of nephrologists.


The concepts underpinning the associations expressed in the above equations are based on steady-state quantities of changes in blood volume and blood pressure during a cardiac cycle. Based on the concept of the duty cycle (as described above), it is assumed that changes in volume and pressure occur as average quantities, that is, there is no involvement of instantaneous time-varying quantities in relation to the duty cycle. Clearly, blood is ejected due to the time-varying contraction of the ventricular muscle, and so the stroke volume ($SV = \Delta V$, mL) is the time integral of the ventricular outflow rate ($Q(t)$, mL/s) during the ejection (systolic) period (Ts, seconds) of the cardiac cycle:

$$SV = \int_0^{Ts} Q(t) \cdot dt \qquad (1.4)$$

The volume in a closed compartment is intrinsically associated with the storage property of the vascular compartment, that is, arterial compliance. When the volume moves with time, the rate of flow ($Q_r(t)$) is associated with a component of the system that offers resistance (R) to flow under pressure ($P(t)$). (This is analogous to Ohm's Law in electrical circuits: pressure analogous to voltage and flow rate analogous to current), i.e.,

$$P(t) = Q_r(t) \cdot R \qquad (1.5)$$

Since R is a scalar quantity, Eq. (1.5) suggests that time-varying pressure and flow profile would be identical.

FIGURE 1.2 The Windkessel model of the systemic vasculature represented as a fluid dynamics model and electrical analogue (RC circuit). The heart ejects blood (fluid or flow or current) in an oscillating manner into the systemic vessels that have capacitance (C) and resistance (R). The Windkessel properties (R,C) convert a square wave input to an output wave profile with exponential rise and fall. The Windkessel model can be expanded to capture characteristic impedance and blood inertia (inductance).

However, at steady state and at a given instant of time, the total flow from the left ventricle $(Q(t))$ consists of a component which is stored $(Q_c(t))$ due to the elastic expansion of the arterial wall constituting arterial compliance, and a component $(Q_r(t))$ flowing through the peripheral resistance:

$$Q(t) = Q_c(t) + Q_r(t) \qquad (1.6)$$

If R represents the total peripheral resistance and C the total compliance, or the arterial storage capacity, from Eqs. (1.1)−(1.6), an expression can be obtained where the relationship between aortic pressure and aortic flow is determined by an exponential function (which can be estimated during diastole when flow is zero) and the combination of R and C. That is, for a given time-varying flow profile $(Q(t))$, the resulting time-varying pressure $(P(t))$ is a function of the product of R and C (R times C has units of time (sec) and is related to the exponential time constant τ ($\tau = RC$), the time taken for the pressure to decrease by 63% of an initial value).

For a given value of R and C (and so of the time constant, τ), the pressure decay during diastole $(P_d(t))$ is given as

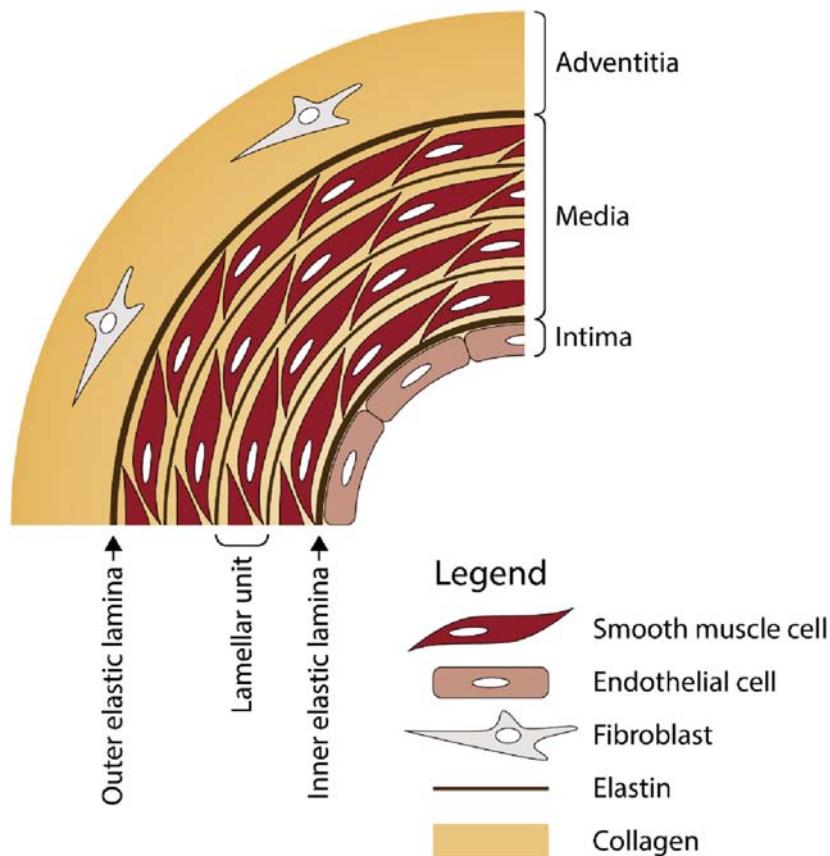
$$P_d(t) = P_0 \cdot e^{-t/\tau} \qquad (1.7)$$

where P_0 is the value of pressure at the beginning of diastole.

Since during diastole there is no ventricular outflow, arterial pressure is related to $Q_r(t)$ and $Q_c(t)$ and peripheral resistance and arterial compliance, respectively, hence the value of the time constant becomes a determining factor for pulse pressure; for a given peripheral resistance, the smaller the compliance (C), that is, the higher the arterial stiffness, the shorter the time (τ) to release the volume of blood stored during systole, and so pressure drops more rapidly.

A conceptual representation of this storage function of the arterial vasculature has conventionally been related to the inverted dome of a fire engine, where the intermittent input of volume of water is converted to a quasi-steady-state hose outlet due to the storage properties of the dome—a model conventionally known as the Windkessel[12] (Fig. 1.2).

As described in detail in Chapter 3, the Windkessel model offers a useful approach to illustrate basic concepts of the effects of arterial stiffness and peripheral resistance on blood pressure and flow, and can be further formalized to describe the concept of reservoir pressure.[13] However, it is based on a "lumped parameter" approach in which there are no physical dimensions, and the parameters only exist as scalar mathematical quantities; that is, a "zero-dimension" model. Clearly, the distributed structure of the arterial tree will involve the propagation of the ventricle's energy output in terms of blood pressure and flow over different path lengths from the aortic valve to the periphery of the systemic vasculature. Indeed, the true relationship of pressure and flow in the three-dimensional structure of blood vessels as elastic conduits is complex and extremely challenging to be completely and accurately described, as this would require the complete solution of the Navier−Stokes equations of fluid flow (requiring powerful computational algorithms). However, very good approximations can be obtained by considering blood flow in the axial direction and averaged over the entire arterial cross section.[14] This approach has been shown to be adequate to describe the relationship of blood pressure and flow as time-varying quantities traveling in one dimension, that is, along the axial length of arterial segments, resulting in approaches using one-dimensional models.[15]

Basic principles related to hemodynamic pulsatility and arterial stiffness will be addressed in subsequent sections of this chapter using the approach of one-dimensional flow and propagation of pulsatile energy as periodic wave of pressure and flow, with further details addressed in other chapters (Chapters 3, 7 and 11).


Elastic vessels

Hemodynamic pulsatility and structure of the arterial wall

As distensible conduits, arteries are required to expand and recoil during the cardiac cycle and withstand large ranges of intraluminal pressure (arterial pressure in weightlifters can exceed 480/350 mmHg [systolic/diastolic blood pressure] during a double-leg press[16]). The distensible properties enable the storage function, which determines the degree of pulsatility present throughout the arterial tree, and the tensile properties determine the ability to withstand high pressures. The elastic and tensile properties are largely determined by the two main load-bearing components in the arterial wall: elastin and collagen, respectively.

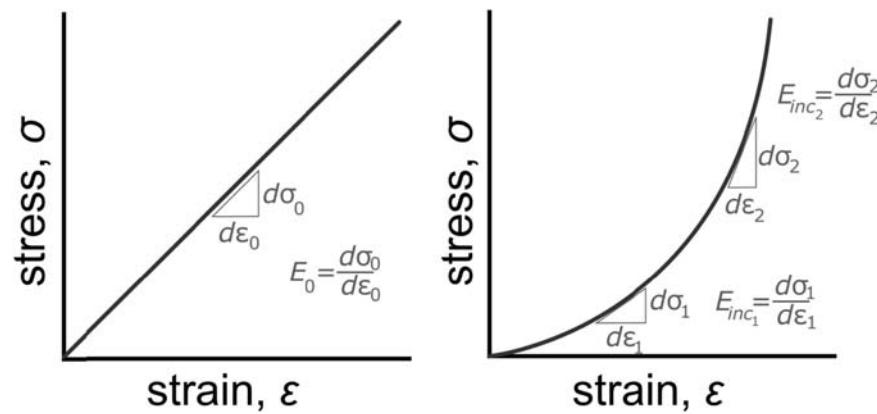
Elastin and collagen are arranged in concentric layers forming a lamellar structure in the arterial media (Fig. 1.3). In the human aorta, there are approximately 60 lamellae,[17] with the number decreasing with vessel caliber. The lamellar unit has been suggested to be a fundamental entity of arterial structure and function, with the tension per lamellar unit being remarkably constant across a broad range of mammalian species.[17,18]

The mechanical properties of the arterial wall are determined mainly by the material components and are characterized by the conventional material response to an applied force, that is, the *stress/strain (σ/ε)* relationships, (where σ is the applied force/unit area in the same direction, and ε is the relative change in length $(L_1 - L_0)/L_0$) in a given direction). Since elastin and collagen constitute approximately 30% and 50%, respectively, of the (dry) weight of the aortic wall,[19] and this is fairly consistent across a large range of animal species,[20] the stress/strain characteristics will be determined mainly by these two components. Hence, at low levels of resting stress (when the wall is subjected to low loading conditions), the amount of stretch is mainly determined by the elastin protein, whereas at high levels of resting stress, the amount of stretch is determined by the collagen protein. In terms of functional performance of arteries, this property is structurally advantageous since the vessel can expand easily at low pressure due to the distensible properties of elastin (and so have increased storage capacity). It will also have a high yield strength (the material property related to the point when there is plastic deformation of the material) at high pressure due to the strong tensile

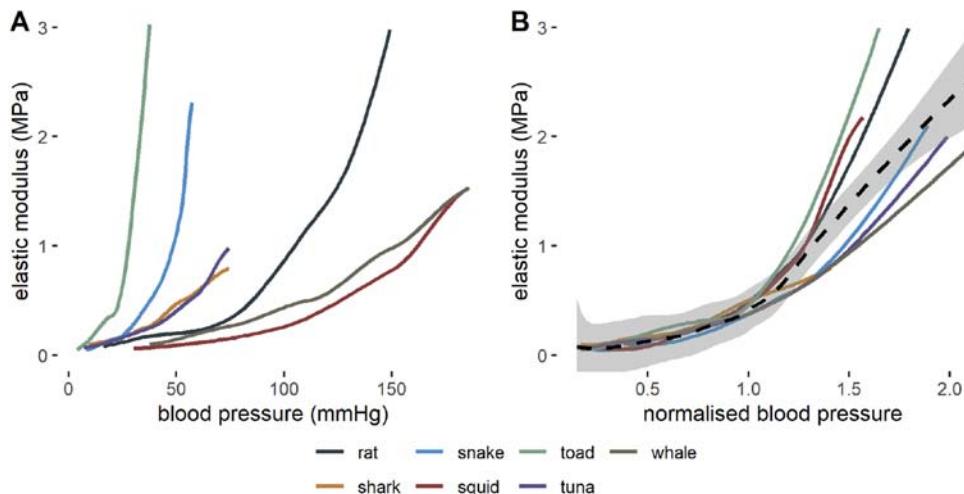
FIGURE 1.3 Schematic illustration of the cross section of the arterial wall showing the components of the adventitia, media, and intima. The number of lamellar units vary with size of vessel and species (e.g., human aorta: ∼ 60; rat aorta: ∼ 5); however, the tension per lamellar unit is quite similar.[17,18]

properties pertaining to collagen, but with a reduced storage capacity, since collagen is much less distensible than elastin, being some 100 to 1000 times stiffer than elastin.[21] The structural properties of the artery wall also determine the static and dynamic (frequency-dependent) elastic properties.[22,23] The dynamic elasticity is seen as a phase delay between pressure and diameter signals and is a measure of the viscoelasticity of the arterial wall.[24] Wall viscoelasticity implies that the wall itself has viscosity, whereby stretch causes some friction that dissipates a small amount of energy as heat, whereas a purely elastic vessel would be one that does not dissipate energy.

The stiffness of a material at a given condition of stress and strain can be defined as the incremental elastic modulus or incremental Young's modulus (E_{inc}): the ratio of incremental stress ($\Delta\varepsilon$) and strain ($\Delta\sigma$) when stretched uniaxially (Eq. 1.8). [*Note 1*: E_{inc} quantifies the stiffness of the wall material and is, hence, a material stiffness metric. This contrasts to structural stiffness metrics such as pulse wave velocity, which quantify the structure of the artery as a whole. This important difference is elaborated in Chapter 9, Box 9.1; *Note 2*: Although E_{inc} is the most commonly used material stiffness metric in clinical studies, other material stiffness metrics that exist, especially in engineering/modeling studies, may be more appropriate. See Chapter 9, Box 9.5].

$$E_{inc} = \frac{\Delta\sigma}{\Delta\varepsilon} \qquad (1.8)$$


If this ratio is the same for all conditions (i.e., if stress and strain relate linearly), the material has a constant value of E, that is, it is a linear elastic material (or Hookean) (Fig. 1.4). However, given the different structural properties of elastin and collagen, E_{inc} cannot be constant; it is low when the artery is distended at low pressure and high when distended at high pressure. Hence, E_{inc} varies with

loading and depends on where the operating point is on the stress/strain curve; that is, arteries become stiffer with increasing pressure (Fig. 1.4). The implications of this property are profound: for the same blood volume stored in an artery during ventricular ejection, the pulse pressure increases with increasing distending pressure. If this is applied to the concept of hypertension, the higher pulsatility associated with higher intraarterial pressure will lead to further arterial deterioration, which can reduce wall distensibility, increase arterial stiffness, and lead to a further increase in pulse pressure. This, of course, constitutes a type of positive feedback or a vicious cycle potentiating compromised function of the arterial vasculature.[28] In this context, the degree of pulsatility associated with the effect of age on large arteries will increase degeneration of load-bearing components due to increase in peak stress.[21]


Pressure dependence of arterial stiffness: an essential ingredient for optimal arterial design

The structural characteristics of the load-bearing components of the arterial wall—elastin and collagen—are responsible for the nonlinear (pressure-dependent) stiffness of arteries. Similar to the relatively constant tension per lamellar unit found across a broad range of species,[17] the elegant work conducted by Robert Shadwick in a range of species (from rat (~ 0.45 kg) to whale ($\sim 40,000$ kg)) concluded that pressure dependence of arterial stiffness is a fundamental property of arterial design, and that it is present in all vertebrates and invertebrates with a closed circulatory system.[29] A remarkable similarity is seen when the relationship is normalized for normal operating pressure of different animal species (Fig. 1.5).

This property of blood vessels is a fundamental determinant of the principal function of arteries as conduits to provide a reliable blood supply to peripheral organs and

FIGURE 1.4 Stress (σ) and strain (ε) relationships illustrating linear and nonlinear elasticity. For a linear elastic material, the elastic modulus (E_o, slope of curve) is constant at all level of stress and srain (left panel). For a nonlinear elastic material, the elastic modulus (E_{inc}) increases with higher stress or strain (right panel). The nonlinear elastic properties of arteries are responsible for the pressure dependence of arterial stiffness.

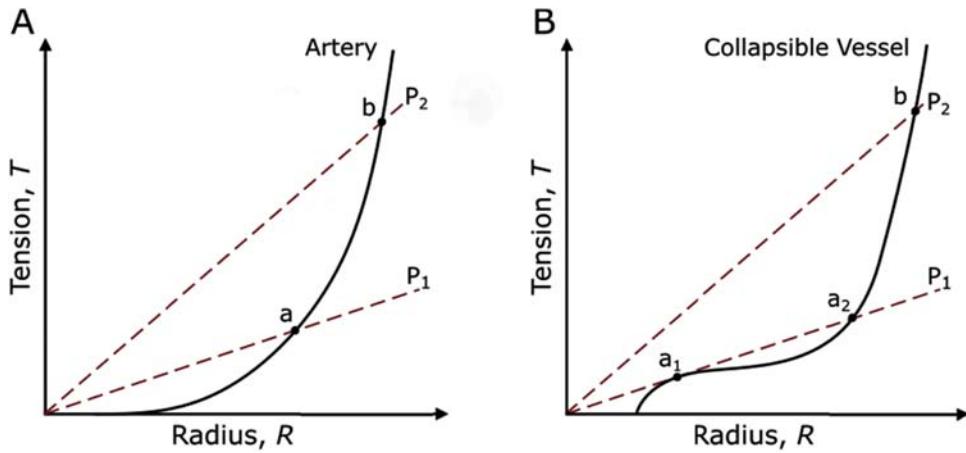
FIGURE 1.5 Pressure dependence of elastic modulus of aortic tissue in a range of species. The degree of dependency (slope) varies with each species (A). However, the slope becomes quite similar and the variation becomes markedly reduced when pressure (units in the *x*-axis) is normalized with the normal operating pressure of each species (B). This suggests a fundamental structural property of arteries that is characteristic of the evolutionary development of the circulation. Black dashed line shows average across the listed species. *Data from Shadwick RE. Mechanical design in arteries.* **J Exp Biol**. *1999; 202(Pt 23):3305−3313.*

body tissue. The property also applies to veins as collapsible tubes (see Section Fundamental importance of pressure-dependent arterial stiffness (nonlinear elasticity) for arteries), with the veins comprising the main capacitive component of the circulatory vasculature where the majority (approximately 75%) of the blood is contained.[30]

Fundamental importance of pressure-dependent arterial stiffness (nonlinear elasticity) for arteries

The word "artery" derives from the original Greek meaning of "αρτηρία" for "air duct." This was probably because when blood vessels were examined postmortem, arterial conduits were generally empty, whereas veins were generally filled with blood or collapsed. The fundamental difference between the two is that arteries never collapse when unloaded and always remain open due to the presence of residual stress in the wall.[31] In terms of evolutionary development, this important property of structure and function ensures reliable movement of blood in the arterial vasculature even with a low transmural pressure. It is of interest to understand how this property is intrinsically related to the obligatory property of nonlinear elasticity, as it is also a basic determinant of the relationship between pulsatile hemodynamic phenomena and arterial stiffness.

Arterial segments can be considered as uniform circular elastic tubes subjected to an internal distending (transmural) pressure (*P*). When inflated to a specific radius (*r*), the distending (radial) force on the wall is balanced by the circumferential tension (*T*) that is supported by the circumferential lamellar structure of elastin and collagen. For a thin-walled vessel, that is, the magnitude of the wall

thickness (*h*) is much smaller than the radius ($h \ll r$; hence *r* can either be the internal or external radius), *P* and *T* are related by Laplace's Law,


$$T = P \cdot r \qquad (1.9)$$

The circumferential wall stress (*σ*), also known as hoop stress, is the tension per unit wall thickness,

$$\sigma = T/h \qquad (1.10)$$

Eq. (1.9) means that a plot of *T* versus *r* will be a straight line with a slope of *P*. As described previously, the structural attributes of elastin and collagen, the proteins which mainly take up the wall tension, also produce the nonlinear elastic properties of the wall. The plot of *T* versus *r* would thus be curvilinear. Hence, the operating point of the vessel would be the intersection of the straight line (*P*) and the *T*-*r* curve. That is, there is always a unique combination of *P*, *r*, and *T* (Fig. 1.6A). This is not the case for a collapsible tube (such as a vein) where the straight line (*P*) and the *T*-*r* curve can intersect at more than a single point (Fig. 1.6B).

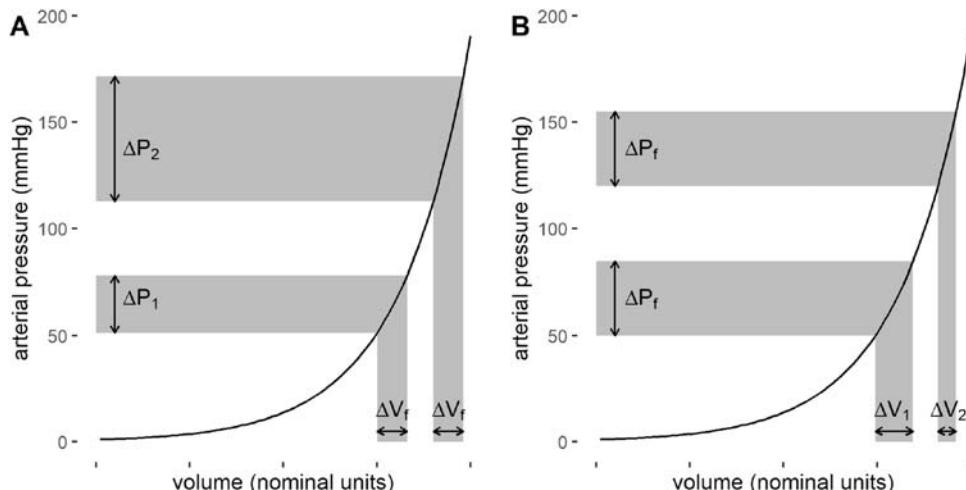
The vascular properties illustrated in Fig. 1.6 indicate that the specific component structure of the arterial wall that gives arteries the property of nonlinear (or pressure-dependent) wall stiffness also endows them with the ability to have a stable operating function (single intersecting point on the *T*-*r* curves, Fig. 1.6A) and thus cannot collapse, as opposed to the instability of collapsible tubes (multiple intersecting points, Fig. 1.6B). [In this context, the notion of "stability" refers to the vessel having only a single possible radius value for a given pressure, whereas "instability" refers to the vessel having more than a possible single value of radius for a given pressure.] It is this


FIGURE 1.6 Schematic illustration of tension/radius relationships for a non-collapsible (A, artery) and collapsible vessel (B). In both cases, the Laplace relationships have linear slopes equivalent to the distending pressures (e.g., P_1 and P_2). However, for the artery, there is always a unique operating point where the pressure curves intersect with the T-R curve (indicating stability of vessel caliber at P_1 and P_2), whereas there can be more than one intersecting point (a_1, a_2) for the same pressure value for the collapsible vessel (indicating stability of vessel caliber at P_2 [with a single possible radius] but instability of vessel caliber at P_1 [with more than one value of radius]).

property of increased stiffness with pressure that also protects arteries from developing aneurysms,[32,33] which of course can develop when the wall tensile properties degenerate.

Influence of pressure-dependent arterial stiffness on hemodynamic pulsatility

From Section Fundamental association of pulsatility and vascular structure and function, it was shown that for an arterial segment, the volume storage capacity (vessel compliance) is inversely related to the structural stiffness of the artery wall. Hence, the increase in structural stiffness with increasing pressure would reduce the storage capacity. Since the normal operating heart can accommodate to

changes in vascular load to eject the required stroke volume for adequate perfusion, the contracting ventricle has sufficient power to force the ejected blood into the vasculature. Although the heart is essentially a power source for the full operating range,[34] under normal operating conditions and to a reasonable approximation, it can be considered a constant flow source (this would strictly apply to a non-diseased heart or in the case where inherent contractility is not reduced). This means that for a constant stroke volume (ΔV) delivered to the arterial vasculature by the ejecting ventricle, the resulting increase in pressure (ΔP) depends on the position of the operating point of the T-R-P curve shown in Fig. 1.6A, or the pressure−volume curve (Fig. 1.7). Hence, the same characteristics of nonlinear

FIGURE 1.7 (A) Schematic illustration of increase in pulse pressure (ΔP) for a fixed change in volume (ΔV_f) on a P-V nonlinear curve at low and high pressure (normal heart). At high pressure, the same fixed volume change causes a larger pulse pressure change ($\Delta P_2 > \Delta P_1$). (B) Schematic illustration of a fixed pulse pressure (ΔP_f) for a change in volume on a P-V nonlinear curve at low and high pressure. ΔV is lower at higher pressure (failing heart, $\Delta V_1 > \Delta V_2$).

elasticity that ensure stability of operation and protect against aneurysm development also have the consequences of increasing pulsatility with increasing pressure throughout the arterial vasculature (Fig. 1.7A).

Although pressure-dependent elasticity is associated with increased pulsatility with a normal heart that does not change its output with increasing arterial pressure, it is not the case for a failing heart, in which myocardial contractility (and therefore ventricular ejection) is sensitive to afterload, and so will decrease with increasing arterial afterload. In this case, the heart cannot be considered a constant flow source, but rather a pressure source, whose output is largely determined by afterload. Thus, for a failing heart, the nonlinear elasticity characteristics do not necessarily result in marked increase in pressure pulsatility (Fig. 1.7B), but may rather result in decreased stroke volume and, hence, tissue perfusion.

The arterial vasculature as a distributed system of branching distensible tubes

Structural implications of arterial branching

The arterial tree, like any branching structure in nature, is subject to fundamental laws underpinning function and form as exquisitely described in D'Arcy Thompson's seminal monograph in the early 20th century.[35] In structures where there is energy transfer across junctions, such as fluid flow, the branching generally obeys principles of optimality, such as minimization of energy losses at branch points. In the vascular system, this principle was developed by Cecil Murray in 1926, where it was applied to the distribution of blood volume[7] and branching angles.[8] This seminal work gave rise to the well-known Murray's Law, which states that the volumetric flow rate (Q) (assumed to be laminar flow) is related to the cube of vessel diameter (D),

$$Q = k \cdot D^3 \qquad (1.11)$$

where k is a proportionality constant.

At branch points, conservation of mass requires that the sum of volumetric flow in the branches ($Q_1 + Q_2$) equals the flow in the parent branch (Q_0). Hence, for a bifurcation,

$$D_0^3 = D_1^3 + D_2^3 \qquad (1.12)$$

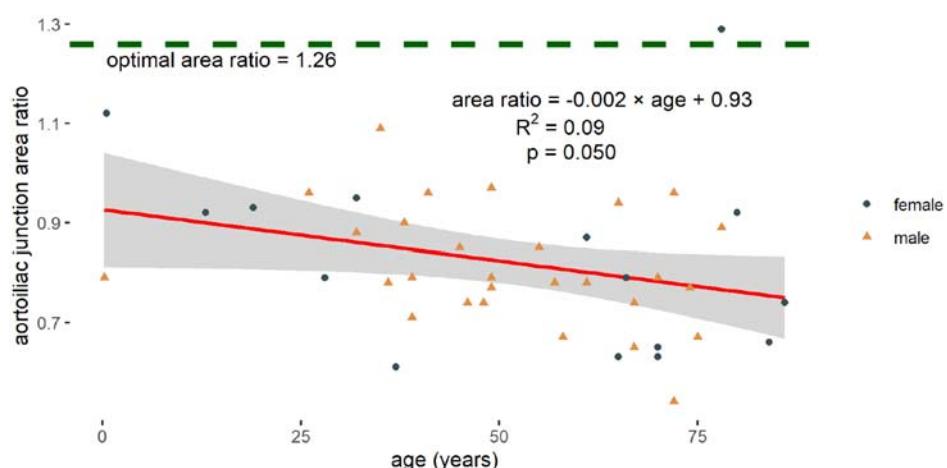
For a symmetrical bifurcation defined by Eqs. (1.11) and (1.12), the optimal (and theoretical) branching angle between the daughter branches is 75 degrees.[8]

Murray's Law assumes complete Poiseuille (laminar) flow, which clearly is not always true in real biological systems, where flow might be disturbed at junctions or at irregular surfaces. There has been vigorous activity in theoretical studies of optimality in attempts to understand how much the exponent of 3 in Eqs. (1.11) and (1.12) varies in real bifurcations.[36,37] Some studies suggest a range between 2.33 and 3.0.[38] However, the underlying basic phenomena inherent in Murray's Law are evident where, in broad terms, similar principles of optimality occur in other branching structures in nature with a requirement for maximizing efficiency of fluid transport, as occurs for blood flow in arteries or transport of water in plants.[39] In relation to pulsatility phenomena, the underlying optimality principles of branching are relevant in the context of energy transport at branch points. According to Eq. (1.11), the energy transfer would be optimal and so there would be minimal reflected energy at individual branch points. That is, the closer the exponent in Eq. (1.11) is to 3, the greater the efficiency of energy transfer at minimum energy cost. In blood flow in arteries, the energy is carried by the time-varying quantities of pressure $P(t)$ and flow $Q(t)$, and the total work (W) during a cardiac cycle (of time T_c) can be quantified by the integral of their instantaneous product,

$$W = \int_0^{T_c} P(t) \cdot Q(t) \cdot dt \qquad (1.13)$$

If there are optimal branching conditions, all (or most) of the energy that arrives at the bifurcation is transmitted; that is, the junction is said to be matched. However, if the conditions are not optimal, thus there is mismatch at the junction, not all the energy is transmitted, and some is reflected. This would cause an increase in net W at the upstream end of the junction and would be associated with an increase in pressure and a decrease in flow. Hence, because of the essential pulsatile function of the heart (see Section Pulsatility as an evolutionary requirement for self-sustaining circulatory systems), the phenomenon of reflection of energy at any location of mismatch in the arterial vasculature usually manifests as increases in the pulsatile component of arterial pressure.

Notwithstanding the obligatory branching structure of the arterial vasculature, and the variability around the principles of optimality underlying Murray's Law, it is of interest to quantify the effect of branching on the phenomena of reflection and pulsatility.

The theoretical and analytical aspects of reflection of the propagating arterial pulse are treated in greater detail in a subsequent chapter (Chapter 11) dealing specifically with wave reflection. However, in terms of the relevance of branching, it is useful to consider a major branch point in the aortic trunk: the aortoiliac junction. For a symmetrical junction with two daughter branches, from Eq. (1.12), the theoretical diameter of the branch vessels would be 0.794 times the diameter of the parent branch. Hence, the optimal area ratio is 1.26 (ratio of areas of the sum of individual branch vessels to area of parent branch). [*Note*: These


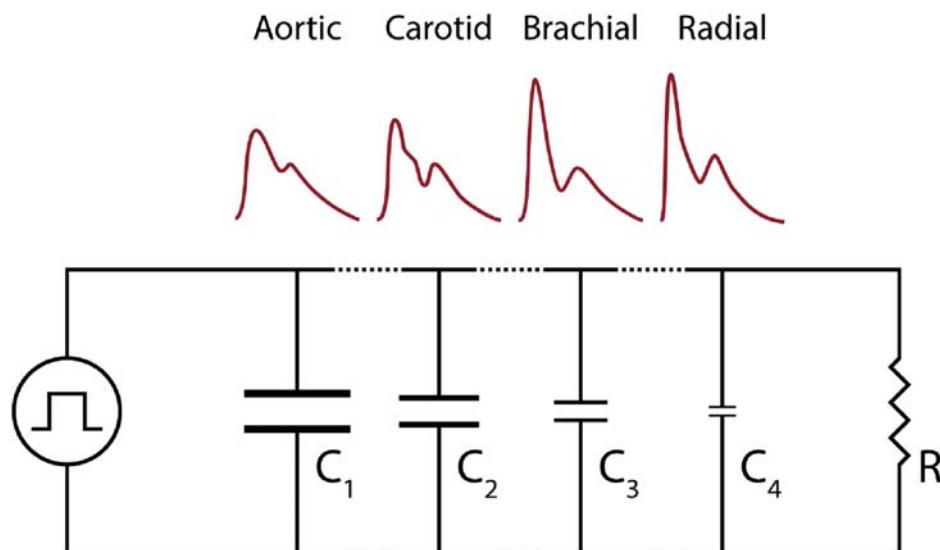
theoretical considerations refer to a branching structure with uniform material properties for parent and daughter vessels, i.e., similar material stiffness and wave speed.] The aortoiliac area ratio (ratio of sum of area of iliac arteries to area of the abdominal aorta) over an age-span of 2 months to 86 years[40] shows that the optimal area ratio of 1.26 is approached only in the very young (Fig. 1.8). The overall trend is a decrease with age from an average of 0.96 in the first decade to 0.77 in the ninth decade, that is, an age-related increase in structural mismatch. These structural changes would imply an increase in impedance mismatch in the human aorta with age. However, this may be explained by compensatory mechanisms of different age-related changes in stiffness of central and peripheral arteries leading to a reduction of stiffness gradient[41,42] resulting in reduced wave reflection. This was confirmed in the same study showing decrease in the magnitude of computed reflection coefficient at the aortoiliac junction with age.[40]

Since arteries are distensible conduits, the degree of matching in relation to energy transfer is determined by the geometric and elastic properties of the parent and branch vessels. Geometric and elastic properties determine vascular impedance, that is, the resistance of the vessel to pulsatile flow (see Section Vascular impedance). So, variability of change in vessel geometry or deviation from the optimal value can be offset by changes in elastic properties to increase the matching properties.[43] This phenomenon has been confirmed by theoretical studies showing that reflections at bifurcations that have large area ratios can only be minimized by larger increases in arterial stiffness of the branches in relation to the parent vessel.[44] This finding

is consistent with the generally accepted phenomenon that arterial stiffness[45] (and so pulse wave velocity,[46] discussed in detail in Section Wave speed and pulse wave velocity) increases with distance along the aortic trunk and peripheral conduit arteries. Although there are other significant factors such as geometric tapering,[45] it is tempting to speculate that, to some extent, the increase of arterial stiffness with distance along the arterial tree might be driven by the underlying optimality principles of minimization of energy cost functions as are inherent in the original concepts of Murray's Law[7,8] and common to branching structures present in nature.[39]

Structural and functional effects of arterial branching on pulsatility phenomena—implications for measurement of blood pressure

In the systemic and pulmonary vasculature, arterial branching generally implies that with each successive generation of branching, there is a decrease in individual vessel caliber, increase in total cross-sectional area, increase in relative wall thickness (ratio of wall thickness to diameter), and increase in structural arterial stiffness. In large conduit vessels, there is also a certain degree of geometric and elastic "tapering," that is, the vessel caliber decreases gradually with axial distance and the arterial wall becomes progressively stiffer.[45] The overall effect of the geometric and material property changes is that there is a graded change in geometric and elastic uniformity from the single uniform segment of the ascending aorta to the peripheral organs and body tissues.

FIGURE 1.8   Change of aortoiliac junction area ratio with age. Dashed line: value of area ratio for optimal branching of a symmetrical bifurcation (area ratio = 1.26). *Data from Greenwald SE, Carter AC, Berry Cl. Effect of age on the in vitro reflection coefficient of the aortoiliac bifurcation in humans. Circulation. 1990; 82(1):114−123.*


The stroke volume ejected into the aorta will be partitioned throughout the arterial tree according to the branch dimensions. Since the storage capacity of any segment will affect the specific relation of stored volume and associated change in pressure (as expressed by Eq. 1.1), any changes in relative volume at different generations of branching will manifest as a change in pressure. Thus, the relative changes in volume (ΔV) for a given resting volume (V_0) will normalize for the change in vascular caliber, and so the effect of change in relative storage capacity of vessels can be compared along the arterial tree. That is, when the storage capacity of the vessel (compliance, $C = \Delta V/\Delta P$) is normalized for the resting volume (V_0), the relative changes can be compared across different vessel sizes in terms of distensibility. Hence, from Eq. (1.1),

$$distensibility = \frac{\Delta V/V_0}{\Delta P} \qquad (1.14)$$

Given the geometric and material property changes, distensibility decreases from proximal to distal segments along the arterial tree. This reduction in distensibility (i.e., a reduction in the relative storage capacity of the distributed component of stroke volume) will inherently be associated with an increase in pulse pressure. Hence, the implication of this conceptual construct is that, in simple terms of storage capacity of vessels, the pressure pulse generated in the ascending aorta will be amplified along the arterial branching structure toward the periphery. As explained in Section Fundamental association of pulsatility and vascular structure and function, this explanation is confined to a "lumped parameter" representation. However, the distributed system can be represented by a series of essentially uniform segments with altered geometric and elastic properties as illustrated in Fig. 1.9 and still applies when considering effects of wave propagation (analogous to transmission lines, in which case the lumped parameter segments have an infinitesimally small "length").

The arterial vasculature exhibits reducing storage capacity with increasing distance from the heart, as well as changes in geometric and elastic material properties, which in turn affect the speed of the traveling pulse, wave transmission, and reflection. These phenomena constitute the basis of underlying mechanisms for the difference in pulse pressure between the central aorta and peripheral arteries. In large arteries, there is minimal change in mean pressure with distance from the heart. Hence, when there is a change in amplitude of the pressure in the presence of no change in mean pressure, by necessity there needs to be a change in shape of the pressure waveform. This change in waveform morphology can thus be exploited to obtain mathematical associations between central and peripheral pressure with knowledge of the transmission properties of the peripheral arterial vasculature. This has been successfully done to provide a means of estimating central aortic pressure from the calibrated peripheral arterial pulse[47] (see Chapter 2).

FIGURE 1.9 Schematic illustration of the changes in arterial compliance with distance from the heart (nominally aortic, carotid, brachial, and radial artery sites) and the resultant amplification of the pressure pulse $C_1>C_2>C_3>C_4$. This illustrates the concept of a tube in which the compliance per unit length decreases with distance (analogous to a nonuniform electrical transmission line in which characteristic impedance gradually increases with distance from the input). This concept can explain how the pulse pressure can increase with distance from the input while the mean pressure remains essentially the same.

Wave propagation phenomena—pulse wave velocity and arterial stiffness

Wave speed and pulse wave velocity

Wave speed

Pulsatility of pressure and flow in the arterial vasculature can be investigated by considering the role of material properties of a distributed system of elastic tubes on wave propagation. If an elastic tube is filled with fluid and a pressure pulse is applied to the fluid at the input of the tube, the disturbance, produced as a local expansion of the proximal wall, will travel downstream with a speed determined by the bulk modulus of the tube material and the density of the fluid. For any material, the bulk modulus is a description of the deformation characteristics, that is, of the stiffness of the material (volume deformation occurs due to an applied force and conservation of mass). Hence, if an increase in pressure (dP) on a material causes a relative decrease in volume (dV/V), the bulk modulus (K) is defined as

$$K = \frac{dP}{dV/V} \qquad (1.15)$$

[*Note*: this is similar to the ratio of stress/strain for material stiffness].

In an arterial segment, the applied force (dF) which moves the blood obeys Newton's Law of motion, where force is the product of blood mass (m) and acceleration (a),

$$dF = m \cdot a \qquad (1.16)$$

If the force is applied over a very short time interval, effect of movement of the proximal blood mass against the inertia of the downstream blood mass is to expand the size of the tube in the radial direction, and the volume of the blood mass which is accelerated can be assumed to constitute the same volume expansion of the vessel segment (dV).

Hence,

$$dF = \rho \cdot dV \cdot a \qquad (1.17)$$

where ρ is blood density.

Since the force (dF) is applied at the cross-section of the tube with an area A, dF can also be written as $dP \cdot A$. Hence, from Eq. (1.17),

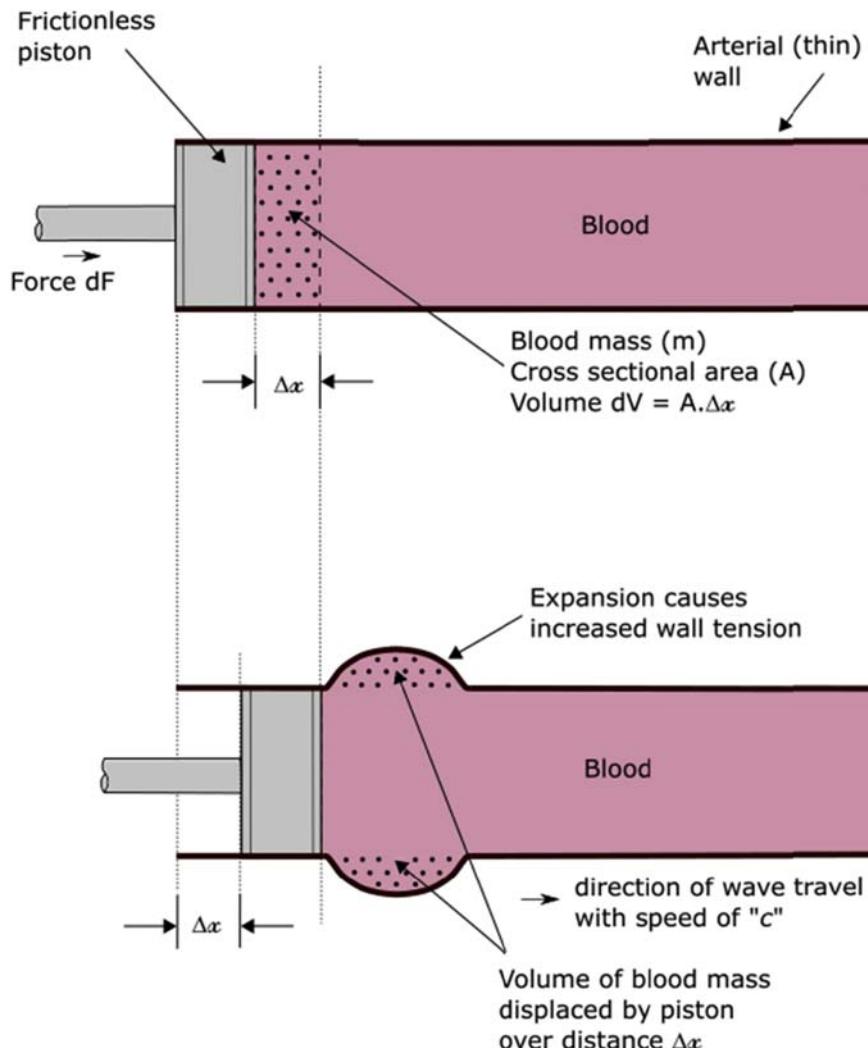
$$a = \frac{dP}{dV} \frac{A}{\rho} \qquad (1.18)$$

If the blood mass is assumed to be accelerated over a small distance Δx, and the blood mass is contiguous with the vessel wall, the wall will have the same acceleration as

the blood mass. Both sides of Eq. (1.18) can also be multiplied by Δx,

$$a \cdot \Delta x = \frac{dP}{dV} \frac{A \cdot \Delta x}{\rho} \qquad (1.19)$$

The product $A \cdot \Delta x$ is the volume (V) of the blood mass being accelerated. Since the material properties are related to the pressure/volume relationships of the elastic tube (arterial segment), Eq. (1.15) can be applied to Eq. (1.19),

$$a \cdot \Delta x = \frac{K}{\rho} \qquad (1.20)$$


The term $a \cdot \Delta x$ has units of velocity squared. Hence, replacing $a \cdot \Delta x$ by "c^2," and taking the square root of both sides,

$$c = \sqrt{\frac{K}{\rho}} \qquad (1.21)$$

The term c is designated as "wave speed" (c is conventionally used for this quantity as it refers to "celerity," meaning "velocity" or "swiftness of movement"; it is the basis of the term "acceleration"—change in celerity), a scalar quantity determined by the bulk modulus (overall stiffness) of the vessel wall and blood density. The stiffness of the wall will determine the wall tension due to the applied pressure (Laplace's Law, Eq. 1.9). The wall tension in turn determines the restoring force against the fluid mass that consists of the inertial opposition to the same restoring force supplied by the wall tension.

The above conceptual derivation of the origin of wave speed is illustrated in Fig. 1.10.

Eq. (1.21) is the classical representation of wave speed in a medium. In a closed system, such as the elastic arterial conduits, the disturbance (or wave) generated by the applied pressure at the aortic root can travel along the arterial wall (an elastic material) or through the blood (which is an incompressible fluid). In both cases, the value of K is not the same, being much higher for blood ($\sim 2.6 \times 10^8$ N/m^2) than for arteries ($\sim 10.6 \times 10^4$ N/m^2). However, blood is essentially incompressible. This implies that compression waves would involve very little energy (it is much easier for the heart to expand the aorta, than to compress the blood therein). Therefore, for practical purposes, the relevant K for the arteries is that arising from the arterial wall and, hence, the relevant velocities are in the order of 10 m/s. (In the blood the disturbance travels at the speed of sound, approximately 1570 m/s; this high-speed transmission of a system disturbance is a fundamental property of the ballistocardiogram, which can also provide hemodynamic information.[48])

FIGURE 1.10 Schematic illustration of a pulse wave generated in the wall of an elastic vessel (artery). A force (dF) applied by a piston to a small mass of blood (m) that is contiguous with the arterial wall will displace the mass and the wall with the same acceleration. Since blood is incompressible in relation to the elastic wall, and it also has inertia which opposes movement of the total blood column, the displacement (Δx) for the blood mass would be accommodated by expansion of the arterial wall. The amount of expansion is determined by the wall material properties and the wave speed determined by both the wall material properties and the density of the blood mass on which the force acts to displace the wall (see text for details).

When considering blood in an elastic tube, Eq. (1.21) is recast as

$$c = \sqrt{\frac{VdP}{\rho dV}} \qquad (1.22)$$

which is the well-known Bramwell–Hill equation, derived independently by Bramwell and Hill[49] and Frank.[50]

Since arteries mainly expand in the radial direction, changes in volume (dV) are proportional to changes in area or to 2 times change in radius (r) and so the quantity $VdP/$ dV ($dP/(dV/V)$) can be replaced by $dP/(2dr/r)$. From Laplace's Law (Eq. 1.9), pressure changes (dP) can be expressed in terms of circumferential stress (σ) at specific values of wall thickness (h) and r, that its, $dP = d\sigma(h/r)$. The incremental elastic modulus (E_{inc}) is defined as the ratio of the change of stress ($d\sigma$) to change of strain ($d\varepsilon$) at the specific operating point in the stress–strain curve, that is, at the specific value of r. Hence, $d\varepsilon = dr/r$ and so the quantity VdP/dV can be replaced by $E_{inc}.h/2r$. So, the Bramwell–Hill equation of Eq. (1.22) is recast as the well-known Moens–Korteweg equation,

$$c = \sqrt{\frac{E_{inc}h}{2\rho r}} \qquad (1.23)$$

The main assumptions for the above derivation of the wave speed are that the tube is thin walled ($h << r$), that the increase in volume causes small changes in vessel cross-sectional area (A) and wall thickness (h) and that blood is incompressible (no change in density ρ).

As described in Section Pressure dependence of arterial stiffness: an essential ingredient for optimal arterial design, the stiffness of the arterial wall is essentially nonlinear, suggesting that the value of E_{inc} varies with the specific relation of the tension−radius curve and the wall tension determined by the Laplace relation with pressure and radius (Eq. 1.9). Hence, since E_{inc} is a function of pressure, ($E(P)$), c will also depend on pressure ($c(P)$). The implication of this is that the wave speed will change during the time in which pressure changes during the cardiac cycle. Although this can be demonstrated,[51,52] the stress−strain curve during small pressure excursions can be reasonably approximated by a straight line, making E a constant value. This is an important consideration when considering the application of oscillatory analysis for determining vascular impedance from pulsatile pressure and flow wave decomposition (See Sections Oscillatory pressure and flow: impedance and Input impedance), since linearity considerations also take into account that true wave speed is determined by high frequency oscillations.[53]

Pulse wave velocity

At first glance, the distinction between wave speed (c) and pulse wave velocity (PWV) in the context of vascular assessment might seem a semantic exercise. c is a fundamental (scalar) parameter determined from biophysical relationships for wall elastic properties and conduit dimensions at a specific location and under specific loading conditions (particularly pressure), that is, a regional property over an infinitesimally small axial distance (note there is no distance or length quantity in Eq. 1.23). The term "velocity" denotes a vector quantity (with magnitude and direction) whose magnitude is the value of the wave speed. Hence, PWV is strictly a vector quantity, and in vascular assessment it is generally considered as a measured variable of the speed of the traveling pulse along the arterial path

length. It is commonly obtained by measuring the pulse transit time (PTT) over a given distance (d),

$$PWV = \frac{d}{PTT} \qquad (1.24)$$

Clearly, if the arterial segment is uniform over a distance d, then, $c = PWV$ (more specifically, $PWV = U + c$, where U is blood velocity; since $U << c$, particularly at the end of diastole where PTT is usually measured at the foot of the pulse, U is generally ignored). However, PWV is usually measured over long path lengths (e.g., carotid-to-femoral) where there is substantial variability of all arterial quantities in Eq. (1.23). Notwithstanding these caveats, it is generally accepted that in large conduit arteries, the quantity h/r is generally preserved.[17] Furthermore, any irregularity in wall thickness would generally be in intimal changes, and these layers have a much lower stiffness than the arterial media, which is the main vessel component that determines the mechanical properties of the arterial wall. Hence, although an approximation, any measured changes in PWV would indicate that they are mainly due to medial properties that affect arterial stiffness. These concepts have given rise to the important surrogate relationship of

$$arterial\ stiffness \propto PWV \qquad (1.25)$$

Notably, the notion that PWV is a (structural) metric of arterial stiffness does not imply that PWV is the *only* arterial stiffness marker (there is no "=" sign in Eq. 1.25).[54] Hence, care should be taken to always define *which* arterial stiffness metric is reported.

Pulse wave velocity and pressure-independent arterial stiffness index beta (β)

The qualitative relationship of Eq. (1.25) is generally used to quantify changes in arterial stiffness with age, arterial site, or blood pressure. However, because of the pressure dependency of arterial stiffness (and therefore of PWV), it will not be possible to distinguish a difference in stiffness due to structural arterial wall properties (that is, intrinsic arterial stiffness) or due to a change in pressure. It is important to note that a change in stiffness due to pressure would be on the *same* pressure−volume curve, whereas a change in intrinsic stiffness would imply a *different* curve. Detailed analysis is described in Box 1.1.

BOX 1.1 Pressure-independent index of arterial stiffness

To a good approximation, pressure (P) has an exponential relationship with diameter (D) of the form,[25]

$$P = P_{ref}e^{\beta_0(D-D_{ref})/D_{ref}} \tag{1.26}$$

or

$$\ln P = \beta_0\left(\frac{D}{D_{ref}} - 1\right) + \ln P_{ref} \tag{1.27}$$

where β_0 is the index that defines a specific stress–strain curve of the wall stiffness characteristics, and P_{ref} and D_{ref} are reference pressure and diameter, respectively. Hence, if there are two pressure points on the curve (such as systolic (P_s) and diastolic (P_d) pressure associated with systolic (D_s) and diastolic (D_d) diameter), the index β_0 (a measure of intrinsic stiffness) can be obtained by the slope of the logarithmic relationship from Eq. (1.27):

$$\beta_0 = \ln\left(\frac{P_s}{P_d}\right)\bigg/\left(\frac{D_s}{D_d} - 1\right) - \ln\left(\frac{P_d}{P_{ref}}\right) \tag{1.28}$$

This equation is very often simplified by omission of the second term:

$$\beta = \ln\left(\frac{P_s}{P_d}\right)\bigg/\left(\frac{D_s}{D_d} - 1\right) \tag{1.29}$$

Since diameters are not readily measured, use is made of the Bramwell–Hill equation for PWV (Eq. 1.22), and assuming that the volume change occurs only in the radial direction (that is, $\Delta V = 2\Delta D$), where $\Delta D = D_s - D_d$,

$$PWV^2 = \frac{D_s(P_s - P_d)}{2\rho(D_s - D_d)} \tag{1.30}$$

By combining Eqs. 1.29 and 1.30,

$$\beta = \ln\frac{P_s}{P_d} \cdot PWV^2 \cdot \frac{2\rho}{P_s - P_d} \tag{1.31}$$

Hence, since *PWV* can be measured, usually over path lengths from the carotid to the femoral artery, and with measurement of systolic and diastolic pressure, a pressure-independent index of arterial stiffness can be obtained. This has now been accepted in the form of a cardio-ankle vascular index (*CAVI*), where *PWV* is taken along the heart-to-ankle arterial bed.[26] *CAVI* was further improved into $CAVI_0$ by using β_0 instead of β as a starting point (Eq. 1.29 vs. 1.28; $P_{ref} = 100$ mmHg), and by referring the calculations to diastolic pressure (P_d),[27]

$$CAVI_0 = \beta_0 = \frac{PWV^2 \cdot 2\rho}{P_d} - \ln\left(\frac{P_d}{P_{ref}}\right) \tag{1.32}$$

Pulse wave propagation and oscillatory phenomena

The periodic nature of the cardiac cycle enables the analysis of the time-dependent oscillations of pressure and flow in terms of each frequency component of the signal. The fundamental frequency is determined by the time of the cardiac cycle and harmonic components are integer multiples of the fundamental frequency. The complex time-varying signal is considered as a sum of simple time-varying sinusoids at harmonic frequencies with different magnitudes and phase (see Section Oscillatory pressure and flow: impedance). This then allows the quantification of the change in magnitude and time delay of each frequency component. That is, the propagation of the complex wave can be analyzed in terms of propagation coefficients as a function of frequency, consisting of the amount of damping and delay as a function of distance. The delay term is related to the pulse wave velocity of each frequency component. Box 1.2 gives an example of the frequency analysis for a sinusoidal signal of a pressure wave (*P(t)*).

BOX 1.2 Frequency analysis of pulse wave propagation

For description of oscillatory waves as sinusoidal functions, use is frequently made of Euler's formula,

$$e^{-j\omega t} = \cos(j\omega) + j\sin(j\omega) \tag{1.33}$$

where ω is the oscillation frequency in rad/s and $j = \sqrt{-1}$.

Hence, a time-varying sinusoidal frequency component of a pressure wave of amplitude Po is completely described as

$$P(t) = Po \cdot e^{-j\omega t} \tag{1.34}$$

For a uniform arterial segment of length l, the sinusoidal wave from the input of the tube along its length undergoes modification of the amplitude; that is, it is modified in time (t) and space (x).

This can be concisely expressed as

$$P(t, x) = P(t) \cdot e^{-\lambda x} \tag{1.35}$$

where λ is the propagation coefficient, defined as

$$\lambda = a + jb \tag{1.36}$$

where a is the attenuation constant (how much of the traveling amplitude is damped due to viscous losses for blood and wall), and b is the phase constant (the "time delay" of the particular frequency component). [*Note*: with x in meters, $a = 1\ \text{m}^{-1}$ corresponds to an attenuation to $1/e \approx 37\%$ of original amplitude per meter; $b = 1$ rad/m corresponds to a phase shift of 1 rad (~ 57 degrees) per meter.]

Each frequency component will travel at a finite wave speed (c), hence,

$$c = \frac{\omega}{b} \tag{1.37}$$

and

$$P(t) \cdot e^{-\lambda x} = (Po \cdot e^{-ax}) \cdot e^{j\omega\left(t - \left(\frac{x}{c}\right)\right)} \tag{1.38}$$

where Po is the magnitude at the input of the tube and c is the wave velocity of the wave of frequency ω.

The above description is for a uniform arterial segment with no terminal reflection. Hence, the value of the wave speed in Eq. (1.37) is the true wave velocity, which can be reliably estimated from the foot-to-foot time delay of pressure waves.

Forward and backward waves

Pressure (P) and flow (Q) waves can be described as a combination of forward (P_f, Q_f) and backward (reflected) waves (P_b, Q_b), such the reflected waves add to pressure and subtract from flow,

$$P = P_f + P_b \tag{1.39}$$

$$Q = Q_f + Q_b \tag{1.40}$$

The relationship of P_f and Q_f, and P_b and Q_b (Q_b has a negative sign) is determined by the characteristic impedance (Z_c [See Section Vascular impedance and Chapter 3]), such that

$$Z_c = \frac{P_f}{Q_f} = \frac{P_b}{-Q_b} \tag{1.41}$$

This allows calculation of forward and backward arterial pressure waves from measured pressure and flow and

characteristic impedance calculated from frequency- or time-domain analysis of pressure and flow waves (see Chapters 3 and 11),

$$P_f = 0.5(P + Z_c \cdot Q) \tag{1.42}$$

$$P_b = 0.5(P - Z_c \cdot Q) \tag{1.43}$$

Thus, from the above equations, measured pressure and flow waves can be decomposed into forward and back waves. For sampled waveforms, the equations are applied at each sample point.

Vascular impedance

Steady pressure and flow: resistance

The obligatory intermittent ventricular ejection, which occurs for only part of the cardiac cycle, produces pulsatile flow input to the aorta. The elastic properties of the arterial

tree provide a buffer for the intermittent pulsations and storage of blood in the presence of arterial wall tension, such that a positive head of pressure is established in the arterial vasculature to provide potential energy for continuous perfusion of peripheral microvascular beds. At any location in the arterial tree, the flow is determined by the arterial pressure and the resistance to flow due the downstream effects of the blood vessels. (More precisely, the driving pressure is the difference between arterial and central venous pressure, but venous pressure in the systemic vasculature is very much less than in arteries [order of 5%], so it is usually ignored, although this is not the case for the pulmonary vasculature as it operates at lower arterial pressure). Hence, since pulsatility in pressure and flow involves time-varying phenomena, the resistance to flow can be described as the relation of pressure and flow as time-varying quantities.

Since the duty cycle of the heart as a pump can be considered periodic (not all cardiac cycles have the identical duration, but the variability is generally small in normal conditions), the characteristics of the arterial vasculature that determine relationships of pressure and flow can be completely described by the values of pressure and flow as a function of time in a single cardiac cycle. For pressure $P(t)$ and flow $Q(t)$, and a cardiac cycle duration of T_c, the mean values (P_m, Q_m) can be calculated as

$$P_m = \frac{1}{T} \int_0^{T_c} P(t) \cdot dt \qquad (1.44)$$

$$Q_m = \frac{1}{T} \int_0^{T_c} Q(t) \cdot dt \qquad (1.45)$$

The pulsatile component $P_p(t)$ and $Q_p(t)$ can be obtained by subtracting the mean value from the original signal,

$$P_p(t) = P(t) - P_m \qquad (1.46)$$

$$Q_p(t) = Q(t) - Q_m \qquad (1.47)$$

The impedance to flow is calculated as the ratio of pressure and flow. Hence, for the mean values, the resistance (R) is

$$R = \frac{P_m}{Q_m} \qquad (1.48)$$

Arterial properties that determine relationship of steady pressure and flow

Eq. (1.48) gives the value of resistance as the ratio of mean pressure to mean flow. Thus, if pressure and flow are measured at any specific location in the arterial tree, the ratio quantifies the total resistance to flow downstream from the point of measurement. However, this is a computed value and does not describe arterial properties

in an explicit form. The resistance to flow occurs in accordance with the laws of motion of fluid due to an applied force. For a fluid of viscosity μ flowing due to a pressure difference between inlet and outlet of a uniform segment of conduit of length l and internal radius r, the ratio of pressure to flow, designating the resistance (R) of the segment, is given as

$$R = \frac{8\mu l}{\pi r^4} \qquad (1.49)$$

This relation assumes laminar, stationary flow (no turbulence), a Newtonian fluid (constant viscosity), no slip at the wall, and a tube long enough so that the laminar flow is fully developed. Fluid flow can then be calculated for a measured pressure gradient, tube dimensions, and fluid viscosity; this relationship is known as the Hagen−Poiseuille equation[55] (page 10 of Ref. [26]).

Because of the dependency of fluid resistance on the inverse of the fourth power of the radius, the large arteries in the arterial vasculature contribute very little to the resistance to flow. This also illustrates the powerful role of the small vessels in the control of peripheral resistance, such as arterioles being able to modulate vessel caliber under active control of smooth muscle tone[55] (page 36 of Ref. [26]).

For a symmetrical bifurcation obeying Murray's Law of optimality of branching, using Eq. (1.48), the total resistance of the branches increases to 1.26 times the resistance of the parent vessel of equal length. This value is also the optimal area ratio based on maximal energy transmission at branch points (obtained by simple algebraic addition of the individual branch area rations, corresponding to the addition of admittance of the branch, or inverse of resistance). Although not all branch points in the arterial vasculature are theoretically optimally matched, there is still a general increase in cross-sectional area in large vessels with branching generation. However, in small vessels such as arterioles, the caliber is determined by active smooth tone, such that the arteriolar regions become the sites of modulation of maximal resistance, and as a consequence the site of modulation of maximal reflection that would influence pulse pressure.[4]

Oscillatory pressure and flow: impedance

For the pulsatile component, the ratio of the time-varying signals cannot be computed to describe resistance to pulsatile flow. That is, the division of pressure at a particular time point cannot be divided by a flow value at the same time point, as a time-varying resistance does not strictly have any real physiological meaning, and in addition, during diastole, when flow is zero, resistance would be infinite. Furthermore, the rapid changes in flow would cause rapid changes in resistance, and there are no plausible

biological mechanisms that would cause such rapid changes in vascular properties.

For the pulsatile component, use is made of the periodic nature of the signal to decompose the time-varying signal into its sinusoidal harmonic components. From the Fourier theorem, any time-varying signal can be expressed as a sum of a series of sinusoidal waves, whose period depends on the time over which the signal is sampled. Hence, for the cardiac cycle, the first harmonic sinusoid would have the period of the cardiac cycle (T_c), and so the frequency would be ($1/T_c$). For a heart rate of 60 beats, the cycle period would be 1 s and the fundamental (first harmonic) frequency (ω_0) would be 1 Hz. Box 1.3 gives formal expressions for the frequency analysis and its use for calculation of impedance as a function of frequency.

Aortic input impedance is a complete description of the pulsatile load on the left ventricle, and so can also describe the fundamental relationships of ventricular−vascular coupling. Fig. 1.11 shows the comparison between the human and rabbit aortic impedance, with the energy spectrum of aortic flow. The human heart operates against a higher relative impedance than the rabbit heart, suggesting a relatively higher mismatch in ventricular vascular coupling.[56] For further discussion regarding aortic input impedance and its derivation, the reader is referred to Chapter 3.

BOX 1.3 Frequency analysis and impedance calculation

The conversion of the time-varying signals is done by a Fourier transform, which enables the time-varying $P_p(t)$ and $Q_p(t)$ signals to be expressed in the frequency domain.

Any periodic signal $x(t)$, with period T_c, can be expressed as

$$x(t) = \frac{1}{T_c} \sum_{n=-\infty}^{\infty} X_n e^{jn\omega_0 t} \tag{1.50}$$

where

$$X_n = \int_0^{T_c} x(t) e^{-jn\omega_0 t} dt \tag{1.51}$$

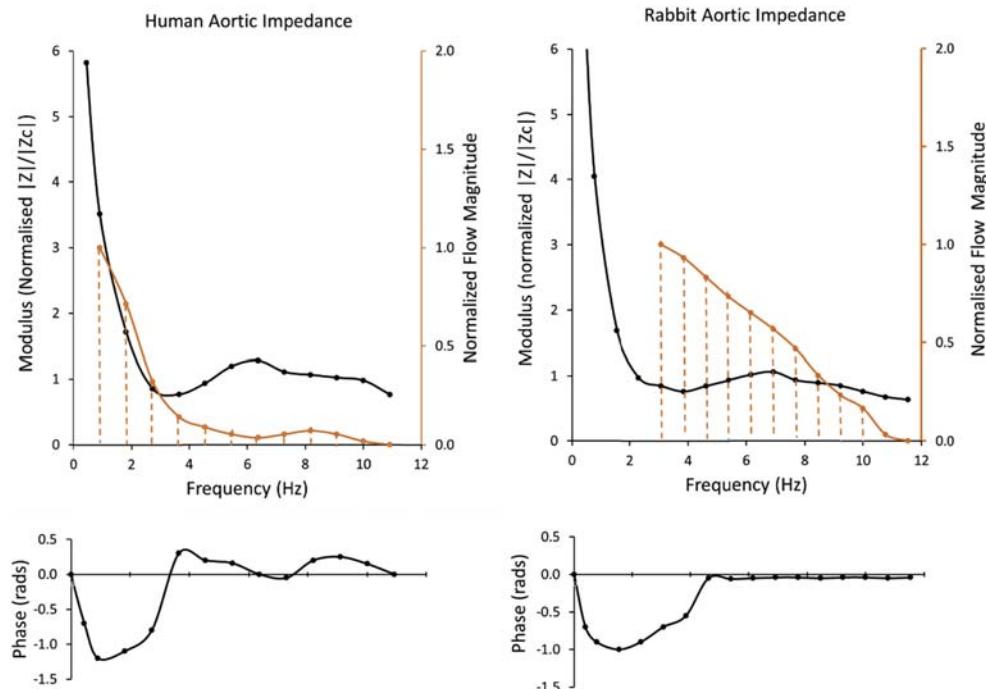
$j = \sqrt{-1}$ and $X_n(\omega)$ is a complex quantity which represents a sine wave at a frequency of $n\omega_0$. That is, for the series of harmonics (n = 1, 2, 3 ...), X_n has a magnitude $|X|_n$ and phase angle ($arg(X)_n$).

Hence, for the respective pressure and flow representation,

$$P(\omega) = |P|_n \cdot \angle arg(P)_n \quad (n = 1, 2, 3, ...) \tag{1.52}$$
$$Q(\omega) = |Q|_n \cdot \angle arg(Q)_n \quad (n = 1, 2, 3, ...) \tag{1.53}$$

where the symbol $\angle$ designates the phase angle representation of the complex quantity.

As in the case for the mean value of $P(t)$ and $Q(t)$ to determine resistance, similarly, the ratio of $P(\omega)$ and $Q(\omega)$ is used to determine the resistance at each specific harmonic component. In analogy with electrical circuits for oscillating voltage and current in the frequency domain, the ratio of $P(\omega)$ and $Q(\omega)$ is designated as impedance, $Z(\omega)$, a complex quantity with a modulus ($|Z|_n$) and phase ($arg(Z)_n$),

$$Z(\omega) = \frac{P(\omega)}{Q(\omega)} \tag{1.54}$$


Hence,

$$|Z| = \frac{|P|n}{|Q|n} \tag{1.55}$$
$$arg(Z)_n = arg(P)_n - arg(Q)_n \tag{1.56}$$

The impedance spectrum consists of a plot of $|Z|n$ and $arg(Z)_n$ as a function of frequency for each harmonic (n = 1,2,3, ...). The value of impedance at zero frequency, that is, for steady pressure and flow, is the value of resistance (R) determined from mean pressure and flow and a phase angle of zero (Fig. 1.11).

FIGURE 1.11 Vascular impedance determined from frequency components of aortic pressure and flow (i.e., aortic input impedance) in humans and rabbits and shown as modulus and phase as a function of frequency. The impedance modulus (Z) is normalized by the characteristic impedance (Zc) computed from the average moduli between 6 and 10 Hz. The impedance spectrum is quite similar for the human and rabbit, with the modulus falling rapidly at low frequencies and the phase having a negative value until around the frequency of impedance minimum. Negative phase indicates a capacitive load, such that flow leads pressure. The orange stippled curve shows the energy in the aortic flow normalized by the value for first harmonic. The overlay of these curves on the impedance curves illustrates the different degree of matching of ventricular–vascular coupling. In the rabbit, most of the flow energy is in the low impedance part of the spectrum, whereas in the human it is in the descending limb and at relatively higher impedance value, suggesting a less efficient matching compared to the rabbit. *Human data obtained from Murgo JP, et al. Aortic input impedance in normal man: relationship to pressure wave forms. **Circulation**. 1980; 62(1):105–116; Rabbit data obtained from Avolio, AP, et al. A comparative study of pulsatile arterial hemodynamics in rabbits and Guinea pigs. **Am J Physiol**. 1976; 230(4):868–875.*

Arterial properties that determine relationship of pulsatile pressure and flow

Due to the periodic nature of cardiac contraction, the associated time-varying pressure and flow in arteries can be considered as periodic oscillations. Just as the vessels downstream of point of measurement present a resistance to steady (i.e., nonpulsatile) flow due to a pressure gradient (Eq. 1.48), they also present an opposition to oscillatory flow. For steady flow, the relevant quantities are the magnitudes of means pressure (P_m) and mean flow (Q_m), and for oscillatory flow they are the magnitudes of the oscillations of $P(t)$ and $Q(t)$. Because, by definition, oscillatory flow implies a change of velocity with time, and since a blood mass is accelerated in an elastic conduit with capacity for volume storage due to its compliance (C), the opposition to flow is due to the blood inertia of the mass (L) and also due to the storage capacity. That is, the opposition to flow will be high for a high inertia and low for a high compliance. In analogy with similar conceptual models of

electrical transmission lines, the resistance to oscillatory flow due to the physical properties is defined as the characteristic impedance (Z_c) and (for large vessels and inviscid fluid) is described as

$$Z_c = \sqrt{\frac{L}{C}} \qquad (1.57)$$

For an arterial segment of length *l*, wall thickness *h*, radius *r*, wall material stiffness *E*, and blood density *ρ*, the value of the tube compliance *C* can be computed as

$$C = \frac{3\pi l r^3}{2Eh} \qquad (1.58)$$

Alternatively, *C* can be estimated as *ΔV/ΔP*. When impedance is determined from frequency components of pressure and flow (Eq. 1.54), Z_c is estimated from the average of the high harmonics of the spectrum of impedance modulus. For the human arterial system, usually harmonics 6–10 are used (see Chapter 3).

Effects of blood viscosity and pulsatile flow: Womersley's alpha

When fluid flows in a tube due to a pressure gradient, the rate of flow is determined by the properties of the fluid (density, viscosity) and tube dimensions (diameter, length). For a constant pressure gradient, flow determined by these properties is steady, and for a long tube it will be laminar flow with a parabolic profile. That is, it has maximum velocity at the center of the tube and low velocity close to the wall. In this case, the relation between the steady pressure gradient and flow would be quantified as a resistance (Eq. 1.48). However, if the pressure gradient varies with time, the relationship between the pressure and flow will be determined by the frequency of oscillation and properties of blood and tube dimensions, with the values of impedance converging to Eq. (1.48) for a frequency of zero. This advanced analysis is described in Box 1.4.

Input impedance

For an arterial segment, the input impedance (Z_{in}) would be similar to the characteristic impedance (Z_c) if it were uniform and had a matched terminal impedance (Z_t). This relationship is defined by a reflection coefficient (Γ),

$$\Gamma = \frac{Z_c - Z_t}{Z_c + Z_t} \tag{1.63}$$

Eq. (1.63) suggests that for a uniform arterial segment, the amount of wave reflection is determined by the degree of impedance matching.

An important consideration when addressing vascular impedance is that each frequency component of the pulse wave undergoes transformation of its amplitude along the traveled distance, as described by Eqs. 1.33–1.38, where the change in amplitude and delay on the traveled path is determined by the propagation coefficient λ.

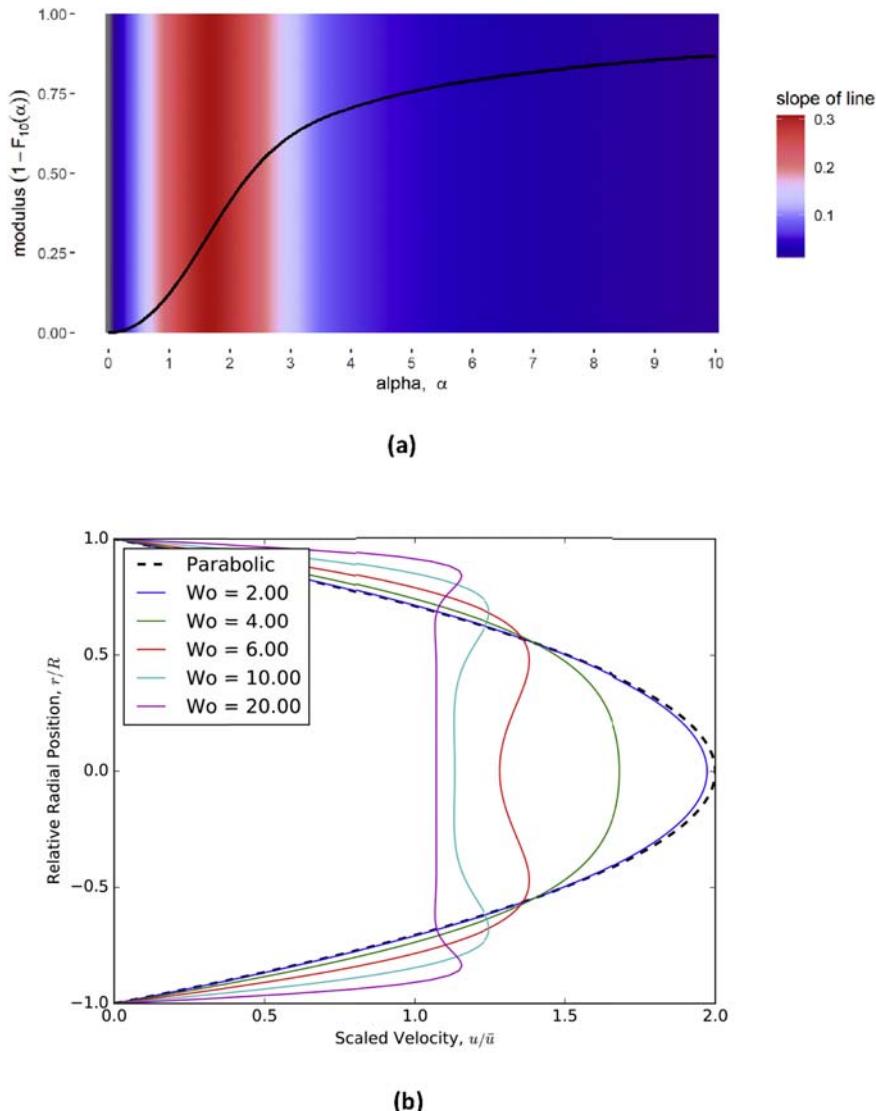
BOX 1.4 Womersley's theory of pulsatile blood pressure and flow in arteries

Womersley's solution of the Navier–Stokes equations of fluid flow in circular boundaries enabled the computation of fluid flow profiles due to an oscillating pressure gradient[3] and by knowledge of vessel mechanical and geometric properties. For a sinusoidal oscillation of frequency ω, the closed-form solutions involved a nondimensional parameter (alpha, α) and a series of Bessel functions, which modify the characteristic impedance as a function of alpha values, Womersley's alpha (α) is defined as

$$\alpha = r\sqrt{\frac{\omega\rho}{\mu}} \tag{1.59}$$

where r is luminal radius, ω is frequency of oscillation, ρ is fluid density, and μ is the fluid viscosity.
    (Note the similarity of the nondimensional parameter (α) with the nondimensional Reynolds number (Re)):

$$R_e = \frac{\rho VD}{\mu} \tag{1.60}$$

where ρ is fluid density; V is fluid velocity; D is linear dimension (diameter for circular boundaries); μ is fluid viscosity.
    "V" in the numerator of the expression for Re corresponds to "ω" in the expression for α. Hence, as Re is a critical parameter for characterization of steady flow phenomena, similarly, α is a critical parameter for characterization of oscillatory flow phenomena.
    The characteristic impedance (Eq. 1.57) is modified as[59]


$$Z_c = \left(\frac{L}{C}\right)^{1/2} \cdot (1 - F_{10})^{-1/2} \tag{1.61}$$

where

$$1 - F_{10} = 1 - \frac{2J_1\left(\alpha j^{\frac{3}{2}}\right)}{\alpha j^{\frac{3}{2}} J_0\left(\alpha j^{\frac{3}{2}}\right)} \tag{1.62}$$

and J_0 is Bessel function of the first kind of zero order, J_1 is Bessel function of the first kind of first order, α as in Eq. (1.59); $j = \sqrt{-1}$.
    The values of function $(1-F_{10})$ are plotted as a function of α (Fig. 1.12A), showing that the greatest effect is for range of low values of $\alpha < 3$ and values of α affect the cross-sectional flow profile (Fig. 1.12B).

(a)

(b)

FIGURE 1.12 (A) Function of $1-F_{10}$ as a function of alpha (α). Maximum change occurs for α values below 3. This suggests the combination of vessel size (radius), frequency (heart rate), and blood properties (density and viscosity) that give values of α in the red region will affect the dynamic relationship of pressure and flow. (B) The flow profiles are also affected by the values of α (designated as Womersley's Number [Wo] in the above figure). Profiles are shown for normalized tube radius (r/R) and normalized relative to mean flow ($u/\bar{u}$). The parabolic flow corresponds to $\alpha = 0$, where the viscosity is the main determinant of the flow profile. This is generally maintained for low values of α. As α increases, blood inertia begins to dominate in the central part of the lumen and at high values of α the flow undergoes marked changes to a flat profile, with inertia being the main determinant and the effects of viscosity are seen at the boundary layers adjacent to the wall. Part (B) of the figure is used under Creative Commons License [https://commons.wikimedia.org/w/index.php?curid=54810155 (Rudolf Hellmuth)].

For a tube of length l and with a terminal impedance Z_t, the input impedance Z_{in} is defined by the characteristic impedance (Z_c), the reflection coefficient (Γ), and the wave propagation coefficient (λ),

$$Z_{in} = Z_c \cdot \frac{1 + \Gamma e^{-2\lambda L}}{1 - \Gamma e^{-2\lambda L}} \qquad (1.64)$$

The equations describe the impedance of arterial segments in a closed form in terms of physical geometric and material properties. Thus, with connections of uniform segments in the form of a distributed and branching tree structure, it is possible to investigate spatial and temporal relationships of pulsatile pressure and flow.[59-62]

System linearity

Eq. (1.54) suggests that each frequency component of flow is scaled by a single value of impedance to obtain a single frequency component of pressure. That is, a specific frequency component of flow is uniquely related to the pressure component of the same frequency and no other pressure component. This is an important characteristic of linear systems and is a fundamental assumption for impedance calculation for pulsatile pressure and flow in arteries.[63] The fact that a single frequency component of flow can be related to a single frequency component of pressure assumes that the system is time invariant. That is, during the cardiac cycle (the interval of time for which pulsatile pressure and flow are obtained and analyzed), all properties of the system remain constant. Since a determinant characteristic of pulsatile pressure and flow is arterial stiffness, the implication is that during the cardiac cycle, when pressure increases between the nadir (diastolic pressure) to the peak (systolic pressure), the elastic properties remain constant and there is no change in arterial stiffness. However, as was explained in Section Elastic vessels, the pressure-dependence of arterial stiffness is an inherent property of arterial structure and a fundamental property of arterial design, hence it would seem counterintuitive and contradictory to assume a constant value of arterial stiffness during the time when there is a change in pressure, unless there are justifiable assumptions.

Intermodulation: justification for assumptions of system linearity

The nonlinearity of the system due to a pressure-dependent elastic modulus of the arterial wall would lead to a phenomenon known as intermodulation. That is, if a single sinusoidal frequency of flow were used as the input at the aorta, the resulting pressure would be a single sinusoid at the same frequency but would also include components of differing amplitudes at different frequencies. This important characteristic was examined in some early studies to ascertain whether arterial impedance could indeed be computed from harmonic components of pressure and flow and be able to describe the system with reasonable and meaningful physiological application.[63] When the canine arterial system was perturbed with sinusoidal pumps, power at intermodulation frequencies was found to be very low (around 2%).[64] The fact that it was able to be detected suggests the presence of nonlinearity and it is consistent with the pressure dependency of arterial stiffness. The rather small effect suggests that the excursion of pressure during the cardiac cycle is relatively small compared to the entire range of operating pressure of arteries, and so during this interval, the stress/strain curve of the arterial wall can be approximated with a linear slope.

Nonlinearity in arterial models

Although the assumptions of linearity have been able to facilitate the development of early arterial models using closed-form expressions for hemodynamic relationships[59,61] or physical circuit elements,[62] more recent models that are based on iterative numerical solutions of basic fluid flow equations can readily include features of system nonlinearity by making arterial elasticity dependent on arterial pressure.[60]

Relation between characteristic impedance and pulse wave velocity

If a fluid of density ρ flows with velocity v in a tube and the end is suddenly closed, there will be a change in velocity (Δv) and an associated pressure change (ΔP). The pressure wave will travel in the tube at a wave speed (c) determined by the tube and fluid properties. The relationship is

$$\Delta P = c\rho\Delta v \qquad (1.65)$$

This is the classic water hammer formula (which commonly manifests as a sudden noise in pipes following rapid closure of a tap).

Since volumetric flow $Q = A \cdot v$, where A is cross-sectional area, and characteristic impedance Z_c is the ratio of $\Delta P/\Delta Q$, the relation between impedance and wave speed is

$$c = Z_c A/\rho \qquad (1.66)$$

Eq. (1.66) implies that local wave speed can be determined by computation of impedance by measured pressure and flow. It also implies that if impedance is computed using flow velocity (cm/sec) rather than volume flow (cm^3/sec), (that is, scaled by area), the magnitudes are scaled only by the reciprocal of blood density, and if expressed in CGS units, they are approximately equal (since blood density is 1.06 g/mL). Scaling impedance by area also enables comparisons of impedance spectral patterns in different arterial districts and in different animals of different sizes[58] (since arterial blood pressure and flow velocity do not scale to body size or vessel caliber).

Pressure and flow relationship in the time domain

The periodicity of cardiac contractions has enabled the characterization of the pressure and flow and impedance in the frequency domain, with the assumption of system stationarity. However, since energy is carried by the combination of pressure and flow as time-varying quantities, energy-based analysis can also be used to characterize wave propagation, which does not require any periodicity. The time-domain characterization has been used to describe the reservoir concept[13] and wave intensity analysis.[65] The details of these concepts will be covered in Chapter 3.

Summary

This chapter describes the fundamental biophysical relationships that underpin the physiological understanding of the interaction between pulsatile arterial blood pressure and flow and arterial stiffness. The approach has been to attempt to provide sufficient qualitative background explanation to support the quantitative description of the relationships and to highlight the fundamental significance of pulsatile hemodynamic phenomena. Arterial blood pressure and arterial stiffness are fundamental quantities intrinsic to arterial function (they do not scale to body size as do cardiac output or heart rate) and arterial stiffness is a significant determinant of vascular impedance and wave propagation that form the basis of the interaction of the arterial vasculature and the obligatory action of the heart as a pulsatile pump.

Introduction

Cuff-measured blood pressure (BP) is the most widely applied and clinically important measurement used in clinical practice. The principles of cuff BP measurement used in clinical practice today are based on the technique of cuff mercury sphygmomanometry that was refined by Dr Nikolai Korotkoff in 1905. This method relies on estimating the BP within the brachial artery where the cuff is applied by listening to the sounds (auscultation by stethoscope) within the brachial artery as the cuff is slowly deflated and with BP measured on a mercury sphygmomanometer. A distinctive sound occurring at the onset of flow under the cuff denotes systolic BP (Korotkoff phase 1), whereas the point at which sound disappears denotes diastolic BP (Korotkoff phase 5) and occurs with full restitution of blood flow.[1] These brachial artery sounds are separable in time and distinctive from heart sounds.[2]

When measured carefully using a standardized approach, cuff-measured BP provides critical clinical information relating to the risk of high BP-related disease.[3] A spectrum of clinical conditions occur as a consequence of high BP, which are related to stiffening of large central arteries (particularly the aorta) and accelerated atherosclerotic plaque development, both of which ultimately affect the vasculature and perfusion of the brain, heart, and kidneys, and promote heart disease through direct effects on left ventricular afterload (often referred to as "pressure overload"). Thus, the underlying tenet of accurate BP measurement is to determine the pressure loading and consequent vascular risk at the central arterial beds.[4] This measurement has been coined "central BP," as distinct from standard upper arm cuff BP and represents BP at the ascending aorta.[5] The upper arm is the nearest site at which a cuff can safely be inflated to perform mercury auscultation, and even though this is distal to the central arterial beds, the technique can provide a reasonable determination of an individual's true intra-arterial central BP.

The unequivocal clinical importance of cuff BP measurement was demonstrated in many seminal epidemiology studies and clinical trials throughout the 20th and 21st centuries.[6,7] In the 1970s, the first commercially available devices to measure BP using a "modern" automated technique, known as oscillometric BP, became available. Oscillometric BP was developed as an automated way to derive the same BP values as mercury auscultation and is the current mainstay BP measurement technique used worldwide and recommended by hypertension societies for all modalities of BP measurement (office BP, automated unobserved BP, self-measured home BP, and 24-hour ambulatory BP). Many thousands of unique oscillometric BP devices are sold online globally to millions of people each year. A new wave of techniques and cuffless devices asserting to measure BP at different arterial sites have also emerged, which raise many questions about what is being measured and of what additive value will they provide. In seeking to understand this, we must firstly return to the original BP method from which all others have emerged and (most) seek to emulate: cuff mercury sphygmomanometry.

Cuff mercury sphygmomanometry

In his original thesis of 1896 on the measurement of BP using cuff mercury sphygmomanometry, Riva Rocci considered that the technique provided a measurement of

BP (referring to this as the "total charge") at "… a point fairly close to the aorta…" either "…. in the aorta itself or of the brachiocephalic trunk…."[8] This was a reasonable supposition because sphygmomanometry was applied to a large arterial branch of the aorta. However, as an indirect measure, the veracity of these statements could not be assessed until the 1930s with the advent of intra-arterial BP measurement using calibrated manometers. By the 1950s, results from several small experimental studies led a committee of the Scientific Council of the American Heart Association to conclude that cuff mercury sphygmomanometry was error-prone when compared with the true intra-arterial brachial BP, seemingly to systematically underestimate systolic BP but overestimate diastolic BP a mean error of 8 mmHg may be expected in individual readings of systolic and diastolic pressures.[9]

Many investigators have put forward theories on the origin of Korotkoff sounds and possible explanations for systematic errors of systolic BP and diastolic BP.[10−13] The act of cuff occlusion of an artery in itself may cause hemodynamic changes that contribute to systematic error.[11] However, dynamic reactions also occur during cuff deflation, which can additionally influence cuff-measured BP values compared with intra-arterial BP (see Video 1).[10] A possible explanation for systematic overestimation of diastolic BP is that due to incomplete transmission of pressure in the cuff to the compressed brachial artery, the occluded arterial segment opens at an intra-arterial pressure below that exerted by the cuff.[10] Importantly, the size of the cuff relative to the arm of the person having their BP measured, as well as the shape of the arm relative to the cuff,[14] plays a role in the accuracy of cuff mercury sphygmomanometry. Indeed, good "cuff performance" is more likely using an appropriately sized cuff bladder relative to the circumference of the person's upper arm. Current recommendations are that bladder length should be 75%−100%, and bladder width 37%−50%, of the upper arm circumference.[15]

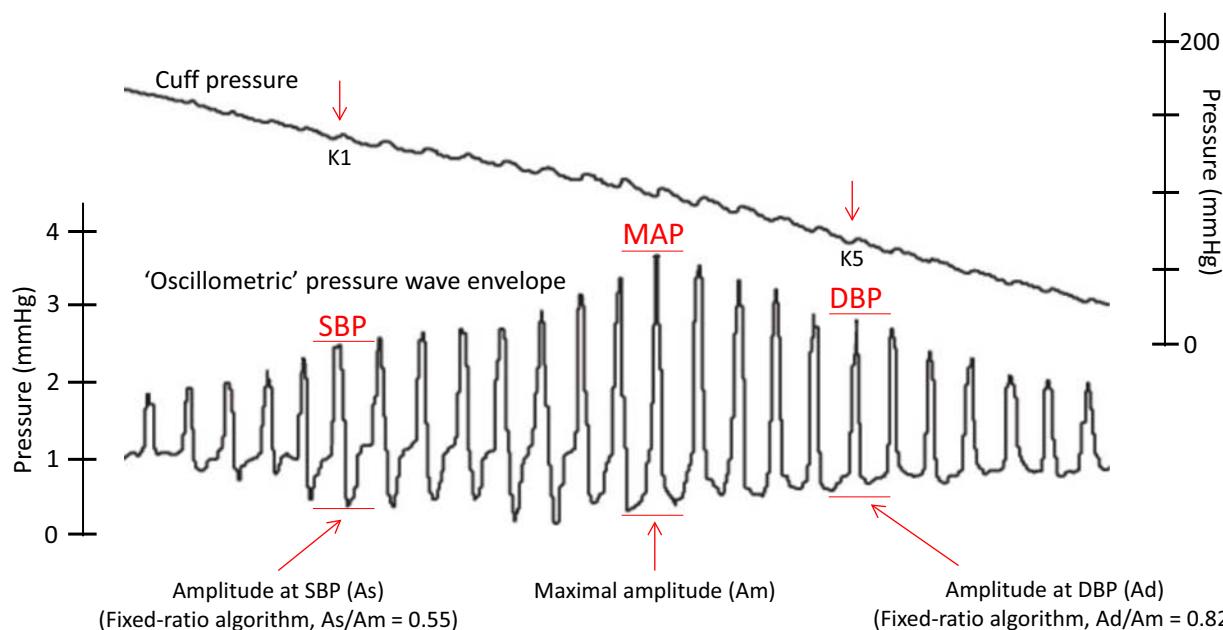
The full extent of the difference of cuff mercury sphygmomanometry BP compared against an intra-arterial reference was only recently appreciated through meta-analyses of individual patient-level data.[16] Even when apparently measured correctly (i.e., with appropriate cuff size) among more than 300 people, on average, cuff systolic BP was underestimated by −3.4 (95% confidence intervals, CI; −6.9 to −0.2) mmHg and diastolic BP overestimated by 6.3 (2.8 to 9.8) mmHg compared with intra-arterial brachial BP. As already mentioned above, the most clinically relevant BP sought to be measured with accuracy is that at the central aorta, but data for this comparison were only available for 21 people using cuff mercury sphygmomanometry (as the majority of available data in this regard is for oscillometric BP).[16]

In any case, the systematic underestimation of brachial systolic BP with cuff mercury sphygmomanometry suggests this cuff method could give a reasonable estimate of intra-arterial central aortic systolic BP, because on average this is lower than intra-arterial brachial systolic BP. But arguing against the consistent accuracy of cuff mercury sphygmomanometry for measuring aortic BP is that: (1) large individual variability in the magnitude of systolic BP difference (>30 mmHg) occurs between the aorta and brachial artery (termed, systolic BP amplification) even among people with similar intra-arterial brachial systolic BP[17]; (2) hemodynamic variations associated with chronological aging, or disease-related vascular aging, create additional error in cuff-measured BP (e.g., greater underestimation of systolic BP and pulse pressure, but overestimation of diastolic BP with advanced vascular aging)[18−20]; and; (3) there is a lack of empirical evidence or biophysical rationale that Kortotkoff sounds denoting systolic BP at the brachial artery directly relate to central aortic systolic BP.[2] Thus, even though cuff mercury sphygmomanometry has been an invaluable clinical tool, it is not always a precise determination of an individual's true intra-arterial central BP.

Together the above observations provide some of the rationale toward efforts to improve the accuracy of cuff-measured BP.[21] But in the meantime, cuff mercury (or mercury-free) sphygmomanometry is still regarded as the reference standard method by which the accuracy (validation) of most other BP measurement techniques are compared.[22] An exception to this is the protocol for the validation of devices that purport to measure central aortic BP, as distinct from standard upper arm cuff BP, whereby intra-arterial central aortic BP is the recommended reference standard (discussed below).[5] Environmental and health concerns associated with using mercury in the manometric column has led to the phasing out of cuff mercury sphygmomanometry from clinical practice, and with replacement mostly by cuff oscillometric BP devices.

Cuff "oscillometric" blood pressure

The automated nature of cuff oscillometric BP is favored for use in clinical practice as it removes the influence of many potential measurement method errors, such as terminal digit preference,[23] but still has a similar "cuff-based" appearance to the widely accepted cuff mercury sphygmomanometry method. Measurement begins with cuff inflation to about 30 mmHg above expected systolic BP and then steady deflation. Miniature piezoelectric pressure transducers are used to record small, so-called "oscillation" waves that are converted from pressure to analog voltage, which is amplified and filtered.[24] The waves first become apparent before registration of systolic BP using the first Korotkoff sound.[25] Initially, the wave amplitude is very small at around systolic BP, reaches maximal amplitude at mean arterial pressure, and then declines in amplitude as the cuff deflates toward and below diastolic BP.

Digital signal processing is used to obtain and analyze the envelope of the recorded "oscillometric" waves using fitting functions and algorithms that may differ between each unique oscillometric BP device and are not publicly


disclosed. Moreover, a clear assessment of wave amplitude at different inflation pressures requires very slow deflation of the cuff, allowing for the acquisition of full cardiac cycles within small pressure inflation ranges; this process is often "abbreviated" and a faster deflation is used to achieve rapid measurements in the clinic, which require indirect algorithm-based inferences regarding the exact amplitude of the oscillometric envelopes at various inflation pressures. Importantly, if different algorithmic approaches are used to construct the wave amplitude envelope, this will result in different estimated BP values.[26] After identifying mean arterial pressure from the point of maximum wave amplitude,[27] systolic and diastolic BPs are estimated often using fixed-ratio algorithms. These algorithms are based on systolic BP and diastolic BP (measured with cuff mercury sphygmomanometry) correlating with points on the envelope where the wave amplitude approximates 55% (0.55) and 82% (0.82) of the maximal amplitude, respectively.[25] Fig. 2.1 illustrates an overview of the technique, highlighting the relations between cuff pressure, Korotkoff sounds, and the wave amplitude trace, as well as example fixed-ratio algorithms to estimate systolic BP and diastolic BP.

The percentage (ratio) estimates to derive BP using this method only represent population averages and have some flaws, including a systematic bias toward greater underestimation of systolic BP as systolic BP increases. This is because the optimal fixed-ratio algorithm required to accurately estimate systolic BP (by comparison with cuff mercury sphygmomanometry) becomes progressively lower as systolic BP increases (e.g., the optimal fixed-ratio for systolic BP approximates 0.57 at 100 mmHg but this falls to 0.45 at 190 mmHg), thus potentially compromising accurate diagnostic assessment of hypertension. A smaller range in the optimal fixed-ratio occurs for diastolic BP (e.g., range approximates 0.86−0.75 across 55−115 mmHg diastolic BP).[25]

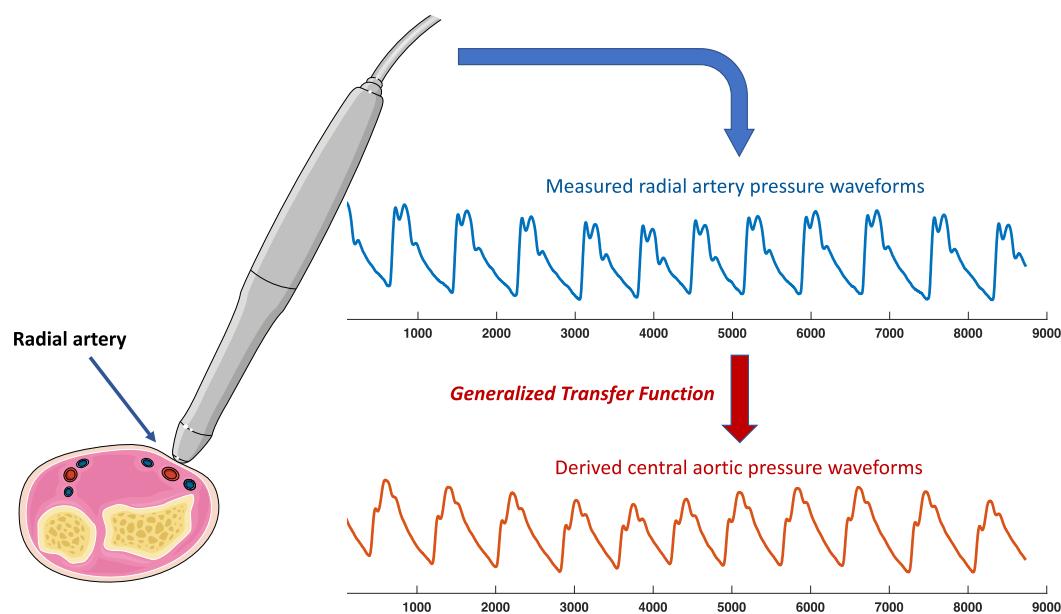
Compared with intra-arterial brachial BP, on average, diastolic BP is overestimated by $\approx$ 6 mmHg, whereas systolic BP and pulse pressure are underestimated by −6 and −12 mmHg, respectively, using oscillometric devices. Unsurprisingly, these discrepancies could have a major influence on correct BP classification.[16] The same general oscillometric method to estimate BP has also been developed using wrist cuff BP devices. Whether they be upper arm or wrist cuff BP devices, the failure of these algorithms to provide consistent accuracy across different BP values, nor account for individual variation in waveform morphology related to accurate BP assessment,[17] leaves room for more sophisticated approaches to improve accuracy.

It is worth briefly reviewing the terminology "oscillometric" BP, which implies that the waveforms are oscillations, but this is not the case.[126] Oscillations are periodic waves in which there is repetitive variation of a measure about a central value, such as an alternating current. In fact, the waves are arterial pressure waves generated by the distending and recoiling brachial artery that occurs with each cardiac cycle. The "oscillometric" method gained this name from historical reference to oscillations by investigators from the 19th century, which was then carried on into the 1970s with the invention of the automated

FIGURE 2.1 Example of the "oscillometric" method to estimate blood pressure. The pressure at the maximal amplitude of the pressure wave envelope represents mean arterial pressure (MAP), and fixed-ratio algorithms are used to derive systolic (SBP) and diastolic blood pressure (DBP). Example positions of Korotkoff phase 1 (K1) and phase 5 (K5) are indicated on the cuff pressure waveform.

"oscillometric" method.[24] Part of the terminology confusion may also originate from the process of filtering the waveforms during processing, which dampens typically recognizable features of arterial pressure waves and could give the (false) impression of an oscillometric wave. More appropriate terminology, such as "automatic sphygmomanometer" has been proposed. For the ease of understanding, the term "oscillometric" is used in this chapter.

Determining the accuracy of oscillometric BP devices is recommended to be performed by comparison with cuff mercury (or mercury-free) sphygmomanometry according to standardized, internationally accepted validation protocols,[22] by investigators who are independent from the device manufacturer to avoid potential bias. Currently, this includes the requirement to be tested among at least 85 people comprising men and women, and across a range of low to high BP values.[15,28] Transparency of findings is paramount, and these should be made publicly available by publication in peer-reviewed scientific journals.[29] While these requirements are desired, they are infrequently achieved because BP devices may be cleared for marketing and sale by regulatory authorities without having undergone rigorous accuracy testing or publication of validation studies in peer-reviewed journals.[30,31] Devices that have not undergone such testing likely have greater inaccuracy compared with cuff mercury sphygmomanometry, are widely used and more likely to contribute to suboptimal medical management.[32−36]

At the time of writing this chapter, there were more than 3600 unique BP device models available for consumer purchase, manufactured by more than 450 different companies worldwide, but less than 20% had undergone the necessary validation testing described above.[37] Among BP devices sold by large e-commerce companies with global reach (e.g., Amazon, eBay), only about 5% of the BP devices were validated, which if used for home BP monitoring could seriously undermine best-practice cardiovascular risk management.[38] A project by the Lancet Commission on Hypertension Group[39] is seeking to redress the above issues to improve the global availability of validated BP devices.[40] Even if achieved, there will be room for improvement because validated BP devices can still have sizable differences from carefully measured mercury sphygmomanometry (e.g., ≥ 10 mmHg difference in 36% of systolic or diastolic BP readings,[41] and a range of 6 to 26 mmHg difference for systolic BP).[36]


With the advent of more advanced technological capabilities, the principles of oscillometric BP have been redeployed into cuffless methods at arterial beds distal from the brachial artery. For example, in the transverse palmar arch artery of the forefinger via a sensor unit embedded on the face of a smartphone that records pressure signals when the finger is pressed up against the unit.[42] This approach replaces the cuff with the finger as the actuator to apply external pressure and generate the wave envelope for analysis and estimation of BPs. A critical factor for accurate BP measurement at vessels peripheral to the brachial artery is that systolic BP may be substantially amplified, but this amplification is of highly variable magnitude (range 0−40 mmHg), and currently there is no way to know the interindividual variability noninvasively.[43] This, together with the known variability in systolic BP between the aorta and brachial artery,[16] infers that clinically meaningful BP measurement becomes increasingly challenging as distance increases from the ascending aorta. Attempts to improve accuracy of BP measurement at distal arteries have been explored using the technique of applanation tonometry, most notably at the radial artery.

Radial artery applanation tonometry

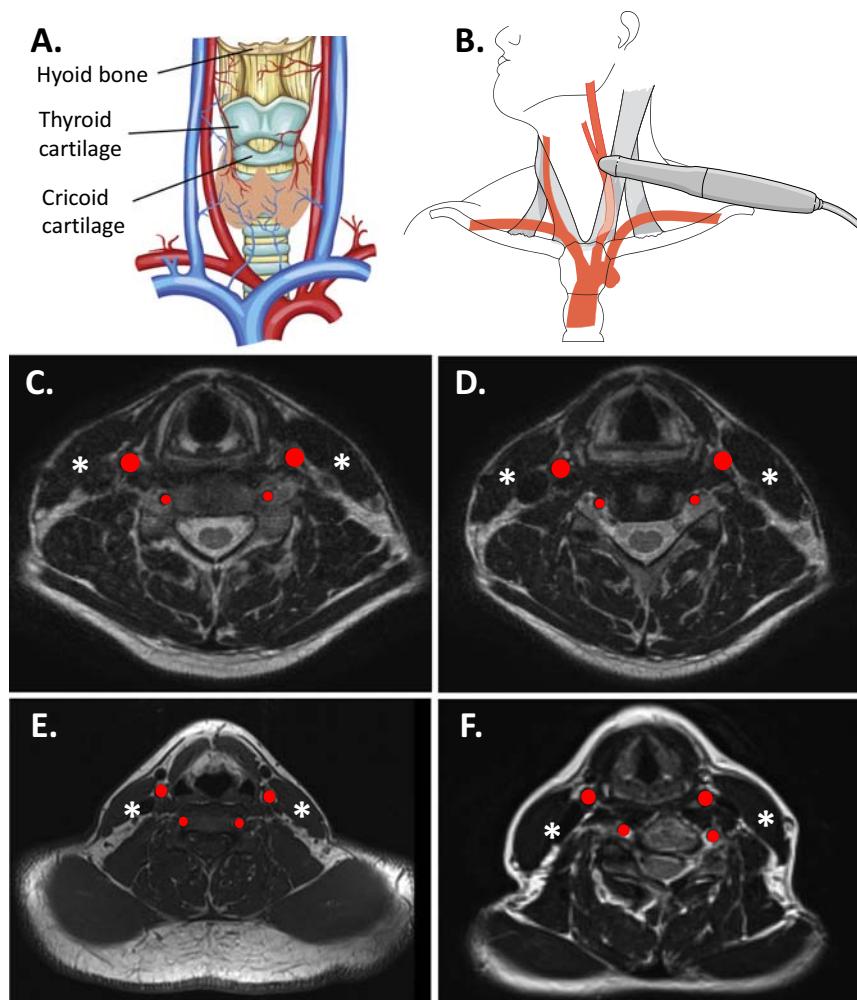
Noninvasive recording of arterial pressure waveforms can be achieved using applanation tonometry at a palpable peripheral artery, usually applied at the more easily accessible radial or carotid arteries. The technique typically involves use of a pen-like tonometer probe housing a piezoelectric pressure sensor at the tip, but can also be undertaken by servo-controlled devices with piezoelectric arrays to help limit movement artifact.[44] The sensor is lightly applied perpendicular to the artery, partially flattening the wall (applanation), which eliminates tangential forces and exposes the sensor to the pressure within the artery. This enables high-quality recordings of the arterial pulse that are similar to that acquired by intra-arterial measurement.[45−47]

With accurate recording of the radial artery waveform, a central aortic pressure waveform can be generated using a mathematical transfer function (Fig. 2.2), often a generalized function assessed from population data.[48,49] Correct calibration of the radial waveform (scaling using units of pressure) is required to generate an accurate estimation of central aortic BP. Indeed, many investigators have shown that calibration using aortic intra-arterial mean arterial pressure and diastolic BP produces accurate central aortic systolic BP values, even among subjects of different age, heart rate, and BP, but also with major hemodynamic perturbations induced by vasoactive medications, Valsalva maneuver, abdominal compression, and exercise.[44,48−51] However, it should be noted that such validation is present only for peak pressure, rather than the details of the waveform, which are required for more sophisticated hemodynamic analyses. Moreover, some evidence indicates the technique is less accurate among populations at higher risk for vascular disease (i.e., type 2 diabetes, chronic kidney disease),[18,52] implying potential weakness of generalized transfer functions being used in people with extreme vascular aging.[20] This issue probably also applies to cuff oscillometric BP,[19,20] but is incompletely understood and requires further research.

FIGURE 2.2   Estimation of central aortic pressure using radial arterial tonometry.

Carotid arterial tonometry can be used to obtain high-fidelity pressure wave forms from the carotid artery, which is morphologically similar (but not identical) to the aortic pressure waveform.[53] This approach is advantageous because it does not require a transfer function. However, the procedure is more technically demanding than radial tonometry. Anatomic and technical considerations for carotid applanation tonometry are discussed in Box 2.1 and represented in Fig. 2.3.

Two factors reported in 1990, using intra-arterial BP measures in patients undergoing cardiac catheterization, emphasized the potential clinical importance of pursuing measurements of central aortic BP as distinct from brachial BP. Firstly, central aortic systolic BP could be significantly different among patients with similar brachial systolic BP (e.g., brachial ≈ 150 mmHg but aortic $\approx 130-150$ mmHg)[54]; meaning that the true risk related to BP could be missed if only focusing on BP measurement at the upper arm. Secondly, the BP lowering effects of antihypertensive agents could be more pronounced at the central aorta compared with the brachial artery, and it was even possible for large BP lowering effects to only occur at the central aorta[54]; meaning that greater precision of hypertension management could theoretically be achieved with knowledge of an individual's central BP. These observations, summarized in Fig. 2.4, provided rationale to pursue development of noninvasive means to record and calibrate radial waveforms and derive central BP from it.

The first commercial device became available in 1996, was intensively used in clinical research and preceded development of many other similar methods.[55] Operation was based on radial artery tonometry and calibration of the radial waveform with conventional cuff systolic BP and diastolic BP. The method held promise[56] and has enhanced understanding of the differential therapeutic effects on cuff BP compared with derived central aortic BP,[57-60] but the method has failed to integrate into practice and accuracy issues have prevailed.[61,62] Unfortunately, the systematic error intrinsic to cuff-based BP, and especially oscillometric, methods (i.e., underestimation of systolic BP but overestimation of diastolic BP) leads to substantial underestimation of the true central aortic systolic BP and pulse pressure (confirmed with intra-arterial assessment).[63-67] Further calibration error also comes from the assumption there is no systolic BP difference between the brachial and radial artery,[68] when in fact there is large interindividual variability.[43,69-72] This has a major influence on estimation of aortic systolic BP[71,73] and emphasizes yet again how difficult it is to achieve accurate and clinically meaningful BP recordings, particularly from measurement at the wrist artery.


Another factor that adds to the lack of clarity in distinguishing the diagnostic utility of the radial tonometry method above and beyond standard cuff BP[61] is the very high correlation that exists between cuff brachial systolic BP and tonometry-derived central aortic systolic BP (e.g., $R^2 = 0.93$).[74] Slight improvement in accuracy of radial tonometry may be achieved by calibration with cuff BP-derived mean arterial pressure and diastolic BP,[67] but this also has fundamental limitations and does not fully resolve calibration problems.[75,76] In seeking to develop better methods that are also more amenable to integration into daily clinical practice, the last decade has seen the field turned toward estimation of central aortic BP using cuff-based approaches with similar modes of operation to standard automated BP devices already in widespread use.

BOX 2.1 How to perform carotid arterial tonometry

Carotid tonometry is best performed in the supine position. A rolled towel under the neck and slight extension may help bring the carotid artery anteriorly and/or stabilize it between the tonometer and underlying anatomic structures. This maneuver may tighten the skin overlying the artery, particularly among subjects with short necks, impeding adequate flattening of the arterial wall. This can be overcome by relaxation/opening of the jaw.

The goal of carotid tonometry is to record intra-arterial pressure waveforms. This can be accomplished by flattening the artery against underlying hard structures in the neck (cartilage and/or bone tissue). Reviewing anatomic relationships between the common carotid artery and these structures is useful, as shown in Fig. 2.3. The common carotid arteries (large red circles) exhibit roughly consistent relationships with the underlying laryngeal/pharyngeal cartilages, the bony structures in the neck (such as vertebral transverse processes, which surround the vertebral arteries), and the sternocleidomastoid muscle.

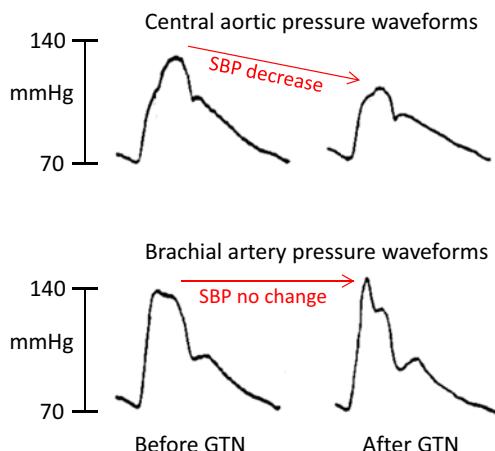
Panel A in Fig. 2.3 shows the relationships between the common carotid and the thyroid and cricoid cartilages. Panel B shows its relationship with the sternocleidomastoid muscle. Panels C, D, and E show examples of these relationships in cross section. It can be seen that the common carotid artery is not superficial but lies medial and posterior to the anterolateral part of the sternocleidomastoid muscle, particularly in the lower part of the neck. These relationships are important to approach the artery in an attempt to position the tonometer directly on top of it (without intervening muscle tissue), flattening it against underlying structures.


FIGURE 2.3 Anatomic considerations for carotid arterial tonometry. Panel A shows the relationships between the common carotid and the thyroid and cricoid cartilages. Panel B shows its relationship with the sternocleidomastoid muscle. Panels C, D, and E shows its relationship with various anatomic structures in cross section. Panel F shows how the relationship changes with slight rotation of the head. The common carotid arteries are marked by big red circles, whereas the vertebral arteries are marked with small red circles. The asterisks mark the sternocleidomastoid muscle. See Box 2.1 text for details.

Another issue to consider is the level of the carotid bifurcation, since the goal of carotid tonometry is to acquire common carotid waveforms rather than external carotid waveforms. The thyroid cartilage ("Adam's apple") is located at the C4 level and is an easily identifiable landmark. The carotid bifurcation usually occurs at the C3–C4 level (between the thyroid cartilage and the hyoid bone), although a small percentage of people exhibit higher bifurcations (more common among Asians) or lower bifurcations.

In the authors' experience, the best way to "trap" the carotid artery against underlying hard structures to obtain high-fidelity recordings is to approach it from the anterolateral aspect, orienting the tonometer posteromedially (toward the back and the midline), gently pulling the sternocleidomastoid muscle posteriorly (i.e., toward the back of the neck), initially with the hand that is not holding the tonometer and subsequently with the pen-like portion of the tonometer, so that the artery can be flattened without intervening muscle tissue between the sensor and the arterial wall. With slight rotation of the head, the carotid can be positioned anterior to the vertebral transverse process and closer to the vertebral body (Panel F in Fig. 2.3), facilitating applanation.

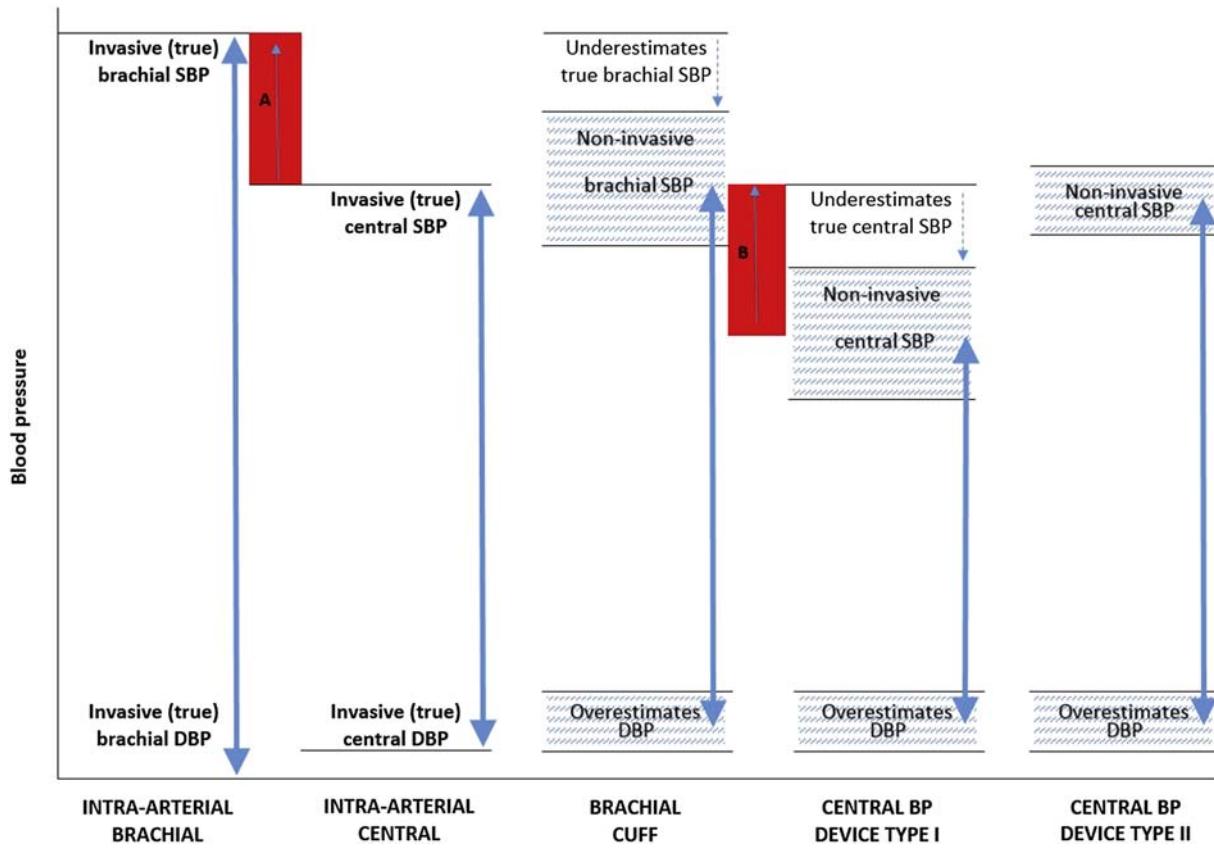
The amount of pressure exerted by the operator on the tonometer should be high enough to acquire a clear signal, but excessive pressure has the potential to result in subject discomfort, vagal responses, and/or the inability to record the pressure nadir. The latter problem can be detected by the presence of a flat late diastolic pressure profile, rather than the expected asymptotic exponential fall. The latter problem is uncommon with carotid tonometry but sometimes occur with radial tonometry when excessive pressure is applied over the artery, which should be avoided.


FIGURE 2.4 Intra-arterial central and brachial pressure waveforms before and after 0.3 mg sublingual nitroglycerin (GTN) in a 59-year-old male. Note that the morphology of the pressure waveforms changes after GTN and for this individual there is a marked drop in central systolic blood pressure (SBP) but no accompanying drop in brachial artery SBP. Other people may experience a decrease in both central and brachial BP. *Adapted from Kelly RP, Gibbs HH, O'Rourke MF, et al. Nitroglycerin has more favourable effects on left ventricular afterload than apparent from measurement of pressure in a peripheral artery.* Eur Heart J. 1990;11:138–144 with permission from Oxford University Press.

Cuff central aortic blood pressure

All cuff methods to estimate central aortic BP, as a separate entity from brachial BP, follow similar principles to radial tonometry, with the main distinction being that the first step of peripheral waveform recording is achieved by cuff sensors at the upper arm/brachial artery instead of the radial artery by tonometry.[55,77,78] Brachial waves are recorded as per the oscillometric method previously mentioned, which may also be referred to as some variation of "pulse volume plethysmography." Depending on the device, brachial waveforms may be recorded at variable cuff pressure, anywhere between subdiastolic to suprasystolic BP, but with all devices using brachial cuff oscillometric BP as the mode of calibration. Proprietary generalized transfer functions that differ between manufacturers are used to generate a central aortic BP waveform and estimate central BP. Thus, it is not unexpected that the same underestimation of the true central systolic BP occurs when waveforms are calibrated with brachial systolic BP and diastolic BP.[79–81] An advantage of cuff-based central BP is that automated, repeat measures can be acquired in the office (observed or unobserved), at home or with 24 h ambulatory BP monitoring.

It was only in 2017 when guidelines on standardized validation protocols for testing the accuracy of central BP devices were developed by a task force of the European ARTERY Society.[5] General integration with existing international protocols for brachial cuff device validation in terms of sample size (n = 85) and subject characteristics were advocated, and a key recommendation was for intra-arterial BP measured by catheter at the ascending aorta to be the reference standard by which device performance is compared.[5] Central BP devices were also broadly classified into two categories of operation: type I devices that purport to estimate central BP relative to brachial BP (which may provide relatively accurate systolic BP difference between central and peripheral sites) and type 2 devices that purport to estimate the intra-arterial (true) central BP, despite inaccuracy at the peripheral site (as detailed previously).[5] Illustration of the differences between devices types is depicted in Fig. 2.5.

FIGURE 2.5   Differences in brachial and central blood pressure (BP), between intra-arterial BP, brachial cuff BP and noninvasive central BP devices Types I and II. Double arrows represent BP ranges; red shaded area A represents the true level of central-to-brachial systolic blood pressure (SBP) amplification, and red shaded area B represents the noninvasive estimated central-to-brachial SBP amplification. The noninvasive central SBP estimated using central BP device Type II may be higher than noninvasive brachial cuff SBP, but this is due to underestimation of true (intra-arterial) brachial SBP with the cuff device and, therefore, does not reflect physiological amplification. The hatched areas denote that there will be a degree of variability in estimated BP between devices. *Reproduced from Sharman JE, Avolio AP, Baulmann J, et al. Validation of non-invasive central blood pressure devices: ARTERY Society task force consensus statement on protocol standardization. Eur Heart J. 2017;38:2805−2812 with permission from Oxford University Press.*

International guidelines recommend diagnosis and treatment based on absolute cardiovascular disease risk rather than single risk factor management (i.e., only focusing on BP or lipids).[82−85] Thus, central BP information derived from type I devices may be best applied when brachial cuff BP is borderline or mildly elevated but absolute cardiovascular disease risk is low and there is an absence of target organ damage. In these circumstances, there may be uncertainty as to whether antihypertensive treatment should be initiated, or uptitrated, and knowing central BP relative to brachial BP could be helpful to resolve clinical indecision. However, whether this adds value in terms of reducing cardiovascular events has never been determined in randomized controlled trials, which is a major gap in knowledge that requires additional research.

Type II central BP devices essentially aim to provide a more accurate measure of a clinically relevant (central aortic) BP than either cuff brachial BP or central BP using a

type I device (noting that both function types may be available within a single device).[5] Greater accuracy is achieved by additional proprietary algorithms to recalibrate the peripheral waveform and generate a central systolic BP closer to the intra-arterial measure.[78,86,87] A nationally representative study in Taiwan reported that the prevalence of hypertension would be increased (from 25% to 33%) if central BP using a type II device was employed in favor of standard brachial cuff BP.[88] Others have shown that central BP recorded using type II device elicits stronger associations with cardiovascular endpoints than either brachial BP or central BP estimated in Type I device operation.[89,90] This is not unexpected given that type II device central BP provides a more clinically relevant BP, but still there is no randomized controlled trial data proving clinical superiority beyond best-practice standard cuff BP methods, and these data are desirable. With type II devices, it will be important to determine whether recalibration of peripheral waveforms

(and therefore estimation of true intrabrachial pressures) as opposed to also estimating a more accurate aortic pressure, is a relevant step in enhancing cardiovascular risk prediction and decision-making.

Cuffless blood pressure wearables

Technological capability to measure biometric signals and convert them to apparent BP values from virtually any body part has burgeoned in recent years.[91] Cuffless BP wearables can be embedded into clothing, worn as ear buds, eyeglasses, soft arm bands, watch-type wristbands, or stick on patches, just to name a few.[92-95] The global market size for wearable BP technologies is on the rise and expected to reach USD $2.25 billion in 2023.[96] Increasing demand for wearable BP monitors is due to increased disease prevalence, increased patient monitoring services, and greater interest in self-monitoring of health. Cuffless alternatives to standard inflatable cuff-based BP also offer more convenient and comfortable means of BP measurement. Although it seems that people trust the accuracy of wearables (>70% in one survey),[97] this could be misplaced confidence if the findings of an Australian study are representative of the global marketplace, where >500 unique wristband wearable BP devices were available for purchase but none had proof of accuracy testing.[38]

Some cuffless BP methods acquire a single "snapshot" BP,[42] which is clinically less useful, whereas others have continuous recording capability for nonintrusive data collection (and intelligent analysis) over much longer time periods relative to cuff-based methods.[94] It is beyond this chapter to detail all methods and readers are directed to an electronic book that is dedicated to the topic.[98] Cuffless devices broadly follow measurement principles of conventional cuff-based approaches in terms of recording a peripheral pressure waveform signal (through various techniques), then applying algorithms (again through various techniques) to generate an estimated BP. A critical step that is different from conventional cuff-based approaches, and currently presenting the greatest challenge for achieving accurate cuffless BP measurement, is correct calibration of the recorded peripheral pressure waveforms so that accurate absolute BP values can be derived. Unfortunately, in most cases, conventional cuff-based systolic and diastolic BP is used to calibrate waveforms from cuffless sensors despite all the inherent inaccuracies previously described, and this calibration error is likely transferred to erroneous cuffless BP estimation.

Highly sophisticated methods based on artificial intelligence and machine learning algorithms have been applied to novel BP assessment tools such as transdermal optical imaging of facial blood flow through smartphone videos.[99] These type of approaches allow for possible contactless BP monitoring, but again, calibration and reference comparators for new cuffless BP technologies are almost exclusively based on cuff-based oscillometric BP methods with inherent accuracy flaws. Having said this, relatively small deficiencies regarding BP accuracy could be outweighed by the extra BP information gained with long-term unintrusive continuous BP monitoring and big data analysis (e.g., better understanding/new discovery on the genesis and early detection of hypertension, and advanced tracking of therapeutic responses). Hybrid approaches incorporating less accurate continuous novel measurement devices with more established, accurate, and precise methods seem attractive to overcome the limitations of each group of measurements in isolation.

Integration of BP data with existing health system electronic databases for better clinical decisions and improved quality of care, underpin the rationale for international prioritization on the development, implementation and scaling up of digital health technologies.[100] This recommendation comes with the warning that the enthusiasm for digital health has driven a proliferation of transitory implementations, an overwhelming diversity of tools with limited understanding of the impact on people and health systems,[100] as we currently see with the cuffless BP device sector. Efficacious BP device companies of the future will have considered integration into clinical systems of care in addition to proving accuracy and clinical value.

Medical device regulators are aware of the need to revise regulatory frameworks and create efficient processes governing the use, safety, and effectiveness of digital health technologies.[101] Accuracy concerns have been identified as a factor that will inhibit market growth in wearables technology,[96] and hopefully this will incentivize manufacturers toward better practice. In the meantime, it is important that the medical community and organized societies promote rigorous validation protocols[102,103] prior to endorsing specific devices or strategies. Similarly, the medical community must stay alert to false claims of accuracy, which have potential for harm via overdetection or underdetection of hypertension.

Invasive, intra-arterial blood pressure

The direct physiological measurement of BP can only be achieved with invasive, intra-arterial methods, as such, all the cuff-based and cuffless BP methods mentioned above provide an indirect estimation of BP.[14] Direct measurement involves the intra-arterial introduction of a fluid-filled or micromanometer-tipped catheter in a sterile medical procedure that is not without risk and thus is not sensible, nor ethically acceptable, to be performed unless clinically indicated (e.g., among people with suspected coronary artery disease requiring coronary artery angiography). It is not surprising then, that the evidence on the risk associated with high BP and the importance of therapy to lower BP

has been derived almost exclusively using noninvasive cuff-based BP methods, and there is limited evidence on the prognostic value of invasive BP.[14,104,105]

Despite limitations of invasive BP measurement, this is the gold standard reference to determine accuracy of central BP devices (minimum n = 85)[5] and may also be used in validation protocols of automated brachial cuff BP devices,[15] albeit with caution in this latter protocol where much fewer subjects are allowable (minimum n = 15), which limits the full range and quality of validation testing. Careful attention to handling of monitoring equipment and procedures of measurement are required to avoid errors with invasive BP.[106] Micromanometer-tipped catheters are preferred, especially where waveform morphology is the subject of analysis (not just systolic and diastolic BP), because additional sources of error can occur with incorrect handling of fluid-filled catheters. However, accessibility to micromanometer-tipped catheters is more difficult as they are expensive and not routinely used clinically. Reassuringly, if meticulously handled, fluid-filled catheters are acceptable for accurate intra-arterial BP measurement.

Readers are directed to detailed information on recommended protocols for intra-arterial BP measurement provided in the International Standard ISO 81060-2,[15] the ARTERY Society task force consensus statement,[5] and other sources.[106–108] Adequate dynamic response of the pressure transducer is required for accurate BP recording and maintenance of arterial pressure waveform features. An under- or overdamped system can influence the quality of waveform recording and lead to incorrect BP values (Table 2.1). For example, underdamping causes pressure "overshoot" resulting in overestimated systolic BP (and pulse pressure), underestimated diastolic BP, a pronounced dicrotic notch, and nonphysiological wave fluctuations during diastole. Overdamping, on the other hand, underestimates systolic BP (and pulse pressure),

overestimates diastolic BP, and smooths out arterial waveform features. A common practical approach for assessing the dynamic response and appropriate dampening of fluid-filled catheter systems is the square wave (fast flush) test, described in Box 2.2 (from References 106–109).

Differences between the transducer level of fluid-filled catheters and the level of the measurement site can create significant error from hydrostatic pressure differences (e.g., 10 cm difference = 7.5 mmHg difference). Therefore, the transducer (stopcock) should be kept at the level of the left ventricle (or vessel of interest) during zeroing and BP recording. Many of the technical issues associated with fluid-filled catheters can be overcome using micromanometer-tipped catheters or pressure wires with a pressure transducer in the tip, providing the most accurate quantification of BP.[110] Implantable invasive hemodynamic monitoring of pulmonary artery pressure is also now available for patients with advanced heart failure where it has been shown to improve outpatient management and reduce heart failure-related hospitalizations.[111] The rationale is that worsening symptoms of heart failure congestion may be identified early from increased pulmonary artery pressure via telemonitoring and thereby prompt remediating action and avoidance of costly hospitalizations.[112]

Summary of blood pressure measurement methods

Beyond biophysical principles of BP measurement, this chapter has presented ideas on the clinical advantages and pitfalls of different BP methods (Table 2.2). The accurate measurement of BP not only relies on valid recording equipment but also on making sure to follow correct protocols of measurement.[113] In 2005, Pickering and colleagues lamented that even though BP was one of the most

TABLE 2.1 Comparison of underdamping and overdamping of fluid-filled catheter systems.

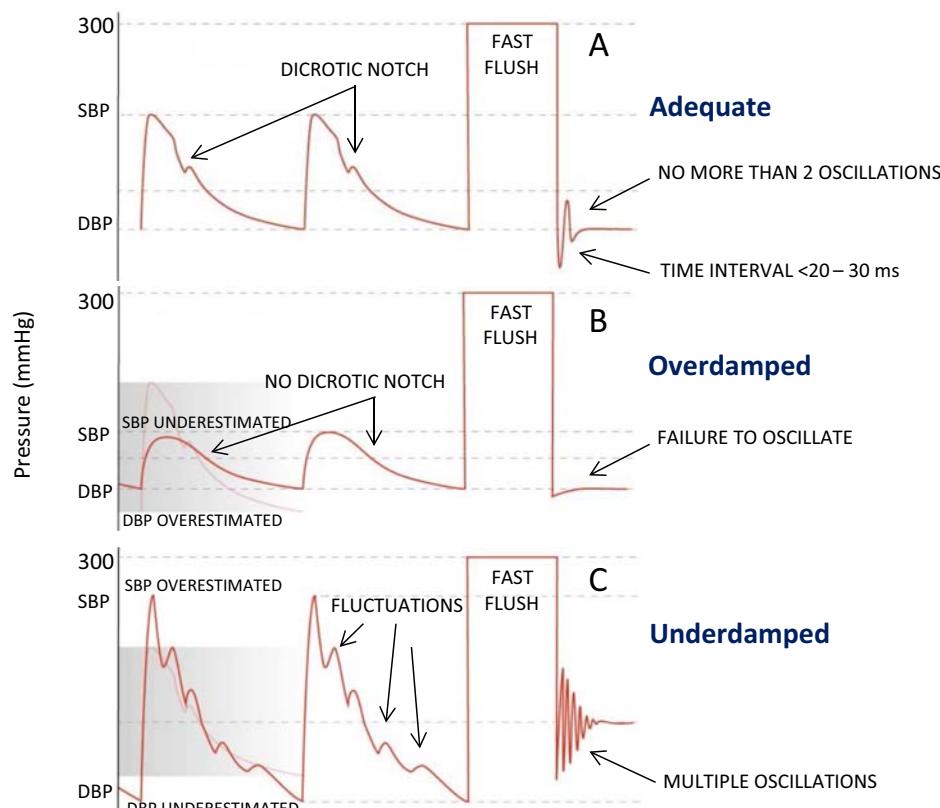
	Underdamping (resonance)	Overdamping
Systolic blood pressure	Overestimated	Underestimated
Diastolic blood pressure (BP)	Underestimated	Overestimated
Pulse pressure	Overestimated	Underestimated
Dicrotic notch	Deep	Absent; however, the absence of a dicrotic notch is sometimes observed in systems with an adequate dynamic response, and should not be considered of overdamping by itself
Other	Nonphysiologic diastolic fluctuations	Slurred upstroke and general loss of detail


TABLE 2.1 Comparison of underdamping and overdamping of fluid-filled catheter systems.—cont'd

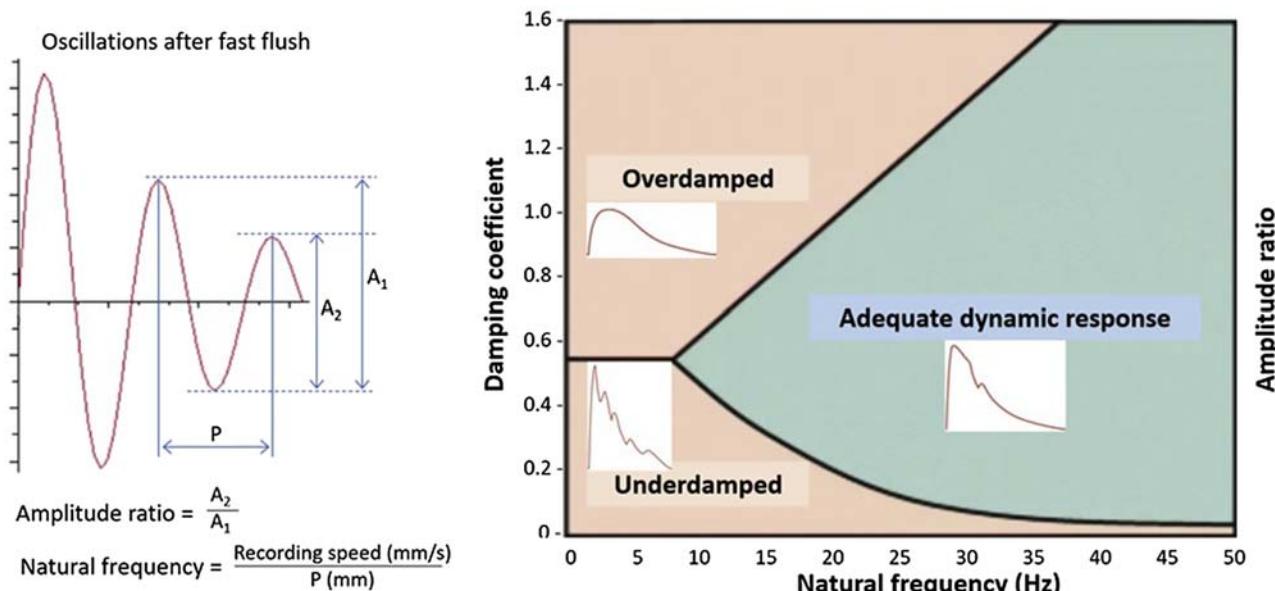
	Underdamping (resonance)	Overdamping
Characteristics in the square wave test	More than two oscillations after the test, high amplitude of oscillations relative to preceding oscillation (as a general rule, the amplitude of each oscillation should be no greater than ~1/3 of the amplitude of the preceding oscillation)	The system does not oscillate after the square wave (there should be one to two "bounce" oscillations)
Reasons	Excessively long and stiff tubing or defective transducer	Low infusion bag pressure, air bubbles or blood clots in the circuit, lose or open connections and kinking or obstruction of the catheter
Strategies to prevent or remediate	• Use of short, stiff tubing • Limit the number of stopcocks • Reduce motion of the catheter in the artery • Adjustable dampening devices	• Avoid kinking • Remove air and blood clots • Replace the catheter as needed

BOX 2.2 How to test the dynamic response of fluid-filled catheter systems?

A dynamic response test determines function of the entire system of recording arterial pressure, from the arterial catheter, tubing, and transducer to the system of recording the arterial pressure waveforms. There are several ways that a dynamic response test may be conducted, and each of which involves perturbing the system with a rapid pressure change, then analyzing the dynamic response to determine the characteristics of the measuring system.

The commonly used fast flush test briefly exposes the transducer to high pressure (i.e., 300 mmHg by a quick turn of a stopcock) from a pressurized saline bag, causing a square wave (a sharp pressure rise followed by a brief plateau then a sharp pressure fall), at the end of which the transducer system returns to baseline. In returning to baseline, the pressure wave briefly oscillates, and analysis of these oscillations is conducted to determine the dynamic response from the natural frequency and damping coefficient.

FIGURE 2.6 Example pressure waveforms from dynamic response testing using the square wave, fast flush test. *Adapted from Deranged Physiology: Arterial line dynamic response testing. https://derangedphysiology.com/main/cicm-primary-exam/required-reading/cardiovascular-system/Chapter%20759/arterial-line-dynamic-response-testing. Accessed October 20, 2020.*


The natural frequency is the frequency of pressure pulse oscillations when not subjected to external force (how rapidly the system oscillates), whereas the damping coefficient is how quickly the oscillations come to rest (the decay of the oscillations).

Fig. 2.6 illustrates the concept of the square wave fast flush test with adequate dynamic response (panel A), as well as example overdamped (panel B) and underdamped (panel C) systems. Key features of a system with adequate dynamic response as per panel A are:

- Short time between oscillations (<20−30 ms)
- At least one oscillation (system is overdamped if it does not oscillate after fast flushing)
- No more than two oscillations (system is underdamped if too many oscillations)
- A distinct dicrotic notch (this is a major waveform feature that can disappear in an overdamped system).

Although there are signs evident in the morphology of the arterial pressure waveform that provide information on the characteristics of the recording system, waveform inspection on its own is inadequate for assessing dynamic response characteristics. For example, there may be no discernable dicrotic notch in the waveforms of some people even in a recording system with adequate dynamic response.

As depicted in Fig. 2.7, the natural frequency of the system is calculated from the quotient of recording speed and the period (P) of one oscillation cycle after the fast flush. The damping coefficient is calculated from the ratio of successive peaks of the oscillations. Note that the dynamic response of the system is determined by a combination of both the natural frequency and the damping coefficient. If the recording system has a high natural frequency (e.g., >24 Hz), it allows for a large leeway in the damping coefficient to achieve adequate dynamic response.

Direct blood pressure measurement–dynamic response requirements.* Anesthesiology. *1981;54:227−236; Deranged Physiology: Arterial line dynamic response testing.* https://derangedphysiology.com/main/cicm-primary-exam/required-reading/cardiovascular-system/Chapter%20759/arterial-line-dynamic-response-testing. *Accessed October 20, 2020.*

important measures in clinical medicine, it was still one of the most inaccurately performed.[3] This statement holds true today despite many efforts to redress, and is a key reason for the focus on accuracy within this chapter. Recent initiatives include providing open access to rapid, free, online certificate training courses in accurate BP measurement,[114] demanding better regulatory control on the accuracy of BP devices,[30,40] establishing listings of validated BP devices,[37,115] and developing consumer resources to help find validated BP devices.[116]

The BP measurement with the most profound and longstanding influence on global clinical practice is cuff mercury sphygmomanometry. This was the reference standard that oscillometric BP devices sought to match and remains the reference standard by which cuff-based BP devices are tested for accuracy.[15] Extensive epidemiology and clinical trial prognostic data over many decades firmly establish cuff-based BP as the *gold standard clinical measure*. However, the nontrivial systematic (and random) differences of cuff-based BP from *gold standard*

TABLE 2.2 Summary of advantages and disadvantages of blood pressure measurement methods.

Method	Advantages	Disadvantages
Cuff mercury sphygmomanometry	• Gold standard noninvasive blood pressure (BP) measurement • Low cost • Reproducible results with minimal maintenance requirements • Amenable for use in low resource settings • Randomized controlled trial evidence to support clinical use	• Susceptible to operator-related error (training required) • Less widely available due to phasing out of clinical use • Systematic error in estimating brachial BP (systolic BP underestimated, diastolic BP overestimated) • May not be a precise estimate of central aortic BP
Cuff "oscillometric" BP	• Low cost, widely available • Automated, easy to use • Suitable for home and ambulatory monitoring • Randomized controlled trial evidence to support clinical use	• Susceptible to device-related error (most available for sale are not validated for accuracy) • Susceptible to operator-related error (training required) • Systematic error in estimating brachial BP (systolic BP underestimated, diastolic BP overestimated) • May not be a precise estimate of central aortic BP
Arterial applanation tonometry	• Enables high-quality noninvasive recordings of arterial waveforms • Enables analysis of waveform features • Carotid tonometry can derive central BP estimates without a mathematical transfer function • May be helpful to resolve clinical indecision based on brachial cuff BP	• Requires operator training and skill • Requires dedicated, costly equipment • Radial tonometry requires accurate calibration which is difficult to achieve noninvasively • Carotid tonometry is more technically demanding than radial tonometry • Lacking randomized controlled trial evidence to support clinical use
Cuff central aortic BP (general)	• Widely available • Automated, easy to use • Suitable for home and ambulatory monitoring • Enables analysis of brachial waveforms • May be helpful to resolve clinical indecision based on brachial cuff BP	• Subject to calibration error and underestimation of central aortic systolic BP for Type I devices • Waveform features may be lost using cuff-based recording methods (especially at subdiastolic BP) • Lacking randomized controlled trial evidence to support clinical use
Cuffless BP devices (general)	• Widely available • Automated, nonintrusive, easy to use • Continuous recording over long time periods (big data analysis) is possible • Potential for more information on BP risk and tracking therapy than cuff-based methods • Potential integration with existing health system electronic records for improved quality of care	• Proliferation of diverse technologies with limited understanding of health value or impact • Measurement accuracy is largely uncertain • Peripheral waveforms require accurate calibration which is difficult to achieve • Peripheral recording sites may not reflect clinically relevant BP • Lacking randomized controlled trial evidence to support clinical use
Intra-arterial, invasive BP	• Gold standard invasive BP measure • Enables accurate BP measurement • Enables arterial waveform analysis • Implantable intra-arterial technology available to aid clinical care for high-risk patients	• Invasive medical procedure not amenable for use without clinical indication • Requires significant technical skill and expensive medical resources to perform safely and accurately

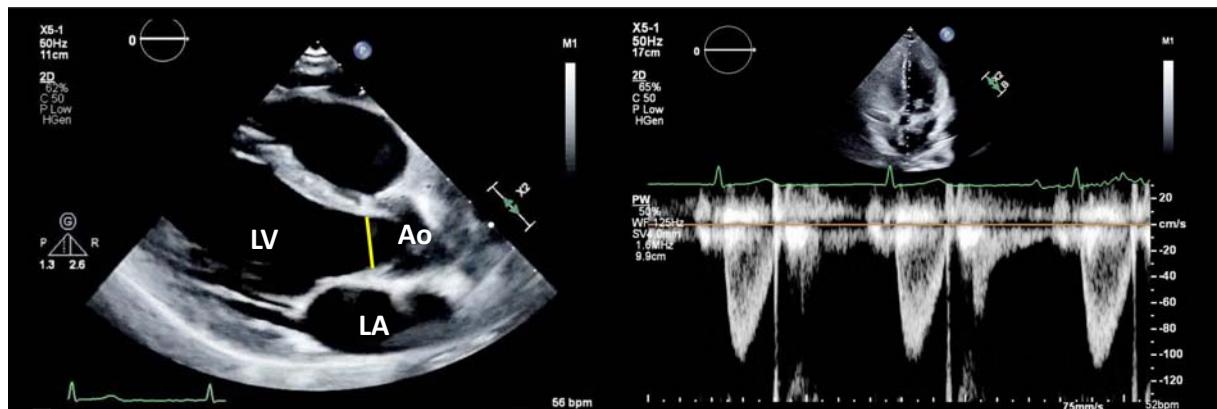
physiological measures of intra-arterial BP cannot be ignored and emphasize an unmet need for improving accuracy. This is a key challenge for high-quality BP device manufacturers of the 21st century.

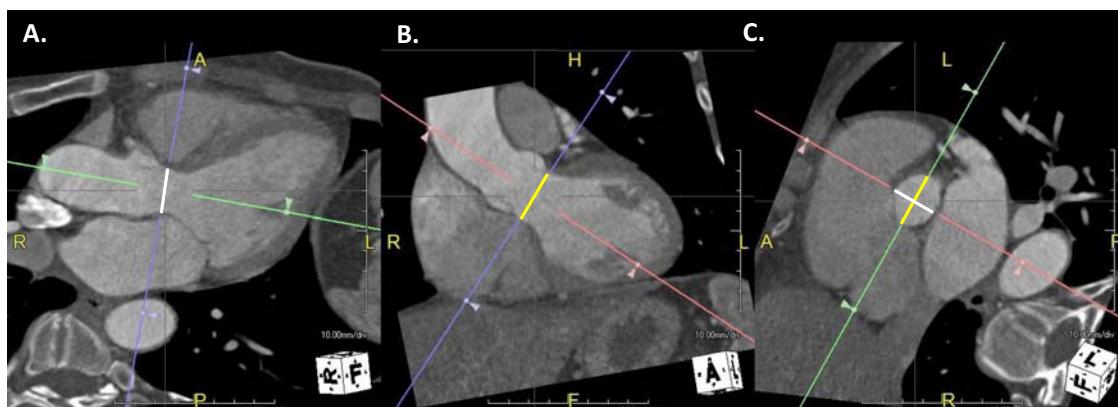
Measurements of arterial flow

The two most widely used techniques for flow measurements in human studies and clinical practice are pulsed wave-Doppler (PW-Doppler) echocardiography and cardiac phase-contrast magnetic resonance imaging (PC-MRI).[117–119] A general comparison of these two techniques is shown in Table 2.3.

Pulsed wave-Doppler

PW-Doppler flow measurements rely on the principle that the Doppler shift of reflected ultrasound waves induced by moving blood particles is proportional to the velocity of those particles.[120] Important considerations for measuring blood flow with PW-Doppler include adequate sample position and volume, gain settings, and Doppler beam orientation, which must be well aligned to the direction of blood flow (zero-insonation angle) to avoid underestimation of flow velocities (although mathematical corrections can be performed for slightly misaligned interrogations).

In practice, flow into the aortic root equals the flow out of the left ventricular outflow tract (LVOT), which is easily visualized with transthoracic echocardiography, allowing for interrogations of LVOT flow velocity and cross-sectional diameter (which in turn is used to compute cross-sectional area), as shown in Fig. 2.8. The latter is important, since volume flow is obtained by multiplying flow velocity times the cross-sectional area of the conduit at the exact point of PW-Doppler interrogation.[120–122] This method assumes a flat flow profile across the vessel lumen and is linearly dependent on cross-sectional area estimations. The latter is generally made from diameter measurements, assuming a circular cross section.


The LVOT tends to be cone-shaped, with the minimal cross-sectional area occurring just below the aortic annulus[122]; often, there is slight widening just underneath the aortic annulus, distal to the narrowest segment, particularly in older patients with septal hypertrophy. When PW-Doppler signals are acquired, the point of maximal flow velocities in the LVOT is identified proximal to the aortic valve, and the velocity signal from that point is recorded; this corresponds to the minimal cross-sectional LVOT area, which is subsequently identified and measured in anatomic images. This is because the continuity principle implies that, in the absence of anatomic defects and assuming a nondeforming LVOT, the volume of blood passing through all points of the LVOT must be equal; since the product of flow velocity and cross-sectional area at any point equals volume flow passing through that point, the point of maximal LVOT flow velocity must correspond to the narrowest area in the LVOT. Another approach is to place the Doppler sample at or immediately below the aortic valve annulus and to measure velocities at precisely this location. Regardless of the approach, the site of flow velocity measurement should always be used along with the diameter measured at the same point, in order to compute volume flow.


An important limitation of the use of LVOT diameter to compute cross-sectional area is the assumption of a circular

TABLE 2.3 Summary of advantages and disadvantages of blood flow measurement methods.

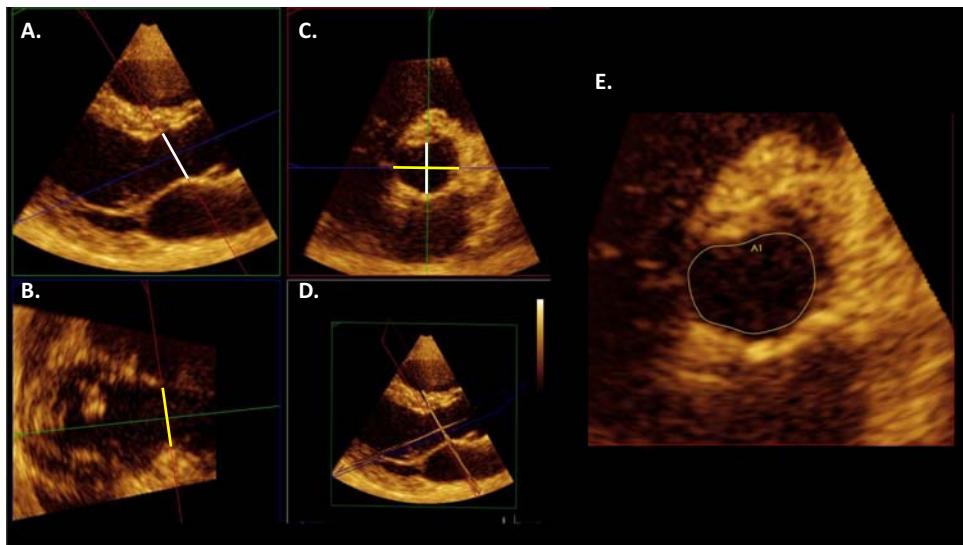
	Pulsed wave Doppler	Phase-contrast magnetic resonance imaging
Advantages	• Low cost and wide availability • High temporal resolution • Can be performed at the bedside • Can be used simultaneously with acquisitions of pressure wave forms • Can be performed in most patients	• Measures volume flow across the entire cross-sectional area • Not limited by acoustic windows or anatomic planes • Does not assume a flat flow profile
Disadvantages	• Limited by acoustic windows • Assumes a flat flow profile or requires correction to account for an assumed profile • Computation of volume flow requires knowledge of vessel cross-sectional area, which is often based on questionable assumptions • Errors in linear measurements are squared for area computations	• Requires expensive dedicated facility • High cost and less widespread availability/expertise • Inconvenient, since it cannot be performed at the bedside • Lower temporal resolution with standard acquisition times • Difficulties in obtaining simultaneous pressure wave forms due to ferromagnetic components in tonometry equipment • Cannot be performed in claustrophobic patients or patients with certain metallic objects


FIGURE 2.8 Measurements of left ventricular outflow tract (LVOT) blood flow with pulsed wave Doppler. The LVOT antero-posterior diameter is typically measured using two-dimensional echocardiography in the parasternal long axis view (left) and the cross-sectional area is computed assuming a circular cross section. LVOT flow velocities are interrogated from the apical five-chamber view, as in this case (right) or from the apical three-chamber view. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle.

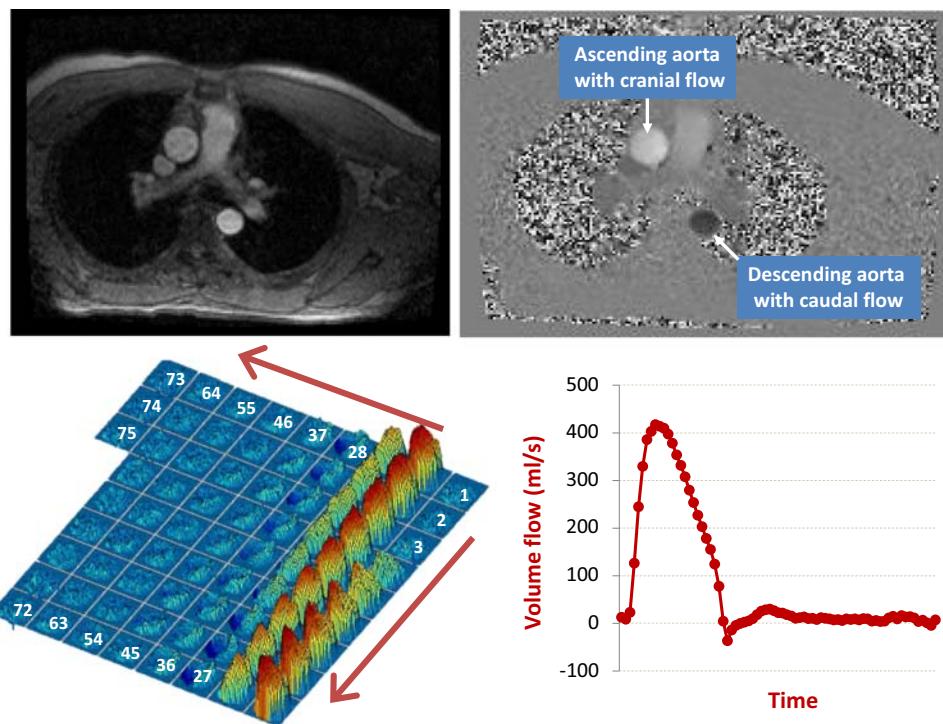
FIGURE 2.9 Example of left ventricular outflow tract (LVOT) cross-sectional geometry using computed tomography three-dimensional reconstruction. Prescription of two orthogonal planes along the long axis of the LVOT (A and B) allows for visualization of a third orthogonal plane (C) which represents the LVOT cross section. An eccentric, rather than circular cross-sectional geometry is present, with the antero-posterior diameter (white line) being shorter than its orthogonal diameter (yellow). Note that the anatomic plane in panel A is similar to the parasternal long axis view (Fig. 2.8A). In cases of LVOT eccentric geometry, the use of this diameter assuming a circular cross-section underestimates the true LVOT cross-sectional area, and thus the volume flow when combined with pulsed wave Doppler flow velocity. *Adapted from Chirinos JA, Segers P. Noninvasive evaluation of left ventricular afterload: part 1: pressure and flow measurements and basic principles of wave conduction and reflection.* Hypertension. *2010;56:555−562.*

LVOT cross-sectional profile (where cross-sectional area equals 0.25π * LVOT diameter2). The LVOT antero-posterior diameter in the parasternal long axis view is typically utilized (Fig. 2.8).[121,122] However, LVOT shape is almost always elliptical, with the antero-posterior diameter usually being shorter than its orthogonal counterpart (Fig. 2.9). Full-volume three-dimensional (3D)-echocardiography with reconstruction of a cross-sectional view can be used for a direct assessment of LVOT cross-sectional area (Fig. 2.10), but it is more technically demanding and time-consuming. With this technique, it is often apparent that the LVOT cross-sectional area can vary throughout systole due to contraction of the basal septum and deformation of the aortomitral continuity (which forms the posterior aspect of the LVOT) during systole.

In a study among 58 adults, we found a mean 2.98 mm-difference between the antero-posterior and its orthogonal diameter and a mean 0.4 cm^2-difference between 3D- and two-dimensional (2D)-derived LVOT area. However, the magnitude of difference varied widely, in some subjects being >1 cm^2. Furthermore, there was only a moderate correlation between 2D- and 3D-measurements ($R^2 = 0.58$).[118] Another limitation of Doppler ultrasound to compute volume flow in vessels is that it assumes a flat flow profile in the vessel lumen (which would result in identical flow velocities at any point in the cross section), a condition that is often not met in arteries in which blood flow exhibits a parabolic profile, or occasionally, highly disorganized profiles (particularly in the distal ascending aorta and aortic arch).

FIGURE 2.10 Example of left ventricular outflow tract (LVOT) cross-sectional geometry assessed with three-dimensional echocardiography. Prescription of two orthogonal planes along the long axis of the LVOT (A and C) allows for visualization of a third orthogonal plane (C) which represents the LVOT cross section. An eccentric, rather than circular cross-sectional geometry is present, with the antero-posterior diameter (*white line*) being shorter than its orthogonal diameter (yellow). Panel D shows representation of the anatomic planes (both orthogonal to the parasternal long axis view). Reconstruction of the LVOT in this manner allows for a direct measurements of cross-sectional area (panel E) that does not assume a circular cross-section. *Adapted from Chirinos JA, Segers P. Noninvasive evaluation of left ventricular afterload: part 1: pressure and flow measurements and basic principles of wave conduction and reflection.* Hypertension. *2010;56:555−562.*

Phase-contrast magnetic resonance imaging


Phase-contrast MRI relies on the fact that, when two opposing magnetic gradient pulses are applied to static nuclei aligned in a magnetic field, the effects of the two pulses on their nuclear spin cancel each other out. However, if a particle moves in the time between the pulses, a shift in the phase of the nuclear spins within the moving particle is accumulated, which is proportional to the velocity of movement along the gradient's direction.[117]

PC-MRI allows for the acquisition of velocity maps along any given anatomical plane. By controlling the gradient direction, velocities can be encoded either "in plane" or "through plane" (in cross section), the latter being particularly useful for assessing flow across an entire vascular cross section without assuming a flat flow profile. With this technique, the anatomic plane should be prescribed exactly perpendicular to the direction of blood flow.

Among other parameters, PC-MRI sequences require a user-defined velocity-encoding sensitivity ("VENC"), which should be as low as possible to maximize the signal from blood flow (thus maximizing the signal-to-noise ratio), yet higher than peak flow velocity in the region of interest to avoid aliasing. VENC should be tailored to individual measurements and iterative PC-MRI acquisitions may be needed, but a good starting point for proximal aortic flow acquisitions is 130−150 cm/s in most cases (unless significant aortic stenosis is present in which case higher velocities are found in some areas of the vessel cross section).

Hyperdynamic LV function or high-output states may also be associated with higher peak flow velocities in some points of the proximal aortic cross section (e.g., 180 cm/s) even in the absence of aortic stenosis, therefore requiring higher VENCs. 2D PC-MRI data are typically acquired over several cardiac cycles and consistent cardiac timing in each cycle is assumed. Prolonged acquisitions may be necessary to accomplish adequate temporal resolution, required for hemodynamic analyses such as pressure-flow analyses.

Limitations of PC-MRI flow measurements include phase-offset errors caused by in-homogeneities of the magnetic field environment (short-term eddy currents).[117] These appear as apparent flow velocities within stationary tissues, typically stable or constant over all frames of a retrospectively gated acquisition.[123] They tend to follow a spatial pattern, such as increasing with distance from the center of the image, which allows for some software correction methods. However, despite correction, even small background velocity offset errors have the potential to result in significant errors in calculated volume flow, due to summation of phase-offset across the entire cross-sectional area of the vessel. Correction for phase-offset can be performed using PC-MRI data acquired from a stationary phantom,[124] but this is not frequently done in practice; moreover, the phase-offset map can change depending on whether the phantom versus the patient is within the bore of the MRI scanner, and therefore the map acquired with a phantom cannot be assumed to be an exact representation of the phase offset present when imaging the

FIGURE 2.11 Measurements of aortic blood flow with through-plane phase-contrast magnetic resonance imaging (MRI). The top left and right panels show magnitude and phase-contrast images of the aortic cross section, respectively. Each pixel in these images represents a voxel (three-dimensional volume with a given thickness). The magnitude image is an anatomic image, whereas the phase-contrast image is essentially a velocity map in which through-plane velocities at each voxel are coded in grayscale in the corresponding pixel. The lower left panel shows the flow velocity profile in the ascending aortic cross-section at each time point in the cardiac cycle (75 time points are recorded in this particular case), and the right lower panel shows the total flow (sum of flow across all individual voxels in the ascending aorta) at each time point. *Adapted from Chirinos JA, Segers P. Noninvasive evaluation of left ventricular afterload: part 1: pressure and flow measurements and basic principles of wave conduction and reflection.* Hypertension. *2010;56:555−562.*

patient. Alternatively, the phase offset can be assessed using information from stationary tissue located in the imaging plane, which generates an error map (including the blood vessel) via interpolation.[125]

Other potential problems in PC-MRI include signal loss due to turbulent flow, partial volume averaging due to limited spatial resolution (since a slice of finite thickness must be interrogated to obtain a sufficient through-plane signal), misregistrations due to in-plane movement of the aorta and pulsatile flow artifacts. PC-MRI is also limited by its high cost, limited availability, incompatibility with patient claustrophobia, and various ferromagnetic objects or implants. The latter also introduces difficulties in truly simultaneous carotid pressure recordings, since available tonometry devices are not MRI-compatible. PC-MRI typically requires breath-hold cooperation for collecting raw data over several cycles, although distal ascending aortic flow can be interrogated during free breathing. An example of through-plane PC-MRI measurements of proximal aortic flow is shown in Fig. 2.11.

Chapter 3

Essential principles of pulsatile pressure-flow relations in the arterial tree

Patrick Segers[1] and Julio A. Chirinos[2,3]

Introduction

In clinical cardiovascular medicine, arterial wave dynamics are most commonly addressed in terms of arterial pressure, which is understandable given the important role of blood pressure in an individual's cardiovascular risk and the relative ease of accurate arterial pressure measurements. Flow is only seldomly considered in terms of wave dynamics. Rather, the heart is implicitly assumed to be a simple flow source, where only the mean flow (or cardiac output) is typically considered of physiological and clinical relevance. There is, however, an intrinsic inconsistency in this approach, since flow is also pulsatile, and pulsatile hemodynamics affect pressure and flow in a closely interrelated manner.

With each contraction of the heart, the ejection of blood from the ventricles into the aorta and pulmonary arteries initiates both pressure and flow waves traveling down the systemic and pulmonary tree. Along their path, waves undergo complex changes in amplitude and shape. For instance, it is well documented that the amplitude (systolic-diastolic difference) of pressure first increases along large and midsized arteries (the so-called pressure amplification)[1,2] before pulsations get damped in smaller arteries to virtually disappear in the microcirculation.[3]

From a biophysics perspective, one cannot study pressure without also considering the flow.[4−6] Both are tightly coupled, and the relation between pressure and flow is entirely determined by the properties of the arterial tree (i.e., the complete topology and branching structure, vessel dimensions and, importantly, the mechanical properties—and thus the composition—of the arterial wall), as well as the properties of the blood flowing in the arteries. Together, they define the opposition to flow that will be generated by the arterial tree, i.e., the arterial (hydraulic) impedance.[7−9] The term impedance is basically a generalization of the concept of resistance, but while the latter is used to express the relation between mean pressure and mean flow, impedance pertains to pulsatile (time-varying) pressure and flow.[10] Further details on the determinants of impedance are extensively covered in Chapter 1.

The eventual pressure and flow that are observed in an individual's arterial system are therefore the result of what we call ventricular-vascular interactions: as the ventricle ejects, it is hydraulically coupled to the arterial tree and its output will be determined by the performance of the heart on one hand, and by arterial impedance on the other.[11−14] We refer the reader to Chapters 15 and 17 of this textbook for more in depth literature on ventricular-vascular interaction.

In this chapter, we will first introduce the concept of arterial input impedance, which fully characterizes the mathematical relation between pressure and flow in the arterial tree. To do so, we will use the Fourier theorem to transform measured pressure and flow waveforms into families of sinusoidal waves ("harmonics" or "overtones" with frequencies that are natural multiples of the fundamental frequency, which is the heart rate). With this approach, the relation between pressure and flow can be expressed per harmonic, and thus as a function of frequency. We will briefly illustrate that we rely on paradigms—models—for the interpretation of input impedance (which is simply the spectrum of the pressure-

flow relation at various frequencies). These models may or may not consider wave travel and reflection, which may or may not be justifiable under certain conditions. We will then focus on "characteristic impedance" (note the difference with "input impedance"), a fundamental local property of an elastic tube that forms the basis of wave separation analysis. We will illustrate how characteristic impedance relates to and can be estimated from input impedance, but also how it can be estimated directly from measured pressure and flow waveforms. This will lead us to the time domain assessment of pressure-flow relations, making use of wave intensity and wave power analyses, techniques that can be used side by side with impedance analysis for a complete assessment of arterial pulsatile hemodynamics. Illustrations throughout the chapter are based on digitized invasively measured pressure and flow waveforms by Murgo et al.[15] A list of symbols and abbreviations utilized in this chapter is shown in Table 3.1.

TABLE 3.1 Symbols and abbreviations.

dP, dQ, dU	Wavelet as used in the time domain analysis of pressure (P), flow (Q), or flow velocity (U); step change in P, Q, or U from instant t_N to t_{N+1} calculated as $P(t_{N+1}) - P(t_N)$, $Q(t_{N+1}) - Q(t_N)$, or $U(t_{N+1}) - U(t_N)$
dI	Wave intensity calculated as $dU.dP$
f	Frequency (in Hz) of a pressure or flow harmonic.
f_{min}	Frequency at which the first minimum in the input impedance modulus occurs. Used to calculate the effective length of the arterial tree using the quarter wavelength formula
I	Complex constant $\sqrt{-1}$
T	Time
A	Cross-sectional area
C	Total arterial compliance (dV/dP with V volume and P pressure)
C_A	Area compliance (dA/dP with A area and P pressure)
L	In context of windkessel models: parameter in the four-element windkessel model representing the inertia of blood in the arterial tree
L	In context of wave propagation: tube length
L_{eff}	Effective length of the arterial tree as derived from the input impedance spectrum and the quarter wavelength formula
P, Q	Pressure (P), flow (Q)
$\overline{P}$, $\overline{Q}$	Mean arterial pressure (P) or flow (Q); the steady (0 Hz) pressure or flow component that is obtained from Fourier decomposition of the pressure or flow waveform
$\widetilde{P}$, $\widetilde{Q}$	Sinusoidal pressure (P) or flow (Q) harmonic obtained from Fourier decomposition of the pressure or flow waveform, characterized by an amplitude, frequency, and phase angle
$\widetilde{P}_f$, $\widetilde{P}_b$, $\widetilde{Q}_f$, $\widetilde{Q}_b$	Forward (subscript f) and backward (subscript b) components of pressure and flow harmonics
PWV	Pulse wave velocity
R	Total arterial resistance, obtained as $\overline{P}\big/\overline{Q}$
Z	Impedance, calculated at a given frequency as $\widetilde{P}/\widetilde{Q}$ and characterized by an amplitude and phase angle
Z_c	Characteristic impedance, the ratio of pressure and flow in absence of any wave reflections
∂	Differential operator (change in a given variable)
λ	Wavelength
$d\pi$	Wave power calculated as $dQ.dP$
φ_P, φ_Q	Phase lag of pressure (P) or flow (Q) harmonics
φ_Z	Impedance phase angle, calculated as $\varphi_Q - \varphi_P$
ρ	Density of blood
ω	Angular frequency (in rad/s) of a pressure or flow harmonic
Γ	Reflection coefficient
Π	Hydraulic power, approximated as by $P.Q$ (pressure power)

Arterial input impedance: a frequency-domain characterization

Impedance: generalizing resistance for sinusoidal signals

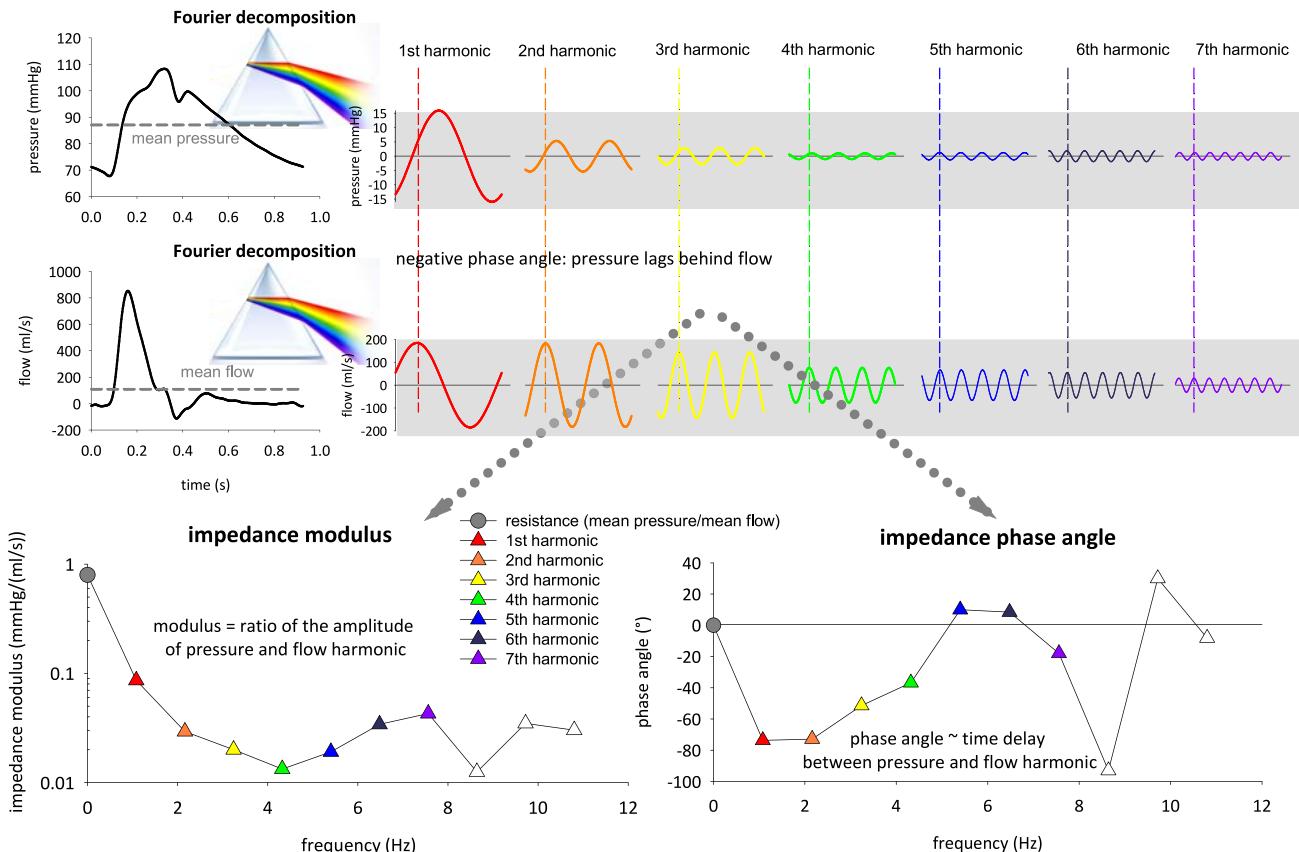
Assume a given systemic or pulmonary arterial tree, in which we position ourselves at its inlet. In order to generate a *constant* flow, $\overline{Q}$, in that system, we would have to generate a *constant* pressure $\overline{P}$. In a linear system (as is usually assumed for the arterial system in vivo), $\overline{P}$ is proportional to $\overline{Q}$ such that $\overline{P} = R\overline{Q}$ (analogous to Ohm's law in electrical theory) with R the total arterial resistance that mainly results from viscous friction forces that the blood exerts on the arterial walls in a normal arterial tree. Note that we hereby assume that venous pressures are small enough to be ignored, and we discard the existence of any zero-flow or critical closing pressure, i.e., a minimal pressure required to generate flow.[16]

If we now impose a *sinusoidally* varying pressure $\widetilde{P}$ (with zero mean value) with a given magnitude and frequency to that same linear(ized) system, this will give rise to a flow $\widetilde{Q}$ that also varies sinusoidally, with the same frequency as the pressure. We call this signal a wave, although we will initially only consider pressure and flow variations in time, and not (yet) in space (thus not considering wave travel for now). Just like resistance represents the ratio of mean pressure and mean flow, the ratio of pressure and flow sine waves represent the impedance at a given frequency. However, sine waves have amplitude and phase (position in time relative to the cardiac cycle). So, for a given frequency, we need two parameters to express the relation between the sinusoidally varying pressure and flow (impedance): the ratio of the amplitude of the harmonics (the impedance modulus) and the phase angle, expressing the phase (time) delay between pressure and flow (Box 3.1).

Calculating impedance at the inlet of the arterial tree

Measured arterial pressure and flow waves are pulsatile, but clearly not sinusoidal (or perfectly oscillatory). Arterial pressure and flow signals are however quasi periodic (i.e., with events consistently occurring at regular intervals) when the cardiovascular system is in steady state. It follows from the Fourier theorem (See basic concept box and Fig. 3.1) that any periodic signal can be decomposed into a steady signal and a series of sine waves (also called harmonics) with frequencies that increase as multiples of the ground frequency of the original signal (in this case, the heart rate). When summed, the result is mathematically identical to the original signal when enough harmonics are taken into consideration. As the Fourier theorem can be applied to measured pressure and flow, the ratio of corresponding harmonics yields impedance for those frequencies present within the spectrum. The value at 0Hz is the ratio of mean pressure and flow ("steady" impedance), which is

---

BOX 3.1 Impedance


A pressure sine wave can be mathematically represented as $\widetilde{P} = |P|e^{i(\omega t - \varphi_P)}$ with $|P|$ the magnitude of the wave, φ_P the phase *lag* (to position it in time), and ω the angular frequency (in rad/s), being equal to $2\pi f$ with f the frequency in Hz. Similarly, we have $\widetilde{Q} = |Q|e^{i(\omega t - \varphi_Q)}$. We can then generally define impedance, Z, for that frequency as

$$Z = \frac{\widetilde{P}}{\widetilde{Q}} = \frac{|P|e^{i(\omega t - \varphi_P)}}{|Q|e^{i(\omega t - \varphi_Q)}} = \frac{|P|}{|Q|}e^{i(\varphi_Q - \varphi_P)} = |Z|e^{i(\varphi_Z)}$$

So, for a given frequency, we need two parameters to express the relation between the sinusoidally varying pressure and flow (impedance): the ratio of the amplitude of the harmonics (the impedance modulus, $|Z|$) and the phase angle (φ_Z), expressing the phase (time) delay between pressure and flow.

The phase angle, and in particular its sign, is important as it reveals some of the underlying physics and properties of the system we are studying. In our notation, with φ_P and φ_Q being phase delays and $\varphi_Z = \varphi_Q - \varphi_P$,

- $\varphi_Z < 0$ implies that the phase lag of pressure is larger than the phase lag of flow, so flow is ahead of pressure. Such behavior indicates a system that behaves as a capacitor, where flow is needed to load the capacitance and build up pressure.
- $\varphi_Z > 0$ implies that the phase lag of pressure is less than the phase lag of flow, so pressure is ahead of flow. Such behavior indicates a system where inertia dominates, and where a certain pressure build-up is required to generate the flow.
- $\varphi_Z = 0$ implies that pressure and flow are in phase, suggesting a resistive-like behavior (whereby resistance is not to be interpreted in terms of viscous resistance as we will see further).

FIGURE 3.1   Practical guide to calculating input impedance. The pressure and flow waveforms are decomposed into their mean (DC) component signal and harmonics (∼spectral components), sine waves with a frequency at a natural multiple of cardiac frequency and a time lag. For each frequency, impedance represents the ratio of the corresponding pressure and flow harmonic, with the impedance modulus being the ratio of their amplitudes, and the phase angle the difference of their phase angles. Negative phase angle implies that flow is ahead of pressure. The value at 0 Hz is the ratio of mean pressure and flow, i.e., total arterial resistance.

equal to the total arterial resistance. With knowledge of impedance, pressure can be calculated when flow is known, and vice versa.

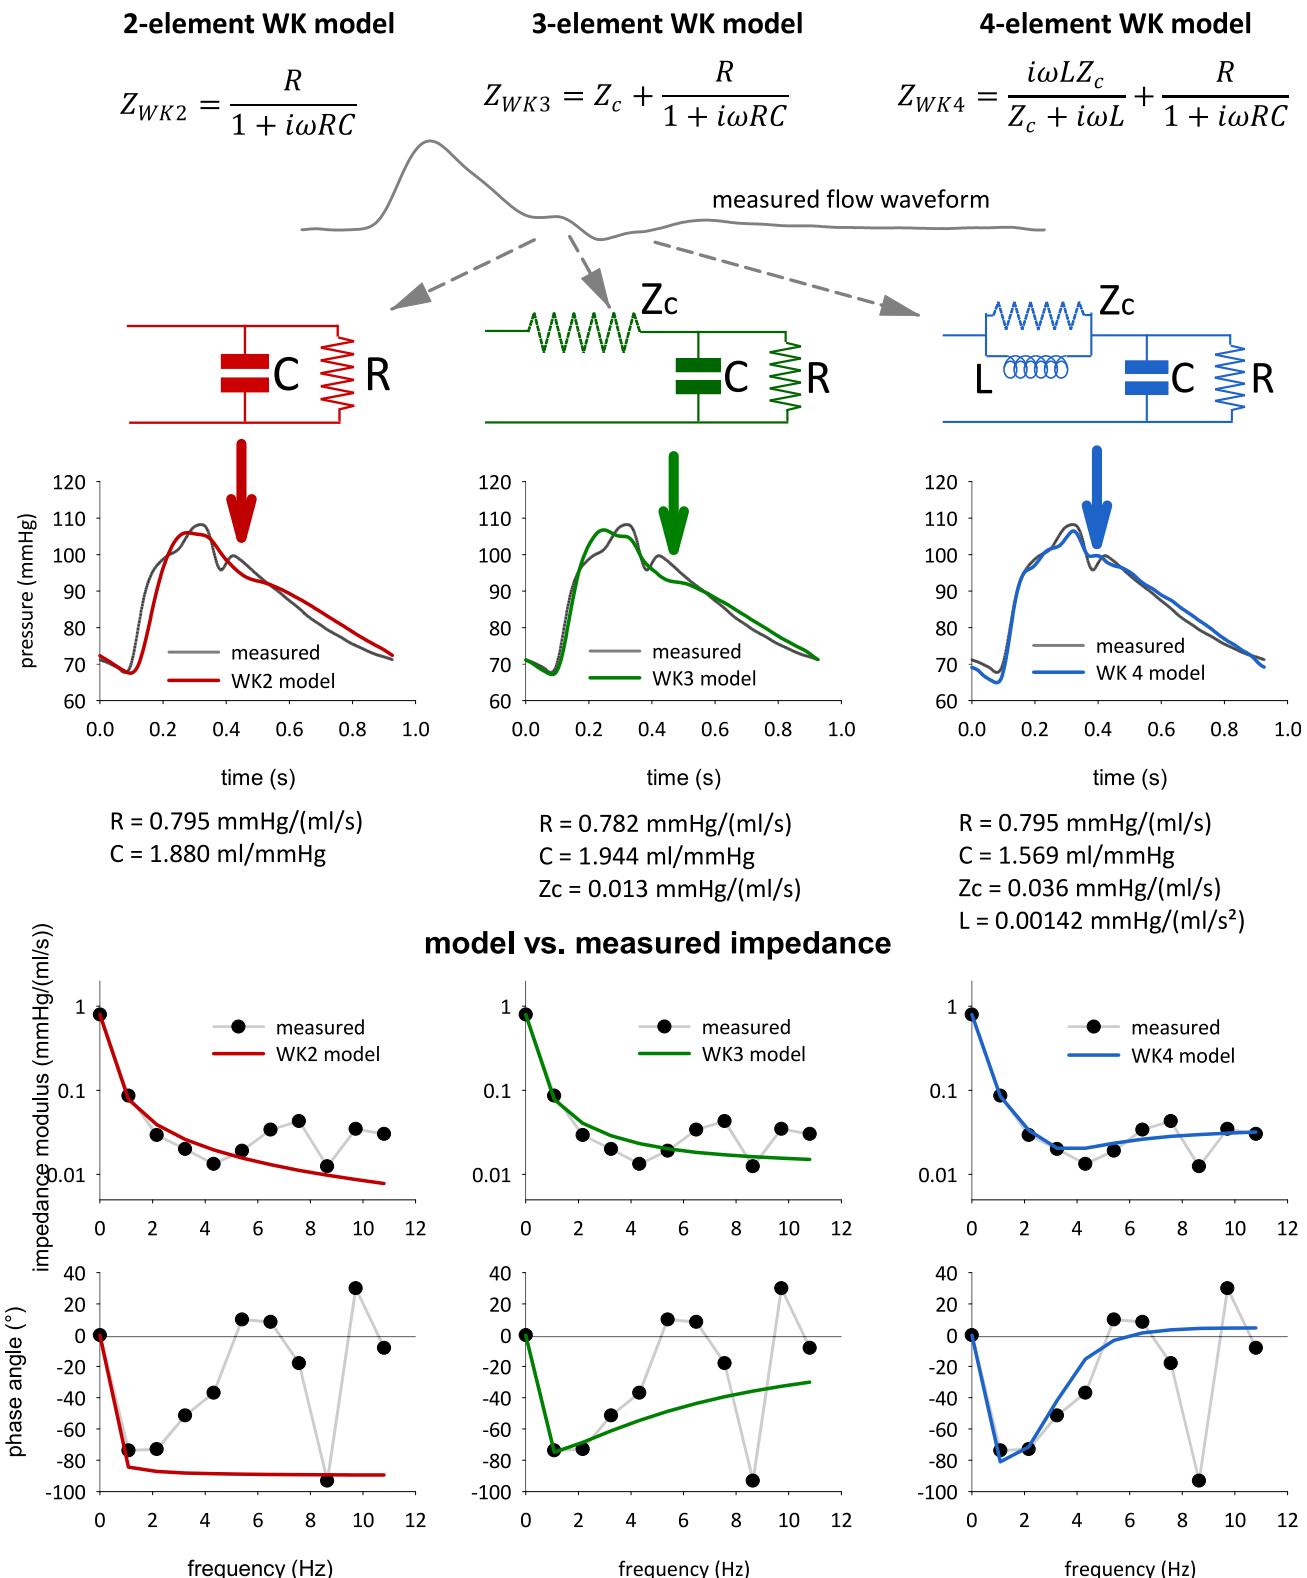
Fig. 3.1 illustrates the steps that are needed to calculate impedance from aortic pressure and flow waveforms measured at the inlet of the systemic circulation (proximal aorta) of a person exhibiting a "type-A" pressure waveform.[15] The data yield a typical human systemic input impedance pattern characterized by:

- A high value at 0 Hz where phase angle is zero (total arterial resistance);
- A fast drop in impedance in the impedance modulus for the first two to four harmonics, for which the phase angle is negative. This is indicative that, for these frequencies, the system behaves in a capacitive way with flow harmonics peaking before pressure harmonics (see Fig. 3.1);
- Impedance modulus reaches a minimum value, while the phase angle goes up, crossing the horizontal axis

for a frequency that (approximately) coincides with the minimum in the modulus;
- Trend toward a constant impedance modulus for the higher harmonics (from the fifth harmonic on) accompanied by a phase angle that oscillates around zero. As we will discuss later, at these higher frequencies, it is thought that a myriad of reflections arriving from multiple locations in the arterial tree cancel each other out at random. Therefore, the remaining impedance is purely dependent on the local arterial impedance (i.e., the characteristic impedance of the vessel at the measurement site, in this case the proximal aorta).

Impedance can be calculated for any point in the arterial tree, but it is most common to calculate it for the ascending aorta, then representing the arterial input impedance (where arterial denotes the entire arterial tree downstream of the proximal aorta). It therefore includes any possible effect of the downstream vasculature on the pressure and flow waves.

Interpreting input impedance: the windkessel perspective

Input impedance in itself can be a fairly abstract concept that is not easily interpreted. One way to approach input impedance is to discard any effects of wave travel and to consider the arterial tree as a system whose properties are lumped in space, so signals (pressure and flow) only vary in time, not in space. The behavior (i.e., the impedance) of such a system can be modeled by a limited number of discrete lumped parameter model components. It is common to mimic the system as an electrical circuit—using resistors (to represent viscous friction experienced by the blood in resistance vessels), capacitances (representing arterial compliance), and inductances (representing blood inertia) as building blocks—but the system can be equally built using hydraulic components, as was demonstrated by Westerhof et al. who developed an artificial arterial system in their studies on heart-arterial interaction in isolated (cat) heart preparations connected to that artificial system.[17]


It takes only two components, a resistance (R) and a volume compliance (C) placed in parallel, to mimic the effect of the resistance vessels and the buffering action of the large arteries, a model known as the two-element windkessel model (the terminology referring to the German word for air chamber after Otto Frank who was the first to document the model).[18] The two-element windkessel model can replicate the low frequency features of the pressure waveform fairly well. Indeed, when imposing a measured flow to the model, the pressure predicted by the model has the correct amplitude (pulse pressure) and shows the exponential pressure decay in diastole (with a rate of decline determined by the time constant RC) as shown in Fig. 3.2. The two-element windkessel model forms the basis of compliance estimation methods as the pulse pressure method,[19] decay time or area method[20] as we will discuss further on.

The two-element windkessel model, however, cannot replicate the higher frequency (or "finer detail") behavior of the arterial tree (visible in the filtered and delayed appearance of pressures predicted by the model—see Fig. 3.2), a problem solved by the three-element windkessel model where a resistive element—characteristic impedance, Z_c—is placed in series with the two-element model.[17] Indeed, for higher frequencies, the model impedance now approaches Z_c, generating the desired behavior for those frequencies. However, while solving the problem at the higher frequencies, Z_c introduces problems for the lower frequencies. It is immediately clear from the expression for impedance that the value at zero frequency is $R + Z_c$ which means that—in this model—Z_c accounts for some of the resistance due to viscous friction, a property ascribed to the resistance vessels and that we preferably capture with R (such that mean pressure/mean flow equals R, and not $R + Z_c$). In addition, the effect of Z_c over the complete frequency range also interferes with the effect of compliance. This becomes most obvious when the three-element windkessel model is used to estimate compliance; compared to other models, it will tend to overestimate compliance to compensate for the presence of Z_c that generates an "impedance offset" in the low frequency band.[21] The higher the ratio of Z_c to R, the more prominent this effect becomes. We demonstrated that the three-element windkessel model particularly overestimates compliance in the pulmonary and in the vasodilated systemic circulation, where resistance is low and the ratio of Z_c to R is higher.[22] Fig. 3.2 reports the parameters of the windkessel model fitted to the data from Fig. 3.1. Note that the three-element windkessel model indeed yields the highest value for C of all models included.

Many other model configurations exist, with more parameters usually improving the ability of the model to mimic impedance or improve model fitting, yet with the drawback that model parameters lose their physiological interpretation and the uncertainty on the fitted parameter value increases. A model worth mentioning is an extension of the three-element windkessel model with an inertial element (L) placed in parallel with Z_c, proposed by Stergiopulos and Westerhof.[23] Having the inertial element in parallel with Z_c is not very intuitive, but authors demonstrated that L represents the inertia of the blood present in all arteries. Interestingly, at zero and low frequencies, the low impedance generated by the inertial element L makes that it acts like a bypass of Z_c; while it forces all "current" (blood) through Z_c at the higher frequencies. As such, the model combines the strengths of the two- and three-element windkessel models and corresponds well to measured input impedance of the arterial circulation in vivo. It is clear from Fig. 3.2 that the four-element windkessel model outperforms the other models, with an excellent fit of the measured impedance modulus and phase, and hence an excellent prediction of the measured pressure waveform.

In summary, windkessel models can be elegant tools to concisely parametrize and quantify basic physiological properties of the arterial tree. With an adequate parameter fit, the parameters of the windkessel model provide the same information as a measured impedance spectrum and therefore capture the relation between arterial pressure and flow. What is important to keep in mind is that these models cannot account for wave travel and reflection. They represent the arterial system and its function as a whole, and parameters cannot not be linked to specific anatomical regions. Below, we expand on the use of windkessel models to estimate total arterial compliance.

2-element WK model

$$Z_{WK2} = \frac{R}{1 + i\omega RC}$$

3-element WK model

$$Z_{WK3} = Z_c + \frac{R}{1 + i\omega RC}$$

4-element WK model

$$Z_{WK4} = \frac{i\omega L Z_c}{Z_c + i\omega L} + \frac{R}{1 + i\omega RC}$$

R = 0.795 mmHg/(ml/s)
C = 1.880 ml/mmHg

R = 0.782 mmHg/(ml/s)
C = 1.944 ml/mmHg
Zc = 0.013 mmHg/(ml/s)

R = 0.795 mmHg/(ml/s)
C = 1.569 ml/mmHg
Zc = 0.036 mmHg/(ml/s)
L = 0.00142 mmHg/(ml/s²)

model vs. measured impedance

FIGURE 3.2   The arterial system can be represented as a windkessel model. The top panels display the mathematical expression for the impedance of a two-, three-, and four-element windkessel model and the electrical analog representation. The middle panels display, for each model, the best possible prediction of the measured pressure when imposing the measured flow waveform and fitting the model parameters to the data. It is clear that the four-element windkessel model provides the best fit. This is also reflected in the two lower rows where the model impedance modulus and phase are shown together with the measured impedance. The two-element windkessel model describes measured impedance well for the first two to three harmonics, but the four-element windkessel model has an excellent fit over the complete frequency range.

Estimating total arterial compliance by use of windkessel models

The most direct way of using a windkessel model to estimate total arterial compliance is to fit the model parameters to measured pressure and flow waveform data as was illustrated above for the 2, 3-, and four-element windkessel model (Fig. 3.2). The value obtained for the model compliance then provides an estimate for total arterial compliance. In this chapter, we limit ourselves to models with a constant, pressure-independent compliance. More advanced models incorporating nonlinear[24] or frequency-dependent values of compliance[25] can be fitted to data, but the clinical application of these models has been limited to date. It is important to keep in mind that different models yield (slightly) different values of compliance and to be aware of the susceptibility of the three-element windkessel model to overestimate compliance, which becomes problematic in the pulmonary circulation or in the vasodilated systemic circulation.[22] We end this section with compliance estimation methods that are based on the two-element windkessel model, but do not require time-resolved pressure and flow waveforms.

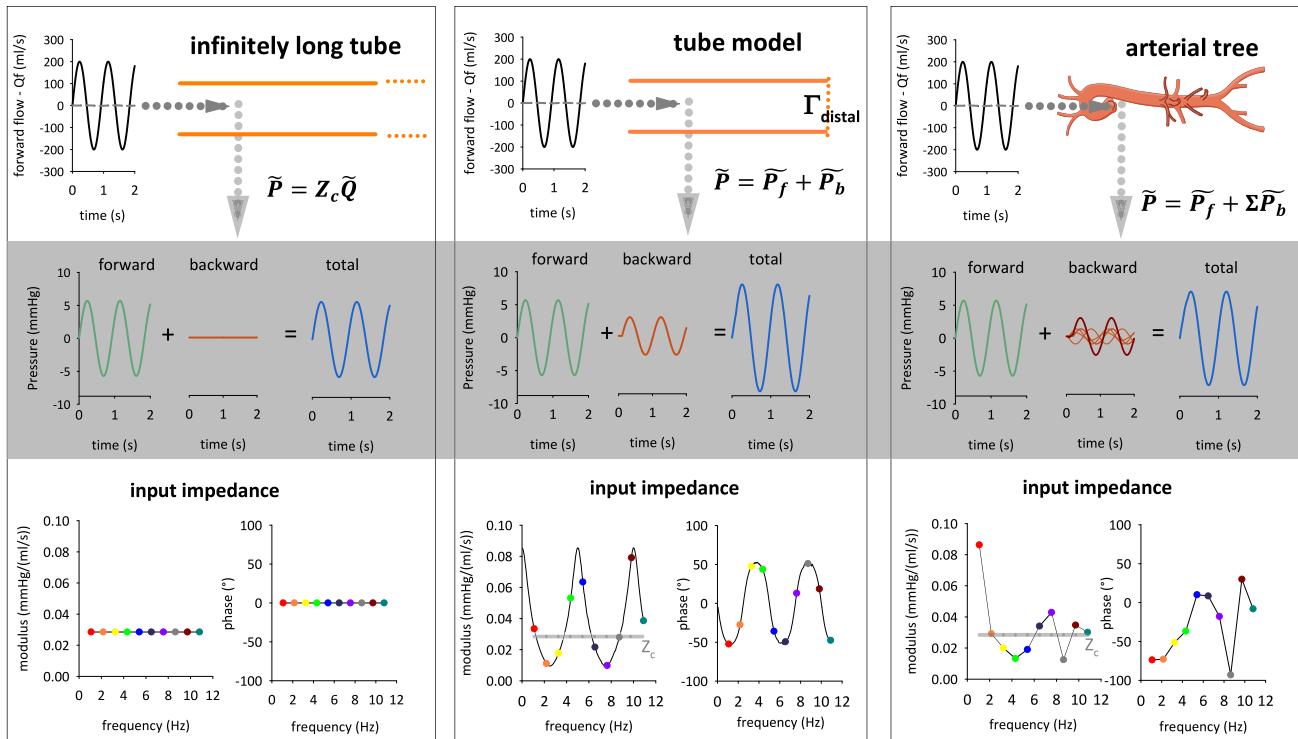
The decay-time and area method

The decay of measured arterial pressure in (late) diastole resembles an exponential function (especially in older subjects) which is the course predicted by a two-element windkessel model with resistance R and compliance C: $P(t) = P_0 e^{-t/RC}$. The decay time method makes use of this property and fits an exponential relation to the pressure in diastole which then yields the time constant, RC. With R calculated as the ratio of mean pressure and flow, C is directly found as RC/R. Given that the exponential relation requires zero inflow, the method is restricted to the central aorta. Physiological oscillations on the measured pressure due to wave travel and reflection may complicate the decay-time method, even when fitting only the last two-thirds of diastole.[26] An elegant work around these diastolic pressure oscillations is found in the area method of Liu et al.[20] They formulated an integral version of the decay time method and find the time constant as $RC = \frac{\int_{t1}^{t2} P(t)dt}{P(t1)-P(t2)}$. The integral in the numerator is the area under the pressure curve between t_1 and t_2. This area method is typically applied using the dicrotic notch and the end of diastole as t_1 and t_2, respectively.

The pulse pressure method

Whereas the decay-time and area method require time resolved arterial pressure (in diastole) and mean flow (cardiac output), the pulse pressure method is applied with knowledge of systolic and diastolic pressure (i.e., pulse pressure) and time resolved aortic flow. The method is again based on the two-element windkessel model; R is calculated from mean pressure and flow, and a value of C is found in an iterative way such that the pulse pressure predicted by the model is equal to the measured pulse pressure.[19] The method has a simple and stable iterative scheme, and results do not depend on a chosen time interval or initial parameter values. The rationale behind the method is that pulse pressure (as the exponential pressure decay) is a low-frequency feature that is well replicated by the two-element model.

Interpreting input impedance: the wave-system perspective

Characteristic impedance revisited: inertia and compliance combined


Consider the inlet of a uniform elastic tube that is infinitely long (Fig. 3.3, left panel). The cross-sectional area of the tube is A, and it is filled with a fluid with density ρ. The compliance (C_A) of the tube is given by $C_A = \frac{\partial A}{\partial P}$ (see also Chapter 7). When imposing a (sinusoidal) flow $\widetilde{Q}$ at the inlet, fluid mass has to be displaced along the tube and accelerated, requiring a proportional increase in pressure $\widetilde{P}$. The mass to accelerate, and the associated velocities will on the one hand depend on the density of the fluid and the cross-sectional area (i.e., inertia $\frac{\rho}{A}$), but also on how much mass can be locally stored in the distending tube (mass that is locally stored does not need to be displaced along the tube), and thus on local compliance C_A. If fluid viscosity is neglected, characteristic impedance of the tube can be expressed in terms of these inertial and local compliance properties, $Z_c = \sqrt{\dfrac{\frac{\rho}{A}}{\frac{\partial A}{\partial P}}} = \sqrt{\frac{\rho \partial P}{A \partial A}}$[4–6]. As above, pressure and flow are linked via $\widetilde{P} = Z_c \widetilde{Q}$.

We can further specify the propagation direction of the wave as forward (or positive, e.g., left to right) and backward (negative, from right to left). In this specific setting of the infinitely long uniform tube, reflection sites are absent and only unidirectional waves can exist. By definition, $\widetilde{P_f} = Z_c \widetilde{Q_f}$ and $\widetilde{P_b} = -Z_c \widetilde{Q_b}$ with subscript f referring to forward and b to backward propagating waves. The minus sign accounts for the fact that, in contrast to pressure, flow is not a scalar property but has a direction, with flow considered negative when flowing from right to left.

We deliberately used the same notation as above for characteristic impedance, as it is in essence the same property that we describe, yet from a different perspective. While Z_c emanated as a resistance from a lumped parameter model perspective (and in particular for the three-element

FIGURE 3.3   Left panels: imposing a sinusoidal flow wave (harmonic) to an infinitely long tube gives rise to a sinusoidal pressure wave of the same frequency and in phase with the flow wave of an amplitude equal to Z_c times the amplitude of the flow wave. Backward waves are nonexisting and the input impedance will be equal to the characteristic impedance for all harmonics. Middle: in a tube model with a single reflection site at its distal end, a backward wave will be generated and the measured pressure will consist of a forward and a backward wave. The input impedance modulus is characterized by successive peaks and troughs (and concomitant zero crossings for the phase angle) nonsymmetrically around Z_c that occur at frequencies for which there is maximum destructive (troughs) or constructive (peaks) interference between the forward and backward pressure wave. Right: In the arterial tree, imposing a sinusoidal flow wave will generate a forward pressure wave that gets reflected at innumerable proximal and distal sites along the arterial tree, leading to a scattered and diffuse reflection patterns. All backward waves add up to one resultant backward wave that is retrieved when performing wave separation analysis. The scattered reflections lead to the typical input impedance pattern that resembles that of the single tube for the lower frequencies, but where destructive interference at higher frequencies yields a system that is seemingly free of reflections with input impedance approaching characteristic impedance.

windkessel model), it here becomes clear that it has nothing to do with viscous friction, but rather integrates local inertia and compliance. Note that it can also be written as $Z_c = \frac{\rho PWV}{A}$ with *PWV* pulse wave velocity, the speed at which perturbations propagate along the tube.

Input impedance: fingerprint of arterial wave reflections

The arterial tree is, obviously, much more complex than a uniform elastic tube free of reflection. Therefore, measured pressure and flow waves are in general composed of forward and backward propagating signals. As such, when we decompose measured pressure and flow waves into harmonics using the Fourier theorem, each of these harmonics will be composed of forward and backward propagating components, adding up to $\widetilde{P_f}$ and $\widetilde{P_b}$ for pressure, and $\widetilde{Q_f}$ and $\widetilde{Q_b}$ for flow. By definition, for each harmonic, it applies that $\widetilde{P} = \widetilde{P_f} + \widetilde{P_b}$ and $\widetilde{Q} = \widetilde{Q_f} + \widetilde{Q_b}$.

Making use of the intrinsic relation $\widetilde{P_f} = Z_c\widetilde{Q_f}$ and $\widetilde{P_b} = -Z_c\widetilde{Q_b}$, it is easily shown that

$$\widetilde{P_f} = \frac{\widetilde{P} + Z_c\widetilde{Q}}{2} \;\; ; \;\; \widetilde{P_b} = \frac{\widetilde{P} - Z_c\widetilde{Q}}{2}$$

Thus, each individual harmonic of pressure (and flow) can be decomposed into a forward and backward harmonic of the same frequency.[27] Adding all backward and forward harmonics in the time domain yields the total backward and forward pressure wave, the end result of a wave separation analysis.

For each harmonic frequency, we can define the reflection coefficient Γ as:

$\Gamma = \frac{\widetilde{P_b}}{\widetilde{P_f}} = \frac{-Z_c\widetilde{Q_b}}{Z_c\widetilde{Q_f}} = -\frac{\widetilde{Q_b}}{\widetilde{Q_f}}$. Again, Γ is a complex number where the modulus expresses the ratio of the amplitude of the backward and forward harmonic, while the phase angle expresses the time delay between the backward and forward harmonic. Bringing the above together, it follows that

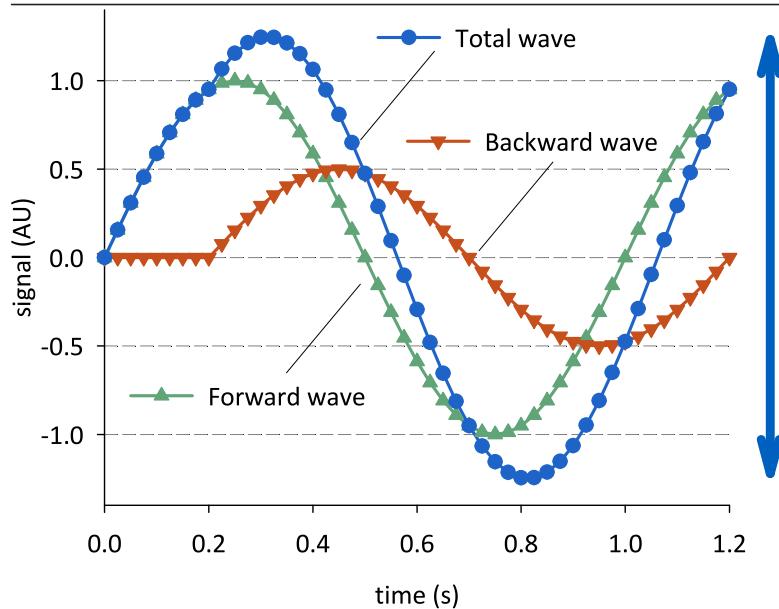
$$Z = \frac{\widetilde{P}}{\widetilde{Q}} = \frac{\widetilde{P_f} + \widetilde{P_b}}{\widetilde{Q_f} + \widetilde{Q_b}} = \frac{\widetilde{P_f}(1+\Gamma)}{\widetilde{Q_f}(1-\Gamma)} = Z_c \frac{(1+\Gamma)}{(1-\Gamma)}$$

Input impedance is therefore nothing but a mathematical representation of how reflection "disturbs" the relation between pressure and flow, deflecting it from characteristic impedance. It is obvious from this formula that the input impedance always equals characteristic impedance when Γ is zero (in the absence of reflections).

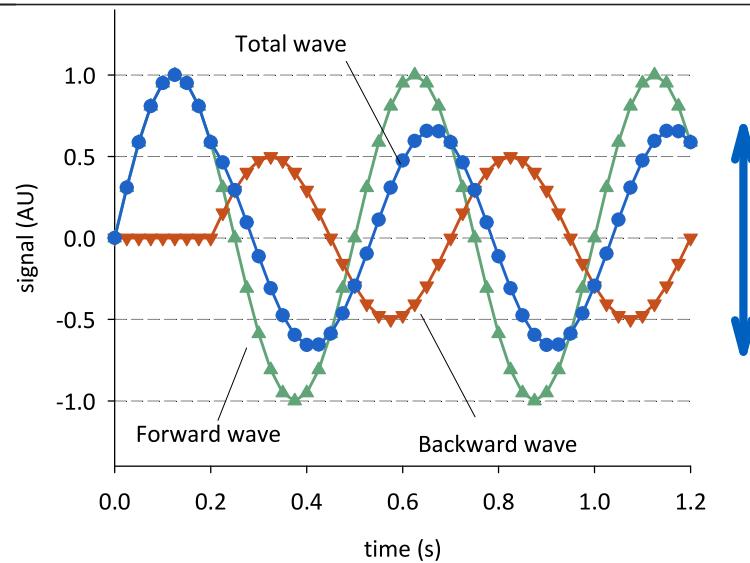
Assuming Γ to be a real number (no phase delays between forward and backward waves), an input impedance higher than Z_c implies $\Gamma > 0$, so the reflected pressure wave adds to the forward wave and increases the amplitude of pressure (constructive interference) (Box 3.2), while total flow will be reduced because of the opposite effect of reflection on the flow wave. Similarly, $Z < Z_c$ implies that $\Gamma < 0$ and reflection now reduces the total pressure (destructive interference) (Box 3.2), while increasing the flow.

It is important to stress that so far we have done nothing but analyze the relation between pressure and flow at a given point in the circulation (usually the ascending aorta or main pulmonary artery) and developed a method that allows us to decompose the measured signals into forward and backward waves with knowledge of Z_c. We did not make any interpretations about the origin or mechanism of wave reflection, which requires further assumptions or the use of models/paradigms. We will discuss several such models/paradigms in the following section.

The arterial system: a network of tubes with distributed reflection sites

The tube model—too simple as a paradigm


The simplest model of the arterial system that accounts for wave travel and reflection is the tube model (Fig. 3.3, middle panel), whereby the entirety of the arterial tree is conceptualized as a uniform tube of a given length L (e.g., 0.5 m), characterized by characteristic impedance Z_c. The distal end acts as a single discrete reflection site where resistance, impedance, or a reflection coefficient can be prescribed.

Assuming a pulse wave velocity of 5 m/s, it will take 0.2 s for a wave to travel back and forth from the inlet to the distal reflection site (see also basic concept box on constructive and destructive interference). The net effect of the reflection will now largely depend on the timing when the backward wave adds to the forward wave, and this will highly depend on the frequency (f) of the harmonic, the associated wavelength $\lambda = PWV/f$ and the phase delay between the forward and the backward harmonic, given by $\Delta\varphi = \frac{2L}{PWV} 2\pi f$. The maximal impact of the backward wave occurs when $\Delta\varphi = n\pi$, with n an integer. When n is even, the backward pressure wave arrives perfectly in phase


with the forward wave leading to maximal constructive interference. The opposite happens for the flow wave, implying a peak in the impedance spectrum for that frequency. Conversely, when n is odd, the backward pressure wave arrives completely out of phase with the forward wave, leading to maximal destructive interference and a minimum in the impedance spectrum. The first minimum occurs for $n = 1$, for a frequency $f_{min} = \frac{PWV}{4L}$ (2.5 Hz in our example). In a tube model, this leads to a succession of peaks and troughs at these frequencies, as illustrated by the impedance spectrum in the middle panel in Fig. 3.3). As there are no apparent phase delays between the total pressure and flow harmonic, the phase angle will be zero at these frequencies.

The arterial tree—scattered reflections

Most insights on arterial impedance and hemodynamics have been gained from one-dimensional (1D) arterial network models accounting for the Navier−Stokes equations (conservation of mass and momentum) and a relation describing arterial distensibility[28−32] or based on electrical transmission line theory.[7,33] These models demonstrate that reflections arise from discrete impedance mismatch (e.g., at bifurcations) but also as a consequence of progressive changes in impedance (geometric and/or elastic taper) which provoke diffuse, continuous reflections.[34] These reflections also get re-reflected as they propagate toward the heart, adding again to the forward wave. As such, what is conceived as "the" forward and backward wave after wave separation analysis is the integrated effect of all simultaneously coexisting forward and backward propagating contributions, with reflections returning from sites close to the heart and further away.[35] For the lower harmonics, these dispersed reflections still act relatively well in phase with each other. For the first harmonic, the net effect of the added reflections is constructive for pressure waves and destructive for flow waves, leading to an impedance higher than Z_c. Most often, one will find a clear local minimum in the input impedance modulus between the second and fourth harmonic where Z drops below Z_c and where the net effect of reflected waves is to reduce pressure and increase flow. With further increasing frequency, however, phase delays are highly variable, with some reflections arriving in phase, while others arrive out of phase. Reflected waves therefore start canceling each other out, leading to a system that is seemingly free of reflections (comparable to what happens in an acoustic chamber, where the walls are constructed in such a way that sound waves reflect scattered in all directions). The frequency corresponding to the minimum (f_{min}) has been used to estimate an "effective length" of the arterial tree as $L_{eff} = \frac{PWV}{4f_{min}}$. Since wavelength $\lambda = PWV/f$, this is known as the quarter wavelength formula. However, the discrepancy between the real arterial

BOX 3.2 constructive and destructive interference

Constructive interference

Destructive interference

The backward wave (in red) arrives in phase with the forward wave (green), such that the amplitude of the total wave (the summation of both) increases (blue).

The backward wave (in red) arrives out of phase with the forward wave (green), such that the amplitude of the total wave (the summation of both) decreases (blue).

tree and a tube model is large, and the tube model paradigm has led to controversial or incorrect interpretations of arterial hemodynamics.[36]

Estimating Z_c from impedance

Fig. 3.1 displays the modulus and phase of input impedance measured in a human subject exhibiting type-A pressure waveforms.[15] It is indeed observed that for higher harmonics (usually from about the fourth to fifth harmonic), the impedance modulus tends toward a constant value, while also the phase angle is about zero or oscillates around zero. For these harmonics, reflections thus appear absent ($\Gamma \approx 0$), which implies that for these frequencies, $Z \approx Z_c$. Therefore, averaging the higher harmonics of input impedance is one way to estimate characteristic impedance.[4−6] In previous work, analyzing noninvasively measured input impedance in middle-aged subjects, we averaged the fourth to 10th harmonic,[37] but other choices are possible. A good criterion is to select the range where the phase angle is zero or oscillates around zero due to randomly interacting wave reflections, which act as noise at these frequencies.

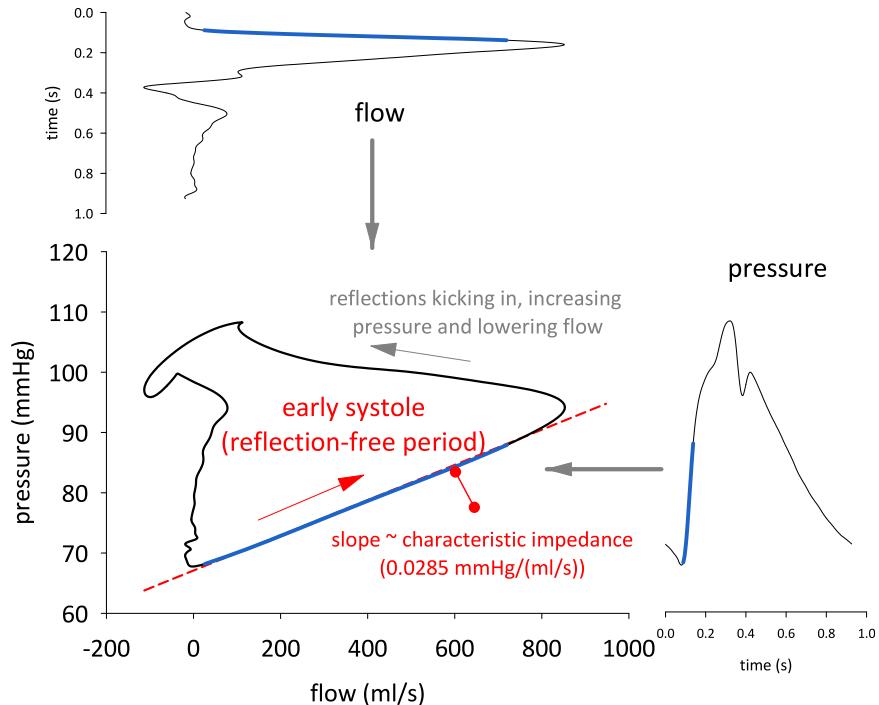
Pressure-flow relations in the time domain

So far, we addressed pressure-flow relations in the frequency domain, hence considering measured signals as the superposition of a constant value and sinusoidal waves, largely building upon the analogy with electrical circuit theory. This approach assumes linearity of the system (harmonics coexist but to not interact with each other), limits the analysis to steady state situations, and is a somewhat abstract way to analyze the system.

Time domain formulation of wave separation equations

An alternative way to assess pressure-flow relations is to simply analyze them in the time domain. To do so, we need to reconsider the definition of "a wave." In our digital world, measured pressure and flow signals are sampled at discrete moments in time, separated by a given time (sample) interval. We can then define $dP = P(n + 1) - P(n)$ and $dQ = Q(n + 1) - Q(n)$ as the discrete change in pressure and flow, respectively, from time step n to $n + 1$, where dP and dQ are considered as wavelets or wave fronts. This definition of a wave is underlying the wave intensity analysis as introduced for hemodynamic analysis by Parker and Jones[38] and what follows is largely based on work of Parker and colleagues. We will, however, use volume flow (Q in m^3/s) rather than flow velocity (m/s) in the analysis to have an immediate parallel with impedance analysis. One is easily converted into the other via the cross-sectional area of the artery.

Again assuming an infinitely long uniform elastic tube (free of any reflections) characterized by Z_c, it follows from the water hammer equations (see Chapter 1) that under these conditions, $dP_f = Z_c dQ_f$ and $dP_b = -Z_c dQ_b$ with subscripts f and b referring to the forward (positive) and backward (negative) direction, respectively. In the arterial system, just like we previously showed that harmonics consist of a forward and backward component, also dP and dQ will be the result of forward and backward waves, such that $dP = dP_f + dP_b$ and $dQ = dQ_f + dQ_b$. These equations can again be combined and lead to the equations used for wave separation analysis[39]:

$$dP_f = \frac{dP + Z_c dQ}{2} \; ; \; dP_b = \frac{dP - Z_c dQ}{2}$$


These equations look identical to equations used to separate pressure harmonics,[27] but have an important practical difference: rather than being applied to harmonics of pressure and flow (for which one needs Fourier decomposition), we now decompose pressure and flow wavelets that are easily calculated in any spreadsheet—with knowledge of Z_c.

Estimating characteristic impedance in the time domain

Fig. 3.4 shows a representative aortic pressure-flow pair, whereby instantaneous pressure is plotted as a function of the instantaneous flow level, forming a pressure-flow loop. When the pressure and flow waveforms are well aligned in time, one will observe that the section of the loop that corresponds with early systole (the first $\sim$ 50−100 ms) is linear. Bearing in mind that it should take some time for forward waves to reach reflection sites and return as backward waves, it is a common assumption that early systole provides a time window where aortic pressure and flow waves are free of reflections. In such conditions, we only have forward waves and $dP = Z_c dQ$. Z_c can therefore be estimated as the slope of the linear segment of the pressure-flow loop.[40] Whether that period is really free of reflections is not entirely clear, however, as linearity of the pressure-flow relation as such does not exclude presence of reflections, as has been demonstrated for carotid pressure-flow relations.[41] It cannot be excluded that this also happens in the aorta,[42] at least in some circumstances that lead to very early systolic reflections such as proximal aortic aneurysms, aortic coarctation, or ascending aortic tapering.

Wave separation analysis in practice: an instruction manual

In this section, we will illustrate with a practical example using the same type-A waveforms how to calculate the forward and backward wave from a given pair of pressure (P) and flow (Q) waveforms which have been properly aligned in time (Fig. 3.5). The data in the example represent one heartbeat, but data from longer time recordings can be used as well. The waveform contains $N = 463$ datapoints

FIGURE 3.4   Time-aligned pressure and flow waveforms are combined in a flow-pressure diagram, which displays a loop. It is assumed that early systole (the segment marked in blue) is relatively free of reflections, leading to a linear relationship between flow and pressure. The slope of the line provides an estimate of characteristic impedance.

sampled each 2 ms. Z_c was estimated as the slope of the linear segment of the PQ loop in early systole (Fig. 3.4)

   Step 1—differentiate: calculate $dP(n) = P(n + 1) - P(n)$ and $dQ(n) = Q(n + 1) - Q(n)$ for $n = 1$ to $N - 1$, i.e., the changes in P and Q as a function of time. Note that these arrays will thus consist of one element less than P and Q.
   Step 2—separate: apply the wave separation equations at each instant in time, yielding $dP_f(n)$ and $dP_b(n)$, with $n = 1$ to $N - 1$. if the flow wave is also to be separated, calculate $dQ_f(n) = dP_f(n)/Z_c$; $dQ_b(n) = -dP_b(n)/Z_c$.
   Step 3—integrate: calculate the total forward (P_f, Q_f) and backward (P_b, Q_b) pressure and flow waves as

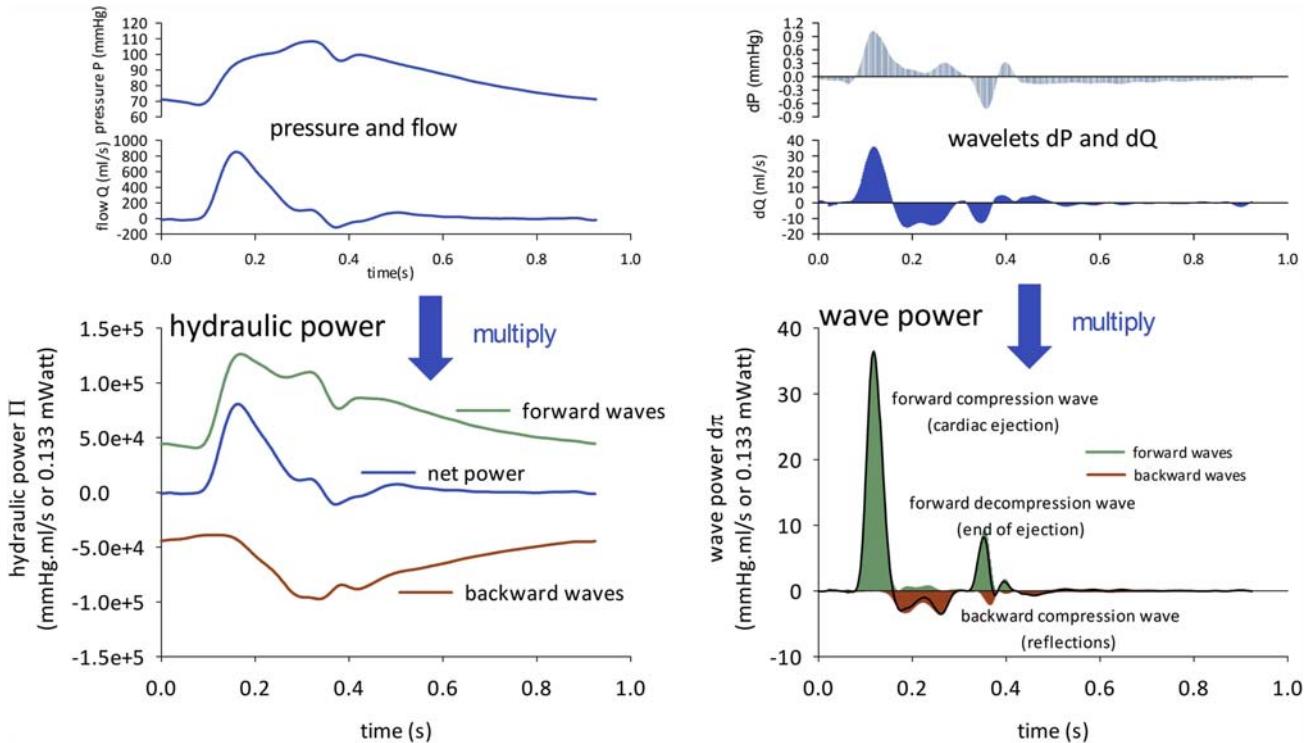
$$P_f(n) = P_f(n - 1) + dP_f(n); P_b(n) = P_b(n - 1) + dP_b(n); n = 1:N - 1$$

$$Q_f(n) = Q_f(n - 1) + dQ_f(n); Q_b(n) = Q_b(n - 1) + dQ_b(n); n = 1:N - 1$$
   In this step, we add the contributions of dP_f, dP_b, dQ_f, and dQ_b at the respective timestep, numerically integrating these waveforms. As this is an integration, we can also add an integration constant. By convention, $P_f(0) = P(1)$ and $Q_f(0) = Q(1)$, while $P_b(0) = Q_b(0) = 0$. This ensures that

$P_f + P_b = P$, and $Q_f + Q_b = Q$. Other choices for these integration constants are, however, possible.
   An intuitive way to visually present the results of wave separation analysis is to simultaneously plot the measured and forward pressure wave; the difference between both then represents the contribution of the backward pressure wave (bottom panel Fig. 3.5). A similar presentation can be used for flow. We also stress here that P_f is *not* identical to $Q * Z_c$, because wave reflection also affects the flow wave (the correct statement is $P_f = Q_f * Z_c$).[43] Also, caution is warranted on the strict interpretation of the forward (and backward) wave, as the forward wave in itself includes backward waves that get re-reflected (rectified) at the ventricular-aortic interface, contributing to the forward wave.[27,35,43] As such, P_f is not to be interpreted as the component of pressure that would exist if the heart would eject in a reflection-fee system.

Wave power analysis: energizing hemodynamics

Readers familiar with the literature on arterial hemodynamics will be well acquainted with wave intensity analysis as introduced by Parker and Jones,[38] with wave intensity (dI) at a given measuring location being a time-dependent variable defined as $dI = dP.dU$ with dP a step change in pressure, as previously defined, and dU a step change in

FIGURE 3.5 Practical guideline on how to separate the measured pressure waveform into its forward and backward components in three steps ("differentiate—separate—integrate"), starting from measured pressure and flow waveforms and with knowledge of Z_c. The bottom panel shows the backward and forward components on top of each. The reader is referred to the text for details on the different steps.


flow velocity. In SI units, dI has the dimension W/m^2 and represents the energy flux carried by the pressure and flow waves. Following Mynard et al., using volumetric flow Q as substitute for U (with $Q = U.A$, A being the cross-sectional area of the artery), one can define wave power $d\pi = dP \cdot dQ$ which is expressed in W (Watt) when using SI units for pressure and flow.[44] Clearly, $d\pi$ closely relates to dI (they scale by a factor A), but has the advantage of representing a conserved quantity, which is not the case for dI (at bifurcations, for instance, $d\pi$ in the mother branch equals the sum of $d\pi$ in the daughter branches, which is not the case for dI).

Wave power to assess the nature and timing of wave reflection

One obvious application of wave power is to just use it as a surrogate of wave intensity, as exemplified in Fig. 3.6 where $d\pi$ was calculated from pressure and flow. With (i)

$d\pi > 0$ indicating forward propagating waves ($d\pi < 0$ indicate backward propagating waves), and (ii) $dP > 0$ indicating compression waves while $dP < 0$ indicates decompression waves, it is immediately clear from $d\pi$ (and dP) which of the four possible wave types dominate at any moment in time: forward compression waves (generated by the heart in early systole), forward decompression (or "suction") waves (generated at end systole due to inertial effects[45]), backward compression waves (as typically observed in the aorta in mid-systole) or backward decompression waves (rarely seen in vivo, but may be observed in case of severe aortic aneurysms, causing the systolic forward compression wave to reflect as a backward decompression wave).[46]

We stressed that $d\pi$ can only reveal the *dominant* wave types. To better appreciate coexisting forward and backward waves, it is recommended to separate $d\pi$ into $d\pi_+$ and $d\pi_-$, the wave power due to the forward and backward pressure and flow waves with $d\pi_+ = dP_+ dQ_+$ and

FIGURE 3.6 Left: hydraulic power Π is calculated as the instantaneous product of pressure and flow. It can be decomposed into contributions of forward and backward waves. Right: wave power $d\pi$ calculated as the instantaneous product of dP and dQ. It is equivalent to wave intensity and can be used to identify the timing and nature of forward and backward waves. Note the difference in y-scale with hydraulic power orders of magnitude higher than wave power.

$d\pi_- = dP_-dQ_-$ and $d\pi = d\pi_+ + d\pi_-$. This is particularly important to reveal early reflections which are easily masked by the dominant systolic forward compression wave. An example of wave power analyses of proximal aortic pressure and flow in a normal adult is shown in Fig. 3.6.

Energetics in the arterial circulation

In their seminal work, Mynard and Smolich elaborated a comprehensive framework on wave energetics and hydraulic power, and how this relates with the wave potential concept (i.e., the potential of a pressurized elastic vessel to generate waves).[44,47] In this final section, we briefly discuss some of their ideas on hydraulic power under the assumption that the undisturbed pressure in the arterial circulation is zero (the equilibrium pressure that is attained when no wave potential or waves exist in the vascular system).

Wave power quantifies the power (energy/unit of time) carried by the waves and due to changes in pressure and flow, irrespective of the absolute pressure level. In the cardiovascular system, however, it is also the absolute pressure and flow levels that matter, as this will largely affect the pressure-volume loop of the heart and hence the

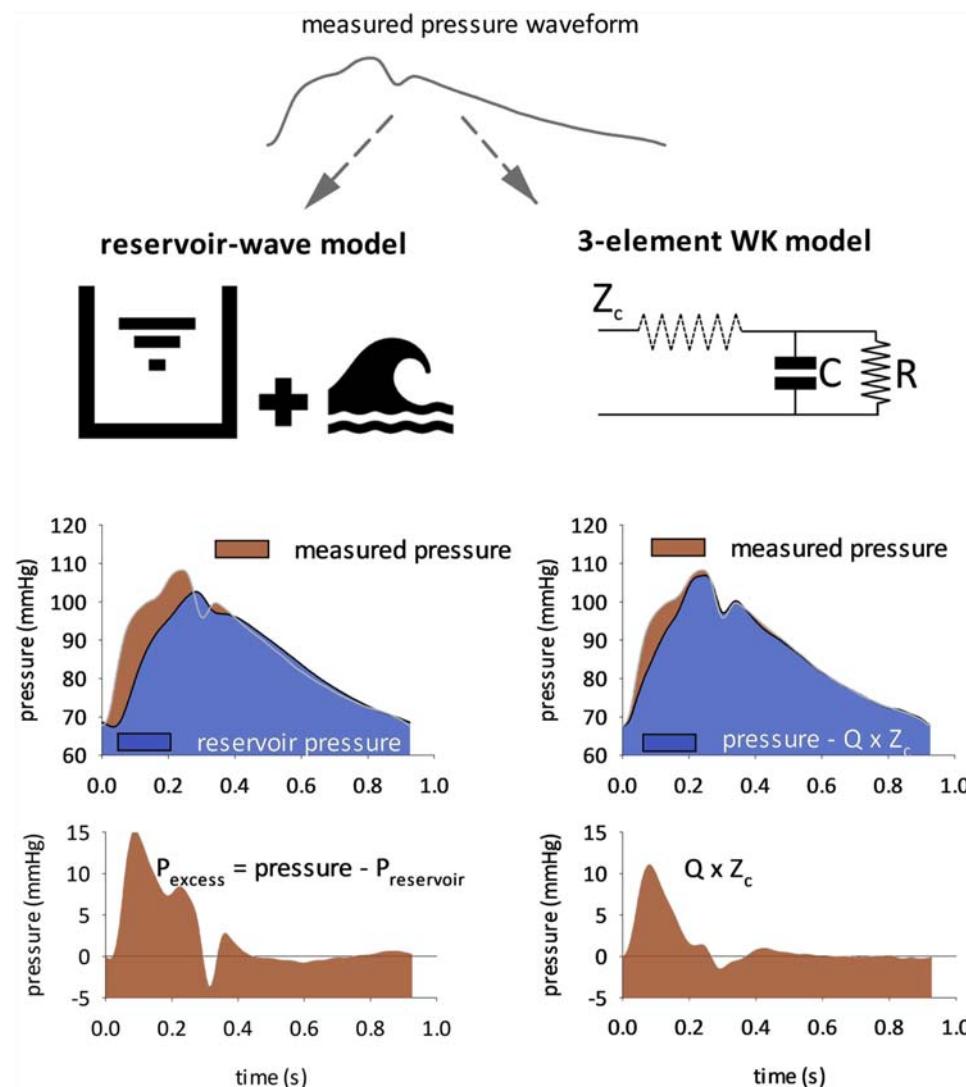
heart's energy expenditure. The quantity to consider then is the hydraulic power Π, which is composed of a pressure component $\Pi_P = PQ$ and a kinetic component which is usually small enough to be ignored in the arterial circulation.[44]

One can then make use of the previously demonstrated wave separation analysis (and with $P_fQ_b + P_bQ_f = 0$) to rewrite $\Pi_P = (P_f + P_b)(Q_f + Q_b) = P_fQ_f + P_bQ_b = \Pi_{P,f} + \Pi_{P,b}$. As such, total hydraulic power can be separated into forward and backward hydraulic power, allowing to quantify the energetic costs of wave reflection.

We repeat that Π_P and $d\pi$—and their forward and backward separated quantities—are pulsatile functions of time with units Watt or Joule/second (J/s) when P is expressed in Pa and flow in m³/s. As such, integration in time (for instance over one heartbeat) of Π_P and $d\pi$ yields the net wave or hydraulic energy (in J) injected into the circulation distal from the point of observation. Separating into forward and backward components allows for the quantification of how wave transmission and reflection contribute to this energy transfer.

As an application of this approach to a clinical problem, we recently utilized these principles to study whether differences of energy transmission into the brain circulation (carotid artery) may play a role in some of the side effects

observed in patients taking organic nitrates (headache and dizziness).[48] In contrast to inorganic nitrates, administration of nitroglycerine, an organic nitrate, led to a significant reduction of aortic hydraulic power, an increase in power penetration to the carotid artery (due to cerebrovascular vasodilation), and an absolute increase in carotid hydraulic power.

The reservoir-wave concept—overarching paradigm or misleading enigma?


Although the presence of pressure and flow waves in the arterial tree is undisputed, the arterial tree does exhibit a windkessel-like function that is typically approached using lumped parameter models, as discussed extensively in previous sections of this chapter. Lumped parameter (windkessel) models, by definition, contain no space dimension and therefore cannot resolve time and space-dependent wave phenomena. The reservoir-wave concept, introduced by Parker and colleagues, aims to reconcile the arterial windkessel function and wave system. The concept was first introduced by Wang et al.[49] and promoted in subsequent papers in which investigators expanded on the analysis of the wave component.[50–52] Briefly, the arterial pressure waveform is considered as the superposition of a reservoir (windkessel) component and an excess pressure that is ascribed to traveling waves (Fig. 3.7). The concept is intuitively appealing, since one can imagine that rapidly acting wave phenomena superimpose on a slower phenomenon, just like ocean waves generated by the wind superimpose on a tidal wave. To some extent, however, the concept is old wine in new barrels, and a time domain representation of the three-element windkessel model: low frequency (slow phenomena) behavior is described by the RC-component in the model, while the characteristic impedance is needed to describe the high frequency (rapid phenomena) behavior (Fig. 3.7). That also explains why the shape of excess pressure and the flow wave is similar, since the ratio of excess pressure and flow is simply the characteristic impedance. In that sense, it is not surprising that excess pressure carries prognostic information in some patient populations,[53] as it is likely a quantification of the effect of characteristic impedance, which in turn depends on ascending aortic size and stiffness.

An important consequence of the originally introduced concept is that it suppresses the importance of waves and wave reflections.[54] It leads to a drastically different interpretation of arterial hemodynamics with a potential impact on therapeutic strategies. Supporters of the concept reported that application of the reservoir-wave concept yields physiologically more plausible patterns of wave travel and reflection in the aorta than conventional analyses: whereas

traditional wave separation analysis (as applied above on recorded pressure and flow waves) does not lead to a backward wave that travels from the distal to proximal aorta, wave separation analysis on the excess pressure (after subtraction of the reservoir component) does show a backward wave traveling from the bifurcation toward the heart.[51] Also, while conventional wave separation analysis leads to self-canceling forward and backward flow waves in diastole (such that total flow is zero), wave separation analysis on the wave component leads to a wave-free period in diastole.[51]

The reservoir-wave concept—as originally introduced—does carry some inconsistencies. First, invasive pressure recordings immediately demonstrate that the pressure waveform propagates as a whole (including the slow varying component) while the original reservoir-wave concept assumes a steady, nonpropagating reservoir pressure that is uniform over the entire arterial tree. Three-dimensional fluid-structure interaction simulations in an in silico model of aortic coarctation failed to demonstrate that reservoir pressure relates to the volume in the aortic reservoir in systole.[55] Computer model studies in 1D arterial network models, confirmed by in vivo experiments have shown that when wave separation analysis is performed on excess pressure, errors are introduced in the timing, nature, and magnitude of reflected waves, suppressing compression waves and amplifying decompression waves.[54] Also, the argumentation that wave separation analysis applied to excess pressure leads to a more plausible timing of the backward wave has been refuted: in a nonuniform and tapering vessel as the aorta, backward waves are continuously generated along the entire tree as the forward wave propagates.[56] It is only in a uniform tube with a discrete reflection site at the distal end that the backward wave would indeed propagate from distal to proximal. As discussed above, the uniform tube is a poor model for the arterial tree.[36]

Mynard conjectured that the inconsistency in the original reservoir-wave formulation arises from the use of hybrid dimensionality, where zero-dimensional (0D) and 1D formulations are inappropriately combined.[45,57,58] The reservoir-like behavior (with the exponential pressure decay in diastole) is quite bluntly treated as a 0D phenomenon, while such behavior is in essence also the consequence of waves propagating back and forth in the aorta during diastole.[47] The energy carried by these waves is, however, low and it is not trivial to demonstrate their existence in vivo using techniques like wave intensity analysis. These fundamental critiques have been acknowledged by Parker and colleagues, who modified the theory. In recent publications, the reservoir pressure is being treated as a propagating wave (but still of a uniform shape along the aorta)[59] and acknowledged to arise from repeated reflections and re-reflections.[60] This is also consistent with

FIGURE 3.7   Illustration of the parallel between the reservoir-wave and three-element windkessel model using the type A dataset digitized from.[15] In the reservoir-wave concept, the reservoir pressure is determined, and excess pressure is calculated as the difference between measured and reservoir pressure. Reservoir pressure was estimated using a pressure-only approach (courtesy of J. Mynard). In the three-element windkessel model, pressure can equally be seen as the superposition of Q x Z_c and the pressure due to the *RC* components (measured pressure—$Z_c \times Q$).

studies reporting that the reservoir pressure is equal to two times the magnitude of the backward wave as obtained when applying conventional wave separation analysis.[53,61] It is important for the scientific community to get fully aware of these most recent insights, and especially of the highly problematic use of excess pressure for wave separation analysis which leads to incorrect assumptions about therapeutic approaches. As convincingly demonstrated using rigorous computer modeling supported by in vivo experimentation, wave patterns based on wave separation analysis of the excess pressure introduce nonsensical errors and contribute nothing to our understanding on the role of wave reflections in the arterial tree. The reservoir-wave paradigm is still being fine-tuned,[60] but we remain

skeptical about using an intuitive at first sight, but ill-fitting paradigm to help us in understanding the complexity of arterial hemodynamics.

Concluding remarks

In this chapter, we aimed to provide an overview of techniques and methods to analyze and interpret pressure-flow relations using both "classical" frequency domain methods (impedance-based) as well as the more recent time domain methods. Both exist side-by-side and should be used as such, exploring strengths of both. Impedance analysis is an excellent way to characterize the arterial system; time domain methods are more suitable to assess

timing and nature of wave reflections. We particularly wanted to convey the message that interpretation of impedance or wave dynamics is explicitly or implicitly based on an assumed paradigm (model) for the arterial circulation. Correct analysis and interpretation of data can only be built on a solid and full understanding of these paradigms, considering their strengths and limitations.

Introduction

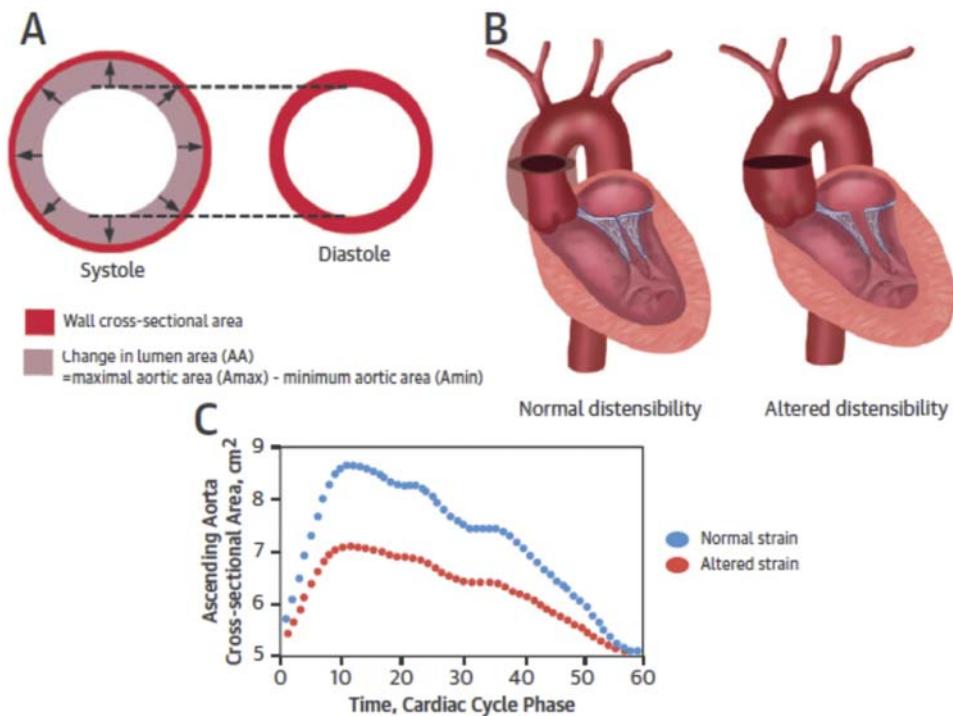
For a comprehensive characterization of changes in aortic morphology, flow, and hemodynamics associated with aging and disease, accurate and reproducible quantitative methods are needed.

Magnetic resonance imaging (MRI) has the unique ability to provide noninvasive, accurate, and reproducible measurements of aortic stiffness measures such as aortic strain, distensibility, and pulse wave velocity (PWV), as well as aortic geometry measures such as aortic diameter, area, or volume,[1,2] length, and curvature.[3] Importantly, MRI allows noninvasive imaging of the proximal aorta and aortic arch that have pivotal roles in the central cardiocirculatory system. Such exploration includes both 2D and 3D anatomy and dynamics as well as time-resolved 2D (2D + t) and 3D (3D + t) flow patterns, allowing for precise local measurements without geometrical assumptions. This chapter describes the methodology and prospects of MRI for the assessment of aortic stiffness and hemodynamics.

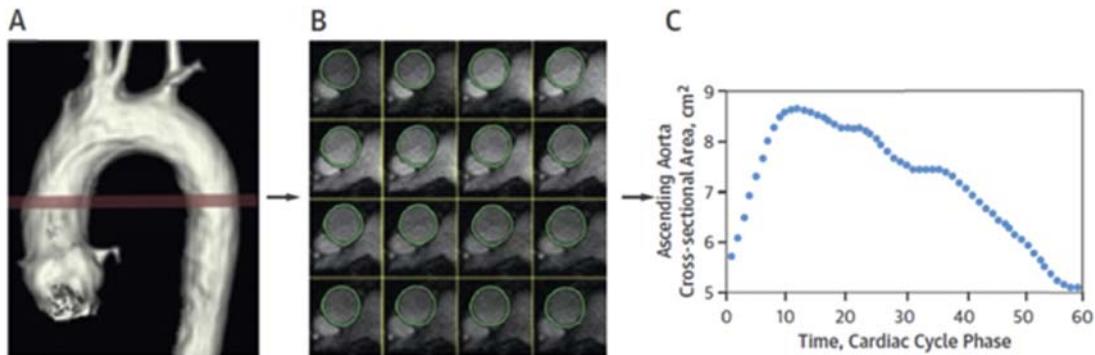
Aortic stiffness assessed by MRI

Aortic strain and distensibility

Aortic distensibility—defined as the relative change in aortic lumen area during cardiac cycle (aortic strain) divided by local pulse pressure—is commonly used as a measure of *local* aortic stiffness in population studies[4−6] (Fig. 4.1). Ascending and descending aortic strains are measured using dynamic MRI images acquired in a plane at the mid-ascending aorta perpendicular to the aortic wall at the level of the right pulmonary artery. Validated

semiautomated software can accurately determine changes in the aortic cross-sectional area throughout the cardiac cycle and represent them as area over time curves[4] (Fig. 4.2). Aortic strain is calculated as follows[7]:


$$\text{Aortic strain } (\%) = [(\text{maximum aortic area} - \text{minimum aortic area})/(\text{minimum aortic area})] \times 100$$

Distensibility is then calculated as aortic strain normalized by the pulse pressure driving systolic wall stretch and diastolic recoil of the aorta.[7]


$$\text{Aortic distensibility}\left(\text{mmHg}^{-1}10^{-3}\right) = [\text{aortic strain / pulse pressure}] \times 10$$

Central pulse pressure instead of brachial pulse pressure should be used in the calculation of local distensibility, in order to account for the highly variable pulse pressure amplification phenomenon across the age spectrum. As discussed in detail in Chapter 2, several noninvasive methods have been developed to estimate central blood pressure using pressure waveforms from the carotid, brachial, or radial arteries, and calibrated for brachial cuff pressure, and which can be measured simultaneously to the aortic MRI acquisitions.

SSFP cine imaging is the most commonly used dynamic sequence and is validated for measuring aortic strain and distensibility, due to its high spatial and temporal resolution and effective flow compensation minimizing flow-related artifacts.[8,9] Studies have also demonstrated that phase contrast MRI (PC-MRI) modulus images can be used in place of SSFP imaging. Using PC-MRI images has the practical advantage of reducing scan time since they will be also used for aortic arch PWV

FIGURE 4.1 Principle of local aortic stiffness: ascending aortic distensibility. (A) The ascending aorta is highly distensible and stores most of the stroke volume from the heart during systole, and, thanks to elastic recoil, redistributes part of this volume to downstream during diastole, thus transforming a pulsatile flow into steadier flow. The relative change in aortic lumen area divide by pulse pressure defines the distensibility. (B) Comparative illustration of preserved (left) and altered (right) distensibility of ascending aorta. (C) Corresponding cross-sectional area to cardiac cycle time curves for preserved (blue) and altered (red) aortic distensibility. *Reprinted from Redheuil A, Wu CO, Kachenoura N, et al. calculation and flow components estimation,[9] without requiring additional scan time. Of note, through-plane motion of the aorta resulting from left ventricular (LV) contraction may impact the assessment of cross-sectional aortic distensibility especially in the proximal aortic segments as it is measured from a fixed acquisition plane. However, this effect, more pronounced closer to the aortic root, can be minimized by measuring aortic strain at the tubular part of the ascending aorta and the descending aorta most often at the level of the center of the right pulmonary artery. In this plane, the ascending aorta is mostly cylindrical with the centerline and aortic walls remaining mostly perpendicular to the acquisition plane with a circular cross section throughout the cardiac cycle.

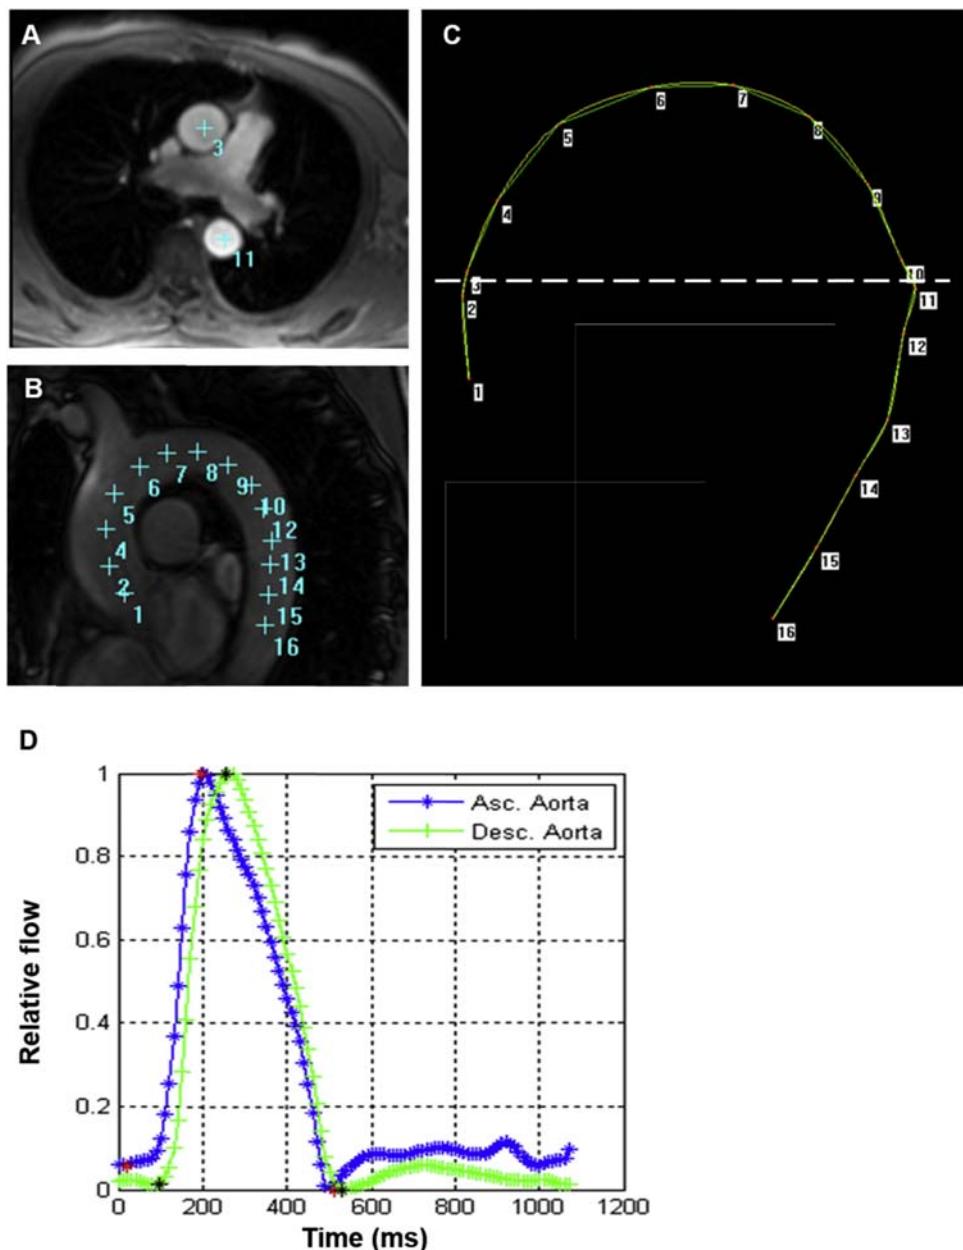
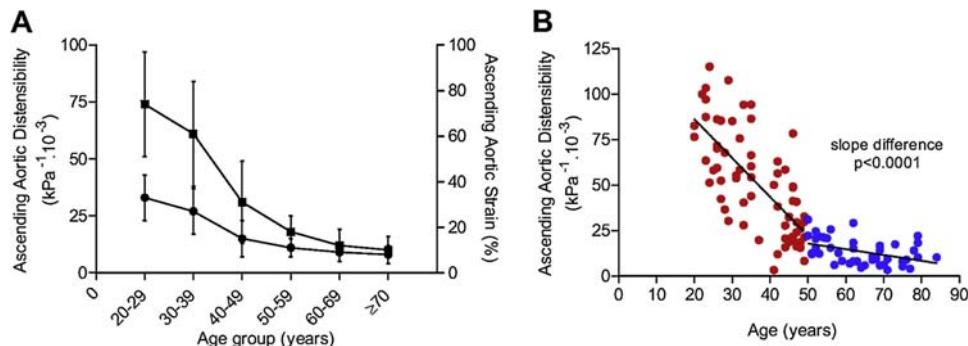
Interestingly, the longitudinal deformation of the aortic root can be also quantified from sagittal SSFP MRI images and was proven of clinical interest in patients with Marfan syndrome.[10]

Aortic pulse wave velocity

The most widely used measure of aortic stiffness overall is PWV, defined as the speed of propagation of the pulse wave along the arterial path,[11] as discussed in detail in Chapters 1 and 7. PWV is calculated as the ratio of the distance between two anatomical locations along the artery to the transit time required for the pressure or flow wave to cover that distance, commonly expressed in m/s. Arterial PWV is commonly measured using applanation tonometry between the carotid and femoral arteries. Carotid-femoral PWV (cf-PWV) is regarded as the reference method for arterial stiffness evaluations because it is relatively easy to use, available in large populations, and has high reliability.[12] However, cf-PWV, measured by applanation tonometry, is affected by inherent measurement errors associated with using the body surface distance as a surrogate for true arterial path length, which ignores the tortuous vessel routes.[7] Such errors are increased in obese (increased body surface) or elderly (increased aortic tortuosity) individuals.[13] Furthermore, cf-PWV ignores the proximal ascending aorta segment since the proximal point of measure regards the common carotid artery. Since the proximal aorta has the majority of the buffering capacity of the arterial system, this omission may have significant consequences in understanding the impact of age and disease on the aorta.


Aortic PWV assessment by MRI is a novel method that reduces measurement error by using accurate aortic length with a three-dimensional imaging approach[1,3] and the corresponding transit time between flow wave measurements[14,15] in precise locations. Aortic PWV assessment using blood flow waves derived from PC-MRI has been well validated in comparison to invasive, intraaortic pressure assessment[14] and to cf-PWV,[16] as well as through the Bramwell—Hill theoretical model.[17] MRI PWV assessment can also provide *regional* aortic stiffness in different segments of the aorta, including the ascending aorta, aortic arch, thoracic descending, and abdominal aorta.[18] Arch PWV is most commonly measured using 2D PC-MRI due to its simple acquisition and high temporal and spatial resolution during a single breath-hold of two PC-MRI planes with a velocity encoding gradient in the through-plane direction,[19,20] making it suitable for routine protocols. To measure aortic arch PWV, images of the ascending and descending aorta are obtained simultaneously in the transverse plane perpendicular to the aortic centerline, at the level of the right pulmonary artery. Specific software for aortic analysis provide an estimate of the transit time between the two flow waves after automated segmentation of the modulus and velocity PC-MRI images[21] (Fig. 4.3).

The disadvantage of MRI for PWV assessment is its relatively lower temporal resolution (10−30 ms, according to breath holding capability and R-R interval) compared to echocardiography and to applanation tonometry. The foot-to-foot method is well established in studies using tonometry to estimate transit time between pressure waves since it avoids the early reflected pressure waves.[7] Transit time estimation using the foot-to-foot method requires high temporal resolution to identify an accurate upstroke time, making this approach unsuitable for flow wave analysis in PC-MRI. Therefore, different methods to estimate the transit time using PC-MRI have been described to overcome such drawback.[14,22−24] In addition to the foot-to-foot approach, the methods to measure transit time by PC-MRI can be classified into two different strategies: (1) point-based methods, using systolic peak-to-systolic peak or maximal upslope acceleration-to-maximal upslope acceleration,[25,26] and (2) wave-based methods using similarity criteria such as cross-correlation as well as Fourier or wavelet analysis to calculate phase differences between two flow curves from different aortic sites.[27,28] While point-based methods have been shown to be robust on pressure waves, it has the disadvantage in MRI of the relatively low temporal resolution of PC-MRI flow curves.[24] Applying the wave-based methods to the whole cardiac cycle can be plagued by the presence of wave reflections that occur in late systole, affecting the morphology of the systolic downslope.[7] To overcome these issues, recent wave-based techniques have been proposed that focus only on the systolic upslope of the PC-MRI flow curves.[14,19,24] These methods have been shown to be more robust for low temporal resolution, especially when performed in the frequency domain using a wavelet approach.[27] Nevertheless, a limited temporal resolution remains the main limitation of MRI, particularly for short arterial path lengths and for patients with highly stiff aortas (and thus very short transit times).

Aging and aortic stiffness measurements in MRI


The relationship of aortic distensibility with age is nonlinear.[19] Recent MRI studies have demonstrated a marked decrease in local aortic strain and distensibility before the fifth decade among asymptomatic general population volunteers.[19] Ascending aortic distensibility measured using central pulse pressure was on average 7.4 ± 2.3 mmHg$^{-1} \cdot 10^{-3}$ between 20 and 30 years of age, 1.8 ± 0.7 mmHg$^{-1} \cdot 10^{-3}$ between 50 and 60 years of age, and 1.0 ± 0.6 mmHg$^{-1} \cdot 10^{-3}$ after 70 years (Fig. 4.4). Furthermore, aortic distensibility was the most sensitive

FIGURE 4.3 Measurement of arch PWV in MRI using ARTFUN software (LIB, INSERM 1146, France). (A) Phase contrast cine transverse view. (B) Aortic arch view with steady-state free precession sequence. (C) Measurement of the transit distance in the aortic arch. Numbers correspond to those in A and (B) (D) Flow wave curves of ascending aorta and descending aorta after peak flow normalization. Transit time is measured as the average time shift that minimizes the least squares difference between systolic upslope data points of the ascending and descending aortic flow curves. *Reprinted from Ohyama Y, Ambale-Venkatesh B, Noda C, et al. and strongest marker of age compared to the following peripheral aortic stiffness measures: carotid distensibility, cf-PWV, and augmentation Index (AIx, which is a surrogate marker of wave reflection).[7] This interesting finding of a dramatic decrease in aortic strain and distensibility—when changes in blood pressure are not yet apparent—is consistent with the mechanical hypothesis of a decline in aortic elasticity in the third decade of life, which results from thinning and fragmentation of elastin fibers caused by repeated deformation and stretch induced by pulsatile stress, among various other biologic processes (discussed in Chapters 19—25).[29]

cf-PWV increases progressively with aging, from approximately 7 m/s at 30 years of age to 12 m/s at 70 years of age.[11] A recent study from the Multi-Ethnic Study of Atherosclerosis (MESA) reports arch PWV assessed by MRI in a multiethnic population aged 45−85 years.[30] MESA is a prospective study designed to evaluate risk factors and mechanisms that underlie the development and progression of subclinical CVD among asymptomatic individuals using MRI to assess cardiovascular structure and function.[31] In that study, arch PWV assessed by PC-MRI increased pronouncedly between participants aged 45−54 years and those aged 54 years and older. Another recent study using PC-MRI has shown that age has different impacts on regional aortic stiffness.[18] The distal aorta exhibited the greatest age-related increase in regional PWV and the aortic arch had the least, whereas the aortic arch had the greatest increase in aortic diameter and length, which may, in part, help offset an increase in wall stiffness by maintaining the capacity of the aorta to store volume during systole. Heterogeneity of structural and functional changes with aging as well as of atherosclerotic burden throughout the arterial tree causes differential regional aortic stiffening.

Cardiovascular risk factors, left ventricular function, and aortic stiffness

Longitudinal studies from MESA have shown that age, high blood pressure at baseline, increase in blood pressure during follow-up, and smoking history were independently associated with the increase over 10 years in aortic stiffness, with a decrease in aortic distensibility, and an increase in arch PWV.[20] In this study, reduction of blood pressure to an adequate level during the follow-up period was associated with less aortic stiffening. In addition, the use of calcium channel blockers was associated with less decrease in ascending aortic distensibility, while other drugs including ACE-I/ARB, beta-blockers, and diuretics did not have the same relationship with aortic stiffness. Recent data

demonstrated an improvement in aortic distensibility in first-time marathon trainers and completers including older participants, shedding light on the possibility to partially reverse this age-related vascular aging phenotype.[32] Future investigations are needed to assess the beneficial effects of different pharmacological and nonpharmacological interventions on aortic function.

MRI has the ability to assess ventricular geometry and myocardial deformation as well as central aortic stiffness simultaneously in a single examination. A recent study on vascular−ventricular interaction has shown the relationship between aortic arch PWV assessed by MRI and LV deformation assessed by tagged MRI as well as LV structure in the MESA cohort. In that study, higher arch PWV was associated with LV remodeling and reduced LV systolic and diastolic function, and this association had a significant gender interaction.[21] In women, greater arch PWV was associated with LV concentric remodeling, worse LV diastolic function, and preserved ejection fraction (EF) with maintained torsion. In contrast, reduced LV systolic function demonstrated as impaired LV circumferential strain and torsion as well as reduced LV concentric remodeling were related to elevated arch PWV in men. This gender difference in the relationship between aortic arch stiffness and LV structure and function may be mediated by hormonal factors and may explain the higher incidence of heart failure with preserved EF among women.

Prognostic value of proximal aortic stiffness measures

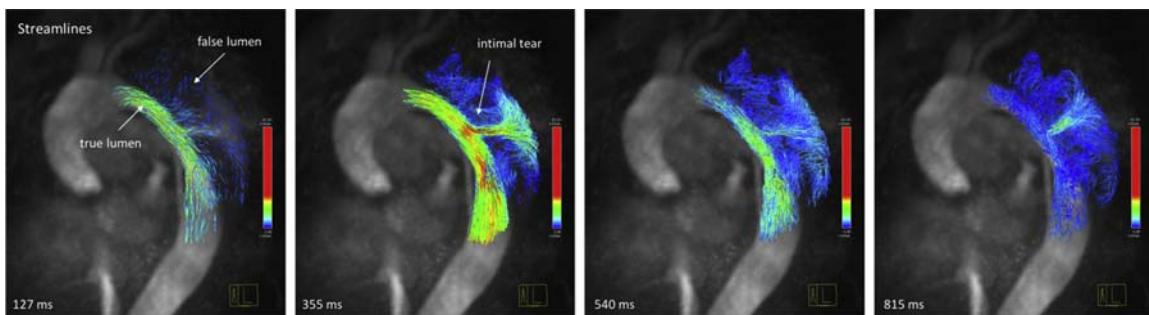
A recent study from MESA showed that decreased ascending aortic distensibility assessed by MRI significantly predicted hard CV events including myocardial infarction, resuscitated cardiac arrest, stroke, and cardiovascular death, and all-cause mortality in individuals without overt CV disease.[4] The hazard ratio for death and hard CV events over 8.5 years was 2.7 and 2.2 for the 20%

of individuals with the stiffest aortas, independent of traditional risk factors. The predictive value of ascending aortic distensibility for CV events was highest in those with low-to-moderate baseline individual risk.

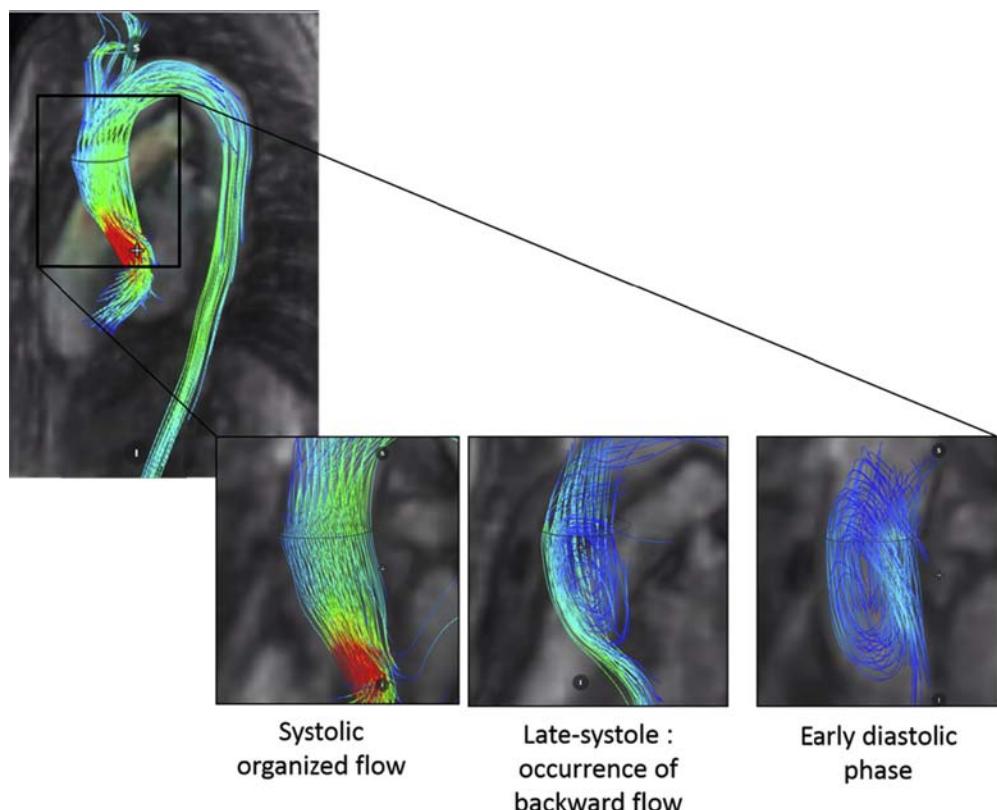
Another study using the MESA cohort showed that arch PWV had incremental predictive value for incident CVD events above traditional CVD risk factors in participants aged 45−54 years in the general population. Arch PWV was not associated with incident CVD events in those aged above 55 years.[30] These findings on the age interaction between arch PWV and events were somewhat consistent with those previously documented regarding the association between PWV and age in metaanalyses.[33] Indeed, the marked increase in predictive power among MESA participants aged 45−54 years compared to those aged over 54 years may reflect the greater predictive value of arch PWV in younger compared to older populations, similar to distensibility. Furthermore, considering the regional heterogeneity of aortic structure, differences in prognostic values may be related to regional differences in the material properties of the aortic wall components and their evolution over time; however, outcome data on such regional differences are lacking.

Advanced methodology to assess pulsatile aortic properties using MRI

Flow analysis

PC-MRI analysis can separate global aortic flow into two components: forward and backward flow. It should be noted that here, we refer to the direction of blood flow in a given region of an aortic cross section due to vortical flow, rather than forward or backward traveling waves which impact net measured pressure and flow (as discussed in Chapters 1, 3, and 11). It has been shown that the magnitude of ascending aorta backward flow increases with age and its onset during a cardiac cycle occurs earlier with aging.[34] Such changes are strongly associated with geometric changes of the aortic arch such as dilation and elongation, that lead to changes in local pressure gradients and local rotating blood vortices.[34] These flow modifications, which might lead to increased LV load and a loss in circulatory system efficiency, partially explain age-related vascular alterations and their potential clinical implications regarding increased CVD risk.


It is also important to note that in PC-MRI through-plane velocity data, the backward flow crossing the ascending aorta section for a single phase of the cardiac cycle includes both backward flow going back toward the heart and locally rotating blood vortices, which reorganize into forward flow in the following phases. These flow patterns can be confirmed using 4D-flow MRI, as further discussed in this chapter.

Combining pressure and flow


According to the American Heart Association's statement on scientific principles of arterial stiffening, the ascending aortic input impedance (Z_{in}) spectrum is the most comprehensive measurement of vascular load in relation to aortic stiffness.[35] Analyses of pressure flow relations are discussed in detail in Chapters 1, 3, 11, and 17. Z_{in} is derived from simultaneous pressure and flow assessments, and characteristic impedance (Z_c) can be estimated in the either frequency or time domain using tonometry and PC-MRI[36,37] or Doppler echocardiography velocity data. Flow assessment by MRI with noninvasive pressure assessment can provide more accurate aortic Zc compared to measures derived using ultrasound flow assessment, which samples the LV outflow tract instead of the ascending aortic flow. In aging, MRI could demonstrate that stiffening of the ascending aorta was related to increased Z_c, concentric LV remodeling, decreased strain, and augmented cardiac work to preserve the vascular–ventricular coupling in asymptomatic individuals.[38] The ability to more accurately measure ascending aortic flow and Z_c would likely provide new insights into aortic function and vascular/ventricular interactions, and the opportunity to clarify the differences and similarities between patients with systolic and diastolic LV dysfunction as the cause of heart failure.[39]

4D flow

More comprehensive 3D cine techniques in combination with three-directional encoding of blood flow velocities (known as 3D cine PC or 4D-flow MRI) over the cardiac cycle (3D + t = 4D) have recently been reported and have greatly expanded clinical and research possibilities regarding the aorta.[40−45] Immediate applications have been toward the visualization and understanding of complex aortic diseases such as aneurysms and complications such as aortic dissection with discernible multilumen flows (Fig. 4.5). The most interesting feature of 4D-flow MRI is its full 4D (3D + t) spatial–temporal coverage of the vessel of interest and the acquisition of multidirectional flow at all locations in a predefined volume (Fig. 4.6). Such volume can also include the aorta and the heart for the evaluation of their coupling when they share the same hemodynamic and loading conditions. Taking into account the unique anatomy of the thoracic aorta in individuals with complex aortic geometry without a priori is one of the advantages of the 4D-flow technique, which enables any desired a posteriori slicing of the acquired volume for local quantitative measures. 4D flow can also evaluate regional PWV at any location of interest in the aorta[41,44,46] and 4D-magnitude images could allow the estimation of local distensibility at multiple locations with adequate postprocessing software. Therefore, 4D-flow MRI could provide a comprehensive assessment of aortic structure, function, and flow

FIGURE 4.5 4D-flow streamlines depicting aortic dissection Stanford type B with a local intimal tear responsible for a false lumen entry of the flow in the proximal descending aorta. *Image: Dubourg B., Redheuil A. (ICT PSL).*

simultaneously, and further elucidate the combined age-related effects of altered aortic geometry, compliance, and pressure on changes in local flow patterns, and partly explain aortic complications.

One of the main drawbacks of 4D flow is its currently low temporal resolution (30−40 ms). Low precision in the assessment of timing has an impact on the precision of the PWV estimate, especially in short aortic segments. To compensate for the low temporal resolution, the time of travel between two planes is routinely calculated by including all intermediate analysis planes, and by linear fitting of the systolic upslope of the resulting series of flow curves to derive the PWV.[41] Several studies have been dedicated to methods comparison for an optimal estimation of aortic PWV from 4D-flow data while comparing to tonometric PWV as well as to the Bramwell−Hill model−derived PWV,[42] corroborating the value of considering all intermediate planes rather than two extreme planes, and also the 2D PC-MRI findings in terms of robustness of transit time estimation.[47]

The 4D flow also provides complex hemodynamic measures, such as helical and vortical blood flow,[48] flow

eccentricity,[49] estimates wall shear stress (WSS),[50] and intraaortic pressure gradients.[51] Abnormal blood flow patterns, flow eccentricity, and increased WSS have been reported in patients with aortic stenosis and may be associated with LV remodeling.[52,53] These hemodynamic measures could also provide useful quantitative description of aortic hemodynamics in patients with other cardiovascular diseases including aortic aneurysm[54] or congenital heart disease.[55] Especially, WSS, that is the tangential force exerted by blood flow on the vessel wall acting on the endothelial cells,[56] can be readily estimated through 4D-flow MRI.[57,58] WSS direction and magnitude can be obtained from spatial derivatives of 3D spatial velocities at the vessel wall from 4D-flow MRI.[57] Recent studies have shown that regions of aortic wall with an elevated estimated WSS correlate with dysregulation of the extracellular matrix and degeneration of the elastic fibers in patients with bicuspid aortic valve.[59−61] Other studies have shown that patients with Marfan syndrome have differences in estimated WSS despite similar aortic dimensions compared to controls. Together with the fact that aortic distensibility is also reduced in such patients irrespective of aortic dimensions,[62] these novel findings implicate that estimated WSS might be useful in prediction of disease progression even in earlier and less severe stages.

It should be noted that current methods of 4D-flow acquisition require rather long, although rapidly improving, scan times (5−20 min), in addition to the complexity of postprocessing that requires specific software, resulting in its still limited use in large populations. However, recent studies showed that compressed sensing could shorten 4D-flow scan times drastically to less than half.[63,64] Furthermore, deep learning enables fast and automated 3D aortic segmentation form 4D-flow MRI angiograms.[65] Such parallel improvements in both 4D-flow pulse sequences and postprocessing methods with expanded calculation power can lead to rapid increase in clinical research use and potential translation to routine clinical use.

Conclusions

MRI has recently been optimized to enable quantification of aortic function and structure with the aim of improving medical diagnosis and risk prediction. The precision and excellent reproducibility of MRI measurements could allow for the assessment of longitudinal variations of aortic parameters with aging as well as the effect of pharmacological and nonpharmacological interventions on aortic function. In practice, aortic flow and functional assessment both visual and quantitative could be added to clinical routine cardiovascular MRI as a comprehensive imaging modality performed primarily for the noninvasive evaluation of LV geometry and function. Advanced imaging such as 4D flow

could further provide noninvasive access to elucidate aortic properties. Further methodological developments and research including acceleration in acquisition sequences, large population studies with normative values with longitudinal follow-up, fast and robust image processing tools possibly relying on machine learning are needed for a more complete understanding of changes in aortic stiffness and hemodynamics in response to aging and disease processes.

Introduction

The aorta is the largest artery in the body. It originates from the left ventricle and conducts oxygenated blood to the rest of the body through a network of smaller arteries and arterioles. To perform such function efficiently, the aorta has unique features in its distinct three wall layers, which provide elasticity to the aortic wall. Various changes in this structure can result in disruption of the cushioning function of the aorta. Aging is a natural process affecting the aortic function; meanwhile, pathological factors can take the form of atherosclerosis and arteriosclerosis of the arterial wall.

Aging and pathological processes cause changes in aortic characteristics like shape, length, diameter, and elasticity.[1] These changes affect cardiovascular health in a negative way.

There are many imaging modalities for the detection of aortic changes with aging and disease, including magnetic resonance imaging and computed tomography (CT), plain radiography, ultrasonography (US), and echocardiography. Currently, CT is the modality of choice for aortic anatomic assessment. With the new generations of CT scanners, the time needed for scans as well as the radiation dose have been minimized.

CT is currently used for the diagnosis of wide variety of pathological conditions related to the heart and vascular tree. It is the first choice in diagnosing aortic aneurisms, dissection, coronary and aortic calcification, and many other disease states. The applications of CT scans expanded from its diagnostic ability into prognostic and predictive abilities. A large number of studies have shown a strong correlation of the presence of certain pathologic processes in the aorta or coronary arteries, detected by CT scan, with the development of cardiac and cerebrovascular adverse events as well as increased mortality. Vascular calcifications, which occur in different vascular beds, including coronary arteries and aorta, can be easily detected by the CT scans in an accurate, noninvasive way and its presence reflects the cardiovascular health status.

Basics of CT and physics

Sir Godfrey Hounsfield invented the first CT scanner in 1967 at EMI Central Research Laboratories, England. It was initially used for brain scanning but was later used for scanning the whole body.

The origin of the word "tomography" is from the Greek word "Tomos" meaning "slice or section" and "Graphe" meaning "drawing." The name itself gives a pretty good idea about the whole concept of the CT.

The idea of CT is based on using an X-ray source emitting thin, fan-shaped beams through the body "slice" in many angles and detectors receiving these X-rays on the opposite side. The X-ray source and the detectors are placed on a circular, rotating frame called "the gantry" (Table 5.1). X-rays are absorbed by different atoms at different rates depending on their physical density and atomic number. This absorption of the X-ray beams while passing through different tissues in the body is detected and represented by brightness on a gray scale in the resulting cross-sectional image where the higher the density, the higher the absorption, and the brighter the structure on the CT image (contrast resolution).

Unlike the conventional CT scanners, electron beam computed tomography (EBCT) does not have a rotating X-rays source and detector. It has a fixed electron beam gun at the back of the machine generating an electron beam directed to four tungsten targets covering 210 degrees of the gantry beneath the patient leading to generation of a 30 degrees fanlike X-ray beams. The X-rays penetrate the patient's body perpendicular to its z-axis. Attenuation of the X-rays is detected by two fixed detector segments on the opposite direction of the tungsten targets covering 210 degrees of the gantry above the patient.

77

TABLE 5.1 Important terms used in the CT scan.

1	Gantry	The circular skeleton containing the rotating X-ray tube and detectors. It has a central opening where the patient is moved in and out for the scan.
2	Matrix	Two-dimensional grid of pixels used to compose images on a display monitor. Numbers of rows and columns in this grid determine the matrix.
3	Pitch	The pitch is defined as the distance traveled by the table inside the gantry in one 360° gantry rotation divided by the total thickness of all simultaneously acquired slices.
4	Scan Field of View (SFOV)	The anatomical area got scanned from the patient's body.
5	Display Field of View (DFOV)	The area of the SFOV reconstructed into images. It can be equal or less than the SFOV.
6	Z-axis	The cranio-caudal axis of the patient.
7	Helical acquisition	The data obtained from the rotating X-ray source and detectors set while the table is moving inside the gantry resulting in a helical path of the X-rays penetrating the patient.
8	Reconstruction	Converting scan data into image data using complicated mathematical formulas and algorithms.
9	Retrospective reconstruction	Creating images from the raw date after the scan when needed.
10	Prospective reconstruction	Automatically creating images from the raw data during the scan.
11	Multiple segments reconstruction	Reconstruction of the combined data obtained for the same view of interest from different gantry rotations in different heart beats.

Data recorded by the detectors are digitized into picture elements called pixels (in 2D) or voxels (in 3D), with known dimensions. A high quality of the resulting CT images is very important for accurate diagnosis. Many factors affect the quality of the images including the following provided below.

Spatial resolution

This is the ability to discriminate small high-contrast objects next to each other as two distinct entities. The size and the number of detectors determine the spatial resolution of the CT scan. With thinner slices, the resolution will increase but so will the radiation dose. The pixels size in the axial view is determined by the ratio of the display field of view to the image matrix. The current multidetector computed tomography (MDCT) scanners use a matrix of 512×512 allowing a spatial resolution in x- and y-axis of 0.35 mm (in axial view). However, the best resolution available in the z-axis for current scanners ranges between 0.5 and 0.625 mm (the width of each detector or the slice thickness) depending on the type of the scanner, which has always been a limitation of the spatial resolution of CT scanners because thinner detectors are not available yet. For 3D images, voxels with equal dimensions in x, y, and z axes (isotropic) are ideal, but cannot be obtained with current scanners due to the slice thickness (z-axis) being greater than resolution in x- and y-axis. However, the x and y dimensions can be adjusted to the resolution in z-axis to get the isotropic voxels required for the 3D images reconstruction but the resolution will be inferior to the axial view

resolution. The area covered with each gantry rotation in the z-axis depends on the number of detector rows, the width of each detector, the pitch at which the table is moving, and the speed of the gantry rotation. Newer scanners like 320 slice-MDCTs can cover large volumes in one rotation. For example, if the detector width is 0.625 mm and the number of detectors is 320, then the area covered in the z-axis with each gantry rotation is 200 mm (0.625 mm $\times$ 320 slices = 200 mm). The whole aorta from the most cranial segment of the arch to the end of abdominal aorta can be scanned within a few seconds.

Flat-panel volume CT scanners, where the detector rows are replaced by an area of detector, have a higher spatial resolution than MDCT scanners, but they are inferior regarding temporal and contrast resolution.[2] Spatial resolution can be increased by decreasing the field of view and using a lower pitch, as usually applied in cardiac CT; however, utilization of a lower pitch increases the radiation dose. The standard CT matrix is 512×512, limiting the number of pixels or voxels which can be represented. Increasing matrix size to 1024×1024 and 2048×2048 in new ultra-high resolution CT scanners have improved the image quality and spatial resolution.[3] Flat-panel volume and ultra-high resolution CT scanners are under development now and have not been used in clinical practice yet.

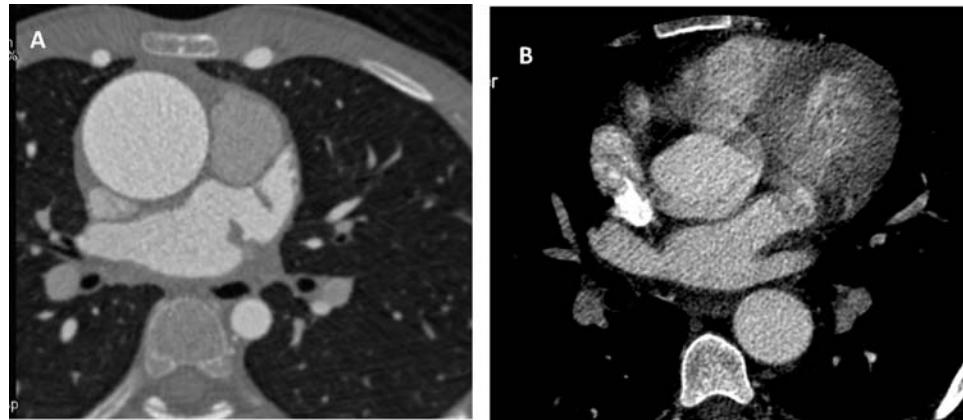
Temporal resolution

This is the ability to freeze the motion during data acquisition. For most applications of CT, it is not that important,

because of the limited motion of organs such as the abdominal aorta. However, in cardiac CT, temporal resolution is critical because the heart, coronary arteries, and thoracic aorta are in continuous motion from the cardiac cycle. This motion creates artifacts in CT images especially during the scan of ascending aorta and aortic valve which can interfere with accurate characterization of them. This can be problematic during assessment of complex aortic anatomy like in case of ascending aortic aneurysm or in the case of interventional procedures depending on accurate scan readings like transcatheter aortic valve replacement. Such problem decreased dramatically with the increased speed of image acquisition in new-generation scanners and with the use of electrocardiographic(ECG)-gating, which synchronizes the acquisition with the cardiac cycle.[4]

Temporal resolution can be improved by using multiple segment reconstruction,[5,6] lower pitch, and higher gantry rotation speed, which is, however, limited due to the G force generated with higher rotation speeds.[6] The limitation of achieving higher rotation speeds led to the appearance of dual-source CT scanners where the gantry has two X-ray sources with corresponding two detector rows perpendicular on each other so that they can cover the whole thickness in a half rotation of the gantry, dramatically decreasing the time needed for the scan. This improves temporal resolution and image quality.[7]

ECG-gated versus non–ECG-gated CTA

ECG gating means that there is synchronization of the CT scanner to the cardiac cycle of the patient, allowing for data acquisition during phases of cardiac cycle where heart motion is minimal. These phases are end systole, early diastole, i.e., (40% phase), or mid-diastole, i.e., (75% phase).[8] There are two methods for gating.


With retrospective gating helical acquisition, data acquisition occurs during the whole cardiac cycle and then the computer chooses the images obtained during specific phases of the cardiac cycle for the image reconstruction. This method is used when the heart rate is irregular because we cannot predict the timing of the relevant phases (typically from 40% to 75% of the cycle). It is also used with higher heart rates since it provides more images and a higher chance to get rid of motion artifacts. It also can detect cardiac motion abnormalities and study the heart during the systole. The downside of this acquisition modality is a higher radiation exposure, which can be reduced in ways we will discuss later.

The second technique is prospective gating (step and shoot), in which the acquisition occurs only during a predetermined time in the cardiac cycle (75% or 40%) and the gantry is moved for a second rotation in a different heartbeat. This method is used in the presence of regular and slower heart rates, because we can predict the phases of the cardiac cycle. This technique takes a longer time depending on the number of rotations and the length needed to be imaged, but it has the advantage of decreasing the radiation dose by up to 80% (15 mSv down to 3 mSv).[9]

The importance of ECG-gated computed tomography angiography (CTA) is not limited to decreasing the radiation exposure in prospective gating[10] but also to eliminating image artifacts which can be misinterpreted as pseudo-dissection of the ascending aorta (image of pseudoaneurysm). It is well known that an intimal flap constitutes one of the main findings on CTA seen in aortic dissection. With non–ECG-gated acquisitions, misalignment of the reconstructed images can mimic intimal flaps, leading to the wrong diagnosis[11] (Fig. 5.1).

ECG-gated CTA requires a longer time for acquisition compared to non–ECG-gated. To overcome this situation in aortic imaging, a combination of ECG-gated imaging for the thoracic aorta and non–ECG-gated imaging for the abdominal aorta can be used to decrease the time of the scan (Fig. 5.1).

FIGURE 5.1 Noncontrast CTA of ascending aorta with ECG gated in (A) versus non-ECG gated in (B).

Contrast resolution

This is the ability of the CT scanner to identify different tissues based on the absorption or the attenuation of the X-rays passing through these tissues. Gray scale values of the pixels within the reconstructed tomogram are defined with reference to the value of water and are called Hounsfield units (HUs) or simply "CT numbers."

There are more than 5000 shades of this gray scale represented on CT centered around zero (water). Each pixel is assigned a value between -1000 (air, black) and $+3000$ (dense bone, white). Typical CT densities of types of structures or tissue are shown in Table 5.2.

Blood and soft tissue (in the absence of vascular contrast enhancement) have similar density, since they consist of similar proportions of the same atoms (hydrogen, oxygen, carbon) thus appearing gray on CT. Bone is rich in calcium and is thus brighter (white) on CT. Fat has an abundance of hydrogen. Lung tissue contains air, which is of extremely low physical density and appears black on CT (HU -1000). CT, therefore, can distinguish blood from air, fat, and bone, but not readily from muscle or other soft tissue (i.e., the intrinsic contrast resolution of the CT is not high for soft tissues).

To identify and differentiate tissues with similar HU we use intravenous nonionic iodinated contrast media (enhanced CT scan) which absorb and attenuate X-rays more than the blood pool and soft tissue, resulting in higher brightness on the gray scale.

The iodine concentration in the contrast media, the rate of contrast injection, and the duration of the injection (resulting in a stable flow rate of the contrast media during data acquisition) play a critical role in achieving optimal arterial enhancement and better diagnostic images on CTA of the aorta. The contrast volume needed for the scan decreased after the new generation of the scanners with increased number of detectors and greater z-axis coverage abilities per each gantry rotation. With injection rates of $4-6$ mL/s in most of the modern scanners and moderate iodine concentration in the contrast media,[12] individualized protocols are important for taking in consideration the patient's body weight, cardiac output, and disease status.[13]

There are two ways to know the perfect timing to start CTA scanning after injecting the contrast. One is called the "test bolus," in which we give a small bolus of the contrast media and watch the increase in HU in the aorta in order to measure the time to reach the peak enhancement; we then give the rest of the contrast and start acquisition after this time delay. The second way is called "bolus tracking" in which the region of interest is placed in the aorta. This area is monitored during contrast injection and the scan acquisition is triggered when a certain density of contrast is detected (usually $110-180$ HU).[14] Injection of a saline flush following the contrast injection is important to washout the contrast from the peripheral circulation, for optimizing contrast delivery in the aorta and for decreasing the required contrast volume[15] (Fig. 5.2).

3D reconstruction

The optimal spatial resolution of the current MDCT scanners, while not perfect isotropic voxels, allows creating 3D volumes of data, which is in turn used to reconstruct true 3D images like multiplanar reformats (MPRs), maximum intensity projections (MIPs), volume renderings (VRs), and visual reality representations (Fig. 5.2).[16] These 3D modalities of CT are crucial for diagnosing various aortic diseases and assessing anatomical variations and abnormalities before interventions in many diseases (such as the diagnosis of aortic aneurysms and planning aortic repairs). Two important modalities in aortic diseases are

(1) MIP where only the voxels of the highest HU will be displayed. With enhanced CT scans where the contrast media will have the highest HU in aortic imaging using MIP, the whole aorta can be assessed for any stenosis, occlusion, aneurysms, etc., but it cannot be used to assess aortic calcifications because the contrast media and calcium can have similar HU, preventing visualization if calcifications.
(2) VR, in which unlike MIP, every voxel is used to create the image. This technique is superior to MIP in detecting aortic calcifications and overviewing the complex anatomical structures in real 3D representations.[17] (Fig. 5.3)

Challenges

Radiation exposure and contrast use limit the applications of CTA. That is why decreasing the radiation dose and

(E) Centerline is used to measure accurate aortic length in curved and straightened MPR views.

contrast became critical to using CTA to its full potential. Ways to decrease radiation and contrast doses include the following:

1 Modulating the milliamperage of the tube current (mA) in retrospectively gated studies according to the cardiac cycle (i.e., decrease the mA dose from the phase corresponding to 80% until the phase corresponding to 40% of the cardiac cycle, and increase it between 40% and 80% to have better images during the phases with the least cardiac motion).
2 Performing prospectively gated studies (on and off).[9,10]
3 Decreasing the kilovoltage (KV) from 120 to 100 when possible.[9] However, this should not be done at the expense of diagnostic image quality.
4 Administering a saline flush after the contrast injection.[15]
5 Using bolus tracking and test bolus methods.[14]
6 Using the new generations of scanners, with higher number of detectors, which also results in a better image quality.[18]

Over the last few years, with the appearance newer scanners with higher speed, greater coverage in the z-axis, iterative reconstruction techniques, and dual-source scanners, the scanning time and radiation exposure has decreased dramatically.[19]

Anatomy of aorta

The aorta is the biggest artery in the body. It originates from the left ventricle and ends at its bifurcation into right and left common iliac arteries at the level of the fourth lumbar vertebra. The aorta is an elastic artery which conducts blood from the heart to the rest of the body and works as a cushion to buffer the pulsatile cardiac ejection. The aortic wall is composed of three distinct layers: the innermost layer is the intima, which contains endothelial cells arranged on a basement membrane and subendothelial loose connective tissue. The outermost layer is the adventitia, which contains connective tissue, some elastic fibers, collagen, and fibroblasts; it also contains nerve fibers and small blood vessels called *vasa vasorum*, which supply the arterial wall with blood. The middle layer is the media, which contains elastic fibers, vascular smooth muscle cells (VSMCs), and collagenous tissue. Changes in the normal histology of these three layers affect the aortic function. The aorta can be divided into two main parts: the thoracic aorta above the diaphragm and the abdominal aorta below the diaphragm. The thoracic aorta is further divided into three parts starting from the aortic root. By drawing an imaginary line between the angle of Louis of the sternum and the lower border of the body of the forth-thoracic vertebra, we can divide the thoracic aorta into (1) The ascending aorta, from the root until this line; (2) The aortic

arch, which is the segment of the aorta cranial to this line; (3) The descending thoracic aorta, below this line and the diaphragm. The aortic arch usually gives three main branches, which supply the upper body: the brachiocephalic, left common carotid, and left subclavian arteries. Normal populations have variations in the origin of these three branches. The most common variation is the "bovine aortic arch," in which the left common carotid artery originates from the brachiocephalic artery instead of the aortic arch itself.[20] Identifying the anatomy of the aorta is critical in treating many aortic diseases like aneurisms or dissections. Whether normal aortic anatomic variations have an effect on pulsatile hemodynamics in the aorta and the brain is unknown.

Aortic assessment using CT for characterizing aortic geometry, diameter, centerline length, and shape

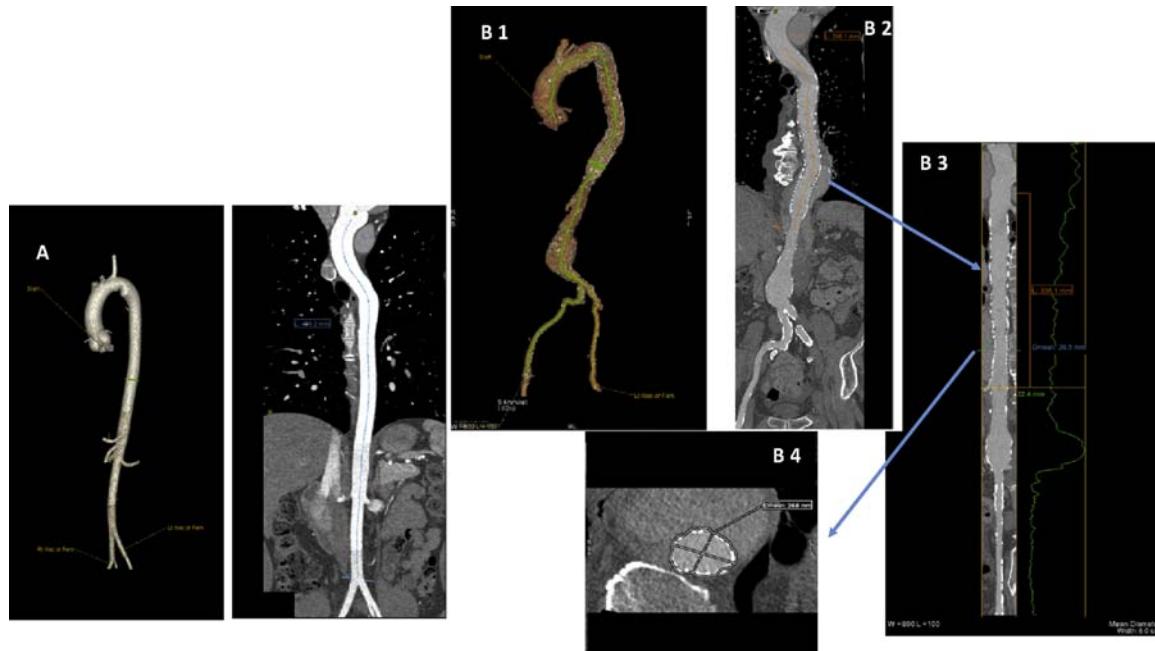
Given the noninvasive nature and high accuracy of the new generations of CT scanners, CT has become the gold standard imaging technique for aortic evaluation in many centers. Aortic assessments depend on the clinical condition and hemodynamic stability of the patient, as well as the underlying pathology and its location in the aorta. CTA of the aorta is used to diagnose different aortic diseases like aortic dissection, aneurysms, intramural hematoma, aortitis, and atherosclerosis, aortic injuries from either trauma or penetrating ulcers and any wall or luminal pathology. In addition, CT is critical in choosing management plans and for patient follow-up.

Aortic imaging is performed using either contrast or noncontrast CTA, depending on the purpose of the scan and the clinical scenario. Noncontrast scans assess aortic calcification and some pathologies like intramural hematoma. Some studies also suggested using noncontrast scan to assess the aortic diameter. Contrast-enhanced, ECG-gated CTA provides an accurate assessment of the aortic geometry. The supervision of an experienced radiographer during the scan is needed to track the contrast peak in the aorta using either the bolus tracking or the test bolus method and to overcome the automated data acquisition if any error occurred for any reason, like abnormal anatomy.

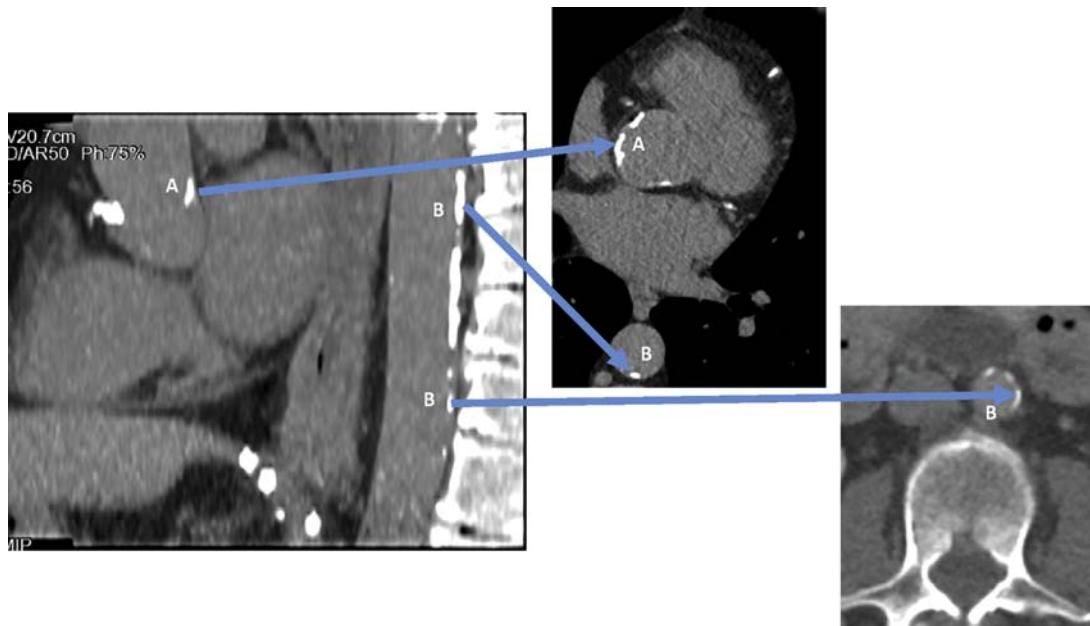
For an accurate assessment of aortic geometry, the acquisition of clear images is important. The use of 3D reconstruction algorithms and centerline extraction and analysis allow for an accurate assessment of various aortic characteristics.[21] An accurate assessment of aortic geometric features is important especially during the preoperative planning of endovascular aortic procedures, because critical decisions in the treatment plan depend on it.

Thanks to the high temporal and spatial resolution of the CT scans and the wide variety of image post processing

techniques, CTA gained the superiority over other modalities used for aortic assessment. One of the important techniques for aortic characterization using CT is centerline extraction and analysis.

Aortic centerline is a thin line drawn in the center of the aorta and used to segment the aortic lumen and to identify the aortic diameter, length, shape, and branches.[22] Many reconstruction software packages can be used to detect the aortic centerline.[23] Many seed points are placed along the course or the aorta. Complex anatomy, angulation, kinking, and tortuosity require the use of more seed points. The software then segments the lumen at the level of the seed point depending on the contrast gradient between the lumen and the aortic wall and the surrounding tissues determining the central point of the lumen. The software then connects all the central points creating a centerline automatically.


Any error of the centerline extraction and measurements will result in inaccurate measurements. That is why a vascular imaging expert should verify the resultant centerline for any errors of the calculation and deviation from the visually correct center of the aortic lumen, especially at the site of angulation and tortuosity. Control points along the centerline is used for manually editing and for correction of the position of the centerline.

After the verification of the centerline, measurements are completed. Cross sections perpendicular to this centerline can be obtained at any point along the vessel course to accurately assess the minimum, maximum, and average diameters, in addition to the wall area of the vessel. These cross sections can be obtained automatically or manually, especially to include the aortic wall or to optimize the measurement in cases of thrombus or calcifications.[24] Centerline analysis also detects the aortic length accurately with the option to display the centerline in a stretched or curved multiplanar reconstruction (MPR).[25] (Fig. 5.4). Tortuous aortas (typical with advanced age and hypertension) can be straightened by use of MPR to accurately evaluate cross sections, aneurysms, and diameters (Fig. 5.5).


The axial view of aortic CT images does not reflect the actual diameter of the aorta because of the oblique course and the tortuosity of the aorta in the body. However, MPR reconstruction of these axial data can be used to "straighten" the aorta in reformatted images to create a plane perpendicular to the aortic lumen giving more accurate measurements correcting for the shape distortion due to the tortuosity.[26,27] (Fig. 5.2).

Many researchers investigated the accuracy and variability of these measurement techniques of the aorta and found that centerline analysis with VR is a more accurate and faster technique than manual interpretation, and it is associated with less interobserver variability compared to other modalities.[28,29]

FIGURE 5.4   (A) Aorta of a 38-year-old patient in volume rendering and curved MPR view appears less tortuous compared to the aorta of a 79-year-old patient in (B). (B 1) Volume rendering image of the tortuous aorta obtained by centerline extraction, showing a stent in the proximal descending part of the aorta and an aneurysm in the infrarenal part. (B 2, B 3) curved and straightened MPR images used to measure aortic length despite increased tortuosity. (B 4) Cross section of the aorta showing the stent and giving an accurate diameter measurement.

FIGURE 5.5   ECG-gated CTA of the aorta without contrast showing aortic calcification in the ascending (A) and descending (B) thoracic aorta.

Changes in aortic geometry with aging

The aortic diameter, wall thickness, wall composition, length, and shape change with aging,[30−32] gender, and various disease states. Many investigators have attempted to establish normal aortic diameters and the changes in aortic diameter associated with aging. Mao et al. evaluated the ascending thoracic aortic diameter of 1442 healthy men and women (mean age of 55 years) referred for CTA and coronary artery calcium (CAC) scoring, using 64 MDCT and EBCT. The investigators found that the ascending aortic diameter increases with age and male gender, with very low variability in measurements between MDCT and EBCT.[33]

Pearce et al. evaluated CT scans performed for clinical patients for nonvascular diagnoses of 389 men and women and measured aortic diameters at four anatomic levels: thoracic aorta and abdominal aorta at the celiac axis, renal arteries, and midway between the renal arteries and the aortic bifurcation. They found that at all levels, the aortic diameter increases with age and male gender; there was also a positive correlation between aortic diameter and body surface area (BSA).[34]

The same results of progressive increase in abdominal aortic diameter with age and male gender was observed by Dixon et al. based on an analysis of CT scans obtained for a variety of clinical indications other than known or suspected aortic disease from 257 male and female participants aged 30−60 years.[35] It was found that different segments of the aorta increase in diameter with aging at different rates. Fleischmann et al. evaluated CT scans of 77 healthy

potential renal donors (33 men and 44 women) aged between 19 and 67 years, to determine age-related geometric changes in the normal abdominal aorta. They assessed the diameter of abdominal aorta using centerline analysis in six consecutive anatomic segments (supraceliac, supramesenteric, suprarenal, interrenal, proximal infrarenal, and distal infrarenal). A significant effect of male gender, BSA, and age was noticed. They also found that the age-related increased aortic diameter is strongly associated with the relative anatomic position along the abdominal aorta where it was highest (0.14 mm/year) in the most proximal segment and diminished gradually when moving distally to (0.03 mm/year) near the bifurcation, causing an increase of tapering of the entire abdominal aorta from proximal to distal with age. However, they found that this proximal-to-distal tapering is not universal in all segments. Diameter increase in infrarenal aorta was absent or mild that caused "negative tapering." They suggested that this age-related tapering in aortic diameter does not occur in people older than 60 years unlike younger people.[22] In the population-based Rotterdam study, which included 5419 men and women aged 55 years and older, Pleumeekers et al. assessed the abdominal aorta using ultrasound. They found that age-related increases in proximal and distal abdominal aortic diameters are (0.07 mm/year) and (0.03 mm/year), respectively.[36] The difference in the segmental growth rate between the two studies might relate to the different age group of the study population.

CTA can also detect changes in aortic distensibility.[37,38] Ganten et al. evaluated changes in aortic distensibility with age among 31 patients without known or suspected aortic

disease aged between 28 and 85 years using retrospective, ECG-gated, time-resolved CT images to detect the change in the aortic cross-sectional area during the cardiac cycle. The authors found a linear decrease in aortic distensibility with aging with greater decrease in the suprarenal versus infrarenal aorta.[39]

Aortic calcification

The mechanisms of arterial calcification are discussed in detail in Chapter 21, but a brief overview will be provided here. It is now well established that aortic calcification is an important predictor of cardiovascular risk. For this reason, early detection and quantification of aortic calcification could be used as a tool for cardiovascular prevention strategies. For a long time, vascular calcifications were thought to represent a passive degenerative process resulting from advancing age. Recent studies demonstrate that vascular calcification is an active process triggered and regulated via different biologic pathways. Calcifications in the vascular tree occur in either the media or the intima of the arterial wall. It is hard to differentiate between these two locations with standard imaging techniques. The mechanisms by which these two types of calcification occur are different.

Intimal calcifications: This type of calcification occurs within atherosclerotic plaques. It is the dominant type of calcification in coronary arteries but also occurs in the aorta. It starts as early as childhood as a part of the atherosclerotic process. Calcification is an active process, rather than passive as believed in the past. Intimal calcification starts as microcalcifications also known as spotty, which coalesce to form larger and more diffuse calcifications, while the atherosclerotic plaques progress forming calcified plaque. Intimal calcification occurs as a result of an imbalance between factors stimulating and inhibiting calcification. The atherosclerotic process causes inflammation in the arterial intima which increases the level of extracellular calcium released from dead cells, favoring calcification. Calcification, in turn, increases the inflammatory process, creating a vicious circle of inflammation and calcification. Bone-forming pathways are involved in this calcification process. VSMCs exhibit transformation into an osteogenic phenotype in atherosclerosis, with expression of many calcium regulating proteins which cause calcification similar to what happens in bone tissue.[40] Macrophages involved in the inflammatory process also initiate and regulate this phenotypic transformation of VSMCs. Apoptosis of VSMCs and macrophages and the formation of apoptotic bodies and matrix vesicles are believed to play a role in initiation of the calcifications.[41] In atherosclerosis, the accumulated lipids in the intima are believed to initiate calcifications in different ways, including stimulation of osteogenic differentiation of VSMCs. In addition, oxidized fatty acids interfere with the clearance of apoptotic cells by macrophages.[42,43]

Intimal calcification plays an important role in plaque stability and rupture. In early stages of atherosclerosis, the heterogeneous nature of the plaques with partial calcifications makes it less stable and more vulnerable to rupture under the effect of mechanical stress. However, it has been noticed that plaques become more stable in the late stages of atherosclerosis when extensive calcification of the fibrous cap of the plaque occurs. On the other hand, well-developed calcified plaques can cause stenosis in the arterial lumen and change the normal hemodynamics of the blood flow, although this is less likely to occur in large arteries like the aorta.

Traditional cardiovascular risk factors that cause endothelial dysfunction and increase the risk of atherosclerosis also increase the risk of intimal calcification. These risk factors include advanced age, male gender, white race, hypertension, diabetes, smoking, hyperlipidemia, and renal failure.

Medial calcification: This type of calcification occurs with or without atherosclerosis or intimal calcification. Medial calcification has a different morphology than intimal calcification. Medial calcification occurs in the elastic layer of the arterial media and appears early as a linear deposit. Later on, it progresses to form circumferential dense calcified layers in the middle of the artery. Medial calcification does not cause arterial occlusion but increases the stiffness of the arterial wall, which alters pulsatile hemodynamics, increasing the pulse pressure. Medial calcification is more common in peripheral arteries and in the aorta. Apoptosis of VSMCs and failure of clearance of apoptotic bodies in the media increases extracellular calcium. In addition, the breakdown of elastin during aging and the production of elastin-derived peptides increase calcium intake into endothelial cells, which participate in the induction of medial calcification. In medial calcification, VSMCs in the media showed activation of many bone-associated genes with expression of bone-regulating proteins.[42,44] The prevalence and severity of medial calcification increases with age; however, it can occur in otherwise healthy young individuals, supporting a role of genetics in the pathophysiology of medial calcification. Medial calcification is more frequently observed in metabolic diseases with electrolyte and pH abnormalities, particularly diabetes and end-stage renal disease (ESRD).

Quantification of aortic calcification

Many imaging modalities can detect aortic calcification, including US and plain X-ray films, but only CT scanning can quantify it in an accurate noninvasive way (Fig. 5.3). The protocol used in CAC scoring is the Agatston method, in which noncontrast, ECG-gated acquisitions of 3 mm-thick

consecutive slices without gaps in between are performed. Voxels having >130 HU with an area >1 mm^2 are included and the intensity of each voxel is weighted using a grading system from 1 to 4. The calcium score of each slice is calculated by multiplying the intensity grade and the area. The total calcium score is calculated as the sum of the scores of all the slices.[45] Calcification and contrast overlap in their HU. Theoretically this overlap can cause unreliable grading and inaccurate calcium scoring using the Agatston method in the setting of intravenous contrast. However, there have been trials of detection calcium scoring in the setting of contrast using the Agatston method.[46]

The quantification is usually performed in a semi-automated manner in which an observer verifies the calcification selection for accuracy. The same protocol is used for the detection of aortic calcification. Noncontrast, ECG-gated studies are used for the ascending aorta to decrease motion artifacts from the heart. For the abdominal aorta, ECG gating is not required because the motion is limited. Another method comparable to the Agatston method is using the volume of the calcified spots. In this method, the amount of voxels above certain cutoff point is multiplied by the volume of each voxel.[47] Many studies have assessed whether automated aortic calcification quantification is as accurate as the semiautomated or the manual methods and found that automated quantification is possible, time-saving and can be used as a risk marker for cardiovascular disease (CVD).[48–50] With deep learning artificial intelligence, the algorithm detecting calcification improved with very high sensitivity and specificity.[48] The first method detected 73.8% of coronary calcifications at the expense of on average 0.1 false positives, and assigned the correct risk category to 93.4% of all scans. In the second study,[50] the authors detected 209 calcifications (sensitivity 83.9%) at the expense of on average 1.0 false-positive objects per scan. The correct category label was assigned to 30 scans and only 2 scans were off by more than one category. Most incorrect classifications can be attributed to the presence of contrast material in the scans. Overall the sensitivity and positive predictive value for the volume of detected calcifications are 0.989 and 0.948. Only one patient out of 40 patients had been assigned to the wrong risk category defined according to Agatston scores.

Tsushima et al. developed a new image analysis software program to quantify aortic calcification volume (ACV) and aortic wall and calcification volume using plain CT images.[51] Few years later, Miwa et al. calculated the percentage of calcified aortic volume against the whole vascular volume (%ACV) using a new image color analysis program.[52] Lindholt et al. also used the aortic cross sections to quantify the calcification as a percentage above or below 50% of the maximal aortic wall circumference based on visual inspection.[53] Hashiba et al. used aortic calcification area to quantify aortic calcification in ESRD patients undergoing hemodialysis.[54]

Other less quantitative scoring systems have been used to quantify aortic calcifications. Kauppila et al. developed a semiquantitative calcium scoring system called Abdominal Aortic Calcification 24-score (AAC-24) among 617 Framingham heart study participants. They included participants who had two lateral lumbar radiographic films acquired at baseline and after 25 years follow-up. The aim was to classify the location, progression, and severity of abdominal aortic calcification and to evaluate the calcification system they used. After they identified the abdominal aorta alongside the first through the fourth lumbar vertebrae, they divided the aorta into three segments per vertebra, and each segment was divided into anterior and posterior, resulting in 24 segments. Each segment was evaluated for the presence or the absence of calcification with a score of 1 or 0, respectively. The final score ranges between 0 and 24. They found that this method is reproducible.[55]

Another simplified scoring system based on the same principle was developed and is called Abdominal Aortic Calcification 8-score (AAC-8). The abdominal aorta alongside lumbar vertebrae L1-L4 was divided into four segments corresponding to each vertebra, with further diving each segment into anterior and posterior, resulting in eight segments. Each segment was scored either 0 or 1 depending on the presence or absence of calcification with a total score ranging from 0 to 8.[56] These two scoring systems are performed manually in a fast way without the need of measurement algorithms. Many studies validated the reproducibility and the predictive value of these scores regarding cardiovascular risk.[57,58]

Other approaches based on radiography to quantify aortic calcifications were investigated over the years.[59–61]

In conclusion, many aortic calcification scoring systems have been used. The Agatston method and volumetric scoring methods using CT scans are more accurate than other methods, but more studies are needed to assess their reproducibility, inter- and intraobserver and scanner variability on a larger number of patients.

Progression of aortic calcification

Aortic calcification is related to increased cardiovascular risk and coronary artery disease (CAD). Detection of the changes in aortic calcification over time may be a valuable cardiovascular risk predictor. CT scan is an excellent tool to detect the progression of aortic calcification over time. Different studies evaluated the progression of aortic calcification using different quantification methods based on serial CT scans to assess the associated risk factors with the calcification progression and to assess the relationship between aortic and coronary calcification.

Kälsch et al. evaluated aortic calcification incidence, progression, and its association with CAC in a population-based cohort study. A total of 3270 participants aged 45−74 years (53.1% women) underwent two cardiac CT scans, at a baseline and after a mean follow-up of 5.1 + 0.3 years. The Agatston method was used to quantify the calcium score in the ascending aorta, descending aorta, and coronary arteries. The authors reported that in patients with a calcium score of zero in the thoracic aorta at baseline, 41.6% developed calcification after 5 years of follow-up and this incidence was associated with age, blood pressure, low-density lipoprotein (LDL) cholesterol levels, and smoking. They also found that participants with elevated initial thoracic aortic calcification, especially in the ascending aorta, tended to have an increased risk of CAC progression and vice-versa.[62]

In Multi-Ethnic Study of Atherosclerosis (MESA), Youssef et al. evaluated thoracic aorta calcification (TAC) incidence and progression over a period of 2.4 + 0.8 years. The Agatston method was used to measure the TAC scores of 5886 participants (mean age of 62 years; 48% male) of four different ethnicities at a baseline and a follow-up second scans. For the follow-up scan measurements, the participants were randomly divided into two groups so that one group had the CTA measurements after 1.6 years and the other group had the CTA measurements after 3.2 years with a mean time between the two scans of 2.4 + 0.8 years. They found that age, systolic blood pressure, lipid lowering medications, diabetes, and smoking were associated with TAC progression.[63]

Pham et al. investigated the relationship between smoking and coronary and aortic calcification among 781 Japanese men aged 40−79 years and free of CVD. The Agatston method was used to measure both aortic and CAC scores. At baseline, the scores were measured using either a 16-MDCT or an EBCT scan. After 5 years of follow-up, the scores were measured using a 64-MDCT scan. With a multivariable analyses controlling for age and other cardiovascular risk factors, they found that current smokers had 147% higher odds of aortic calcification progression compared to never smokers. They also found that the residual adverse effect of smoking on the aorta and coronary arteries is present for at least 10 years after smoking cessation.[64]

Miwa et al. used the %ACV to investigate the relationship between pulse pressure and abdominal aortic calcification progression in 116 patients (74 men and 42 women, mostly middle aged). They included participants who showed aortic calcification in the baseline scan and followed them up for a period of 6.3 + 3.2 years. All participants had well-controlled lipid levels with either statins or other medications. They found that 89% of the participants had calcification progression reflected by increase in the %ACV over the study period. This progression was related to age, body mass index, systolic blood pressure, and pulse pressure, which was the strongest predictor of calcification progression.[52]

Using the Agatston method, Sutton-Tyrrell et al. evaluated the changes in coronary artery and aortic calcification in 80 healthy postmenopausal women by EBCT over an average of 18 months. They found that aortic calcification progression was associated with an increased baseline calcification score, total cholesterol, LDL cholesterol, and elevated pulse pressure. They also noticed that aortic calcification progression correlated with the CAC score.[65]

In a study of 281 kidney transplant recipients, 197 participants had 2 CT scans, 4.4 + 0.28 years apart. The Agatston method was used to measure CAC and TAC scores. Aortic calcification progression was associated with higher baseline aortic calcification score, higher pulse pressure, statin use, older age, higher serum phosphate level, aspirin use, and male sex.[66]

In a randomized clinical trial of 18 ESRD patients undergoing hemodialysis, Hashiba et al. investigated the effect of etidronate, a medication used for the treatment of osteoporosis, on aortic calcification progression. Patients were randomly divided into an etidronate-treated group of 8 patients and a control group of 10 patients. The treatment period was 6 months. The patients had CT scans at baseline, after 6 months and after 12 months to quantify aortic calcification. They found that the progression of calcification in participants treated with etidronate was lower than among patients who did not receive it.[54] This study confirms the role of osteogenic proteins involved in vascular calcification.

From these studies, we conclude that risk factors for aortic calcification include risk factors for atherosclerosis and vascular calcification in vascular beds. Aortic calcification is independently associated with increasing severity of coronary atherosclerosis as measured by CAC. These studies also demonstrated the close relationship between aortic and coronary calcification.

Studies about the progression of aortic calcification using CT scans are relatively scarce. New cohort studies like MESA study will provide further insights about the nature of aortic calcification and its progression. More studies on a larger number of community-based participants for a longer time are needed to better understand the progression of aortic calcification.

The importance of aortic calcification detection

In the recent guidelines issued by the American Heart Association and the American College of Cardiology, CAC score was recommended in asymptomatic adults at low and low-to-intermediate cardiovascular risk to stratify these patients into low-, moderate-, or high-risk patients in order

to implement appropriate preventive strategies. The results of the studies conducted on aortic calcification and atherosclerosis showed that aortic calcification is an independent predictor of CVD. Available data also demonstrate a correlation of aortic atherosclerosis and calcification with cerebrovascular accidents and mortality.[67–71]

As discussed previously, several studies found an association between aortic calcification and CAC.[62,65] On a population of 6807 included in the MESA study, Budoff et al. evaluated that the prevalence of TAC and CAC detected by CT scan using the Agatston method. Over a period of $4.5 + 0.9$ years, the investigators assessed the incidence of coronary heart disease (CHD) events, including hard events (myocardial infarction, resuscitated cardiac arrest and CHD death), in the study population. The investigators found that TAC was an independent predictor of future coronary events only in women.[72] Another study found similar results using plain radiography in which the presence of abdominal aortic calcification in older women was associated with increased mortality.[73]

Takasu et al. found that descending thoracic aortic calcification in the MESA study population is associated with increasing CAC and cardiovascular risk independent of cardiovascular risk factors.[74] In another study, Takasu et al. found that independent of age, descending aortic calcification detected with nonenhanced CT scan was associated with a 3.8-fold increase in the risk for obstructive CAD.[75] Criqui et al. evaluated the association between AAC and CVD in 1974 men and women included in the MESA cohort. He found that AAC was an independent predictor of hard CHD, CVD events, and mortality.[76]

Despite emerging data regarding the prognostic value of aortic calcification detected by CT scanning, the role of aortic calcification on routine risk stratification requires further study.

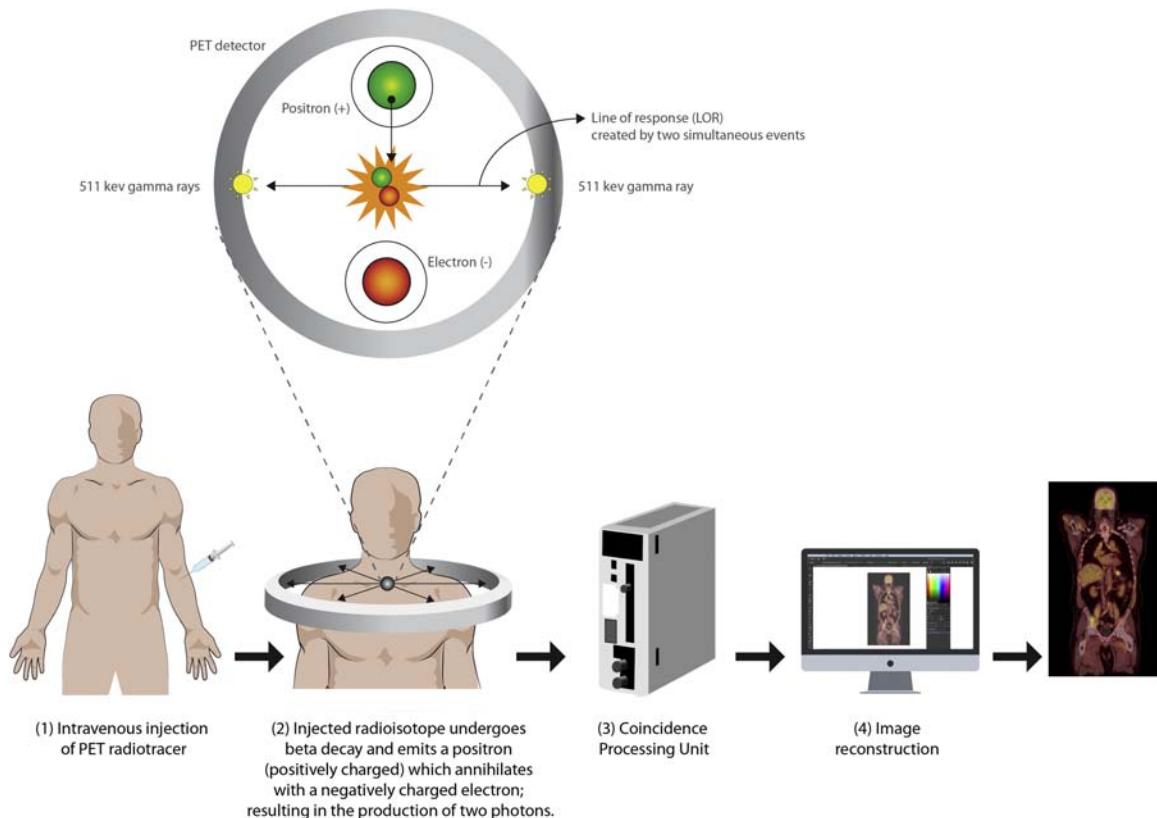
Introduction


Increased large artery stiffness (LASt) is thought to result predominantly from a degenerative process that affects the tunica media of the arterial wall system (arteriosclerosis). LASt is associated with traditional cardiovascular (CV) risk factors and is independently associated with an increased risk of incident CV events.[1-3] The mechanisms of LASt involve a complex interplay between various pathological processes, including elastin degradation, collagen deposition and cross-linking, endothelial dysfunction, inflammation, and medial calcification.[4,5] This eventually results in impaired arterial compliance, a diminished Windkessel effect, and increased pulse wave velocity (PWV) with premature arrival of arterial wave reflections to the proximal aorta, further potentiating systolic hypertension, left ventricular hypertrophy, and heart failure.[6]

Various imaging modalities have been developed for imaging of LASt but are only able to detect the late stages or the hemodynamic consequences of LASt, and do not provide information about biologic activity of the aortic wall. Computed tomography (CT) or X-ray imaging may detect established calcification (macrocalcification) of the arterial wall which is only present at a late stage of the disease process whereby hemodynamic compromise is likely already present.[7] The rising incidence of cardiovascular diseases (CVDs) and associated CV events have stimulated an interest in the understanding of the earliest pathological processes of CVD as well as novel targeted methods for detecting these processes to enable the development of preventative therapies.

As discussed in Chapters 20 and 21, respectively, inflammation and microcalcification often occur in the early stages of vascular remodeling and play an integral role in the development and progression of LASt.[8,9] Local and systemic inflammation is associated with LASt through complex and poorly understood mechanisms and may promote vascular calcification.[8,10] Inflammation may result in destruction and alteration of the extracellular matrix architecture, thereby potentially contributing to LASt.[11,12] Medial aortic wall calcification occurs when calcium and phosphate crystallize in the form of hydroxyapatite in the extracellular matrix of the aortic wall.[13] Both mechanisms are ideal targets for noninvasive molecular imaging modalities.

^{18}F-fluorodeoxyglucose (^{18}F-FDG) and ^{18}F-sodium fluoride (^{18}F-NaF) positron emission tomography (PET) in combination with anatomical imaging using CT (PET/CT) or magnetic resonance imaging (PET/MRI) have emerged as promising modalities for quantitative noninvasive assessment of vascular inflammation and microcalcification, respectively.[10,14-16] PET imaging of the aortic wall using these radiotracers may provide significant insights into the pathogenesis of LASt, prove useful as risk stratification tools and may serve as specific endpoints in the trial of novel pharmaceuticals targeting LASt.[17,18] Both modalities were initially introduced for oncological imaging and were subsequently found to be useful in vascular imaging, predominantly in the context of atherosclerosis. However, their role in imaging aortic disease is becoming increasingly recognized, in part due to common mechanisms (inflammation and calcification) and shared risk factors between atherosclerosis and LASt, and in part due to the independent relationship between medial arterial inflammation and calcification and aortic wall diseases.

FIGURE 6.1 Mechanisms of positron emission tomography (PET) imaging. Upon injection of a radiotracer, the radioisotope undergoes beta-decay and emits a positively charged electron (positron). The emitted positron interacts with a free electron resulting in an annihilation reaction and production of two 511-keV annihilation photons in opposite directions. The annihilation photons strike scintillation crystals and are detected by the PET detectors placed around the patient, creating a line of response (LOR). The distribution of radioactivity within the body is determined by obtaining multiple LORs after a reconstruction of the images in three-dimension while the direction of the annihilation photons helps to localize the origin of the photons.

In this chapter, we discuss the application of ^{18}F-FDG PET/CT and ^{18}F-NaF PET/CT for imaging of inflammation and active calcification of the vascular wall, respectively. These modalities are discussed both in the context of atherosclerosis and LASt, with a greater focus on LASt. The advantages and disadvantages of applying PET imaging to the medial arterial wall are presented. Other potential radiotracers and molecular imaging probes that could be explored for specific targeting of the medial wall pathology are also briefly discussed.

Positron emission tomography imaging

PET is a form of molecular imaging which employs radionuclides or radiolabeled isotopes to visualize, characterize, and measure various biological processes at the molecular and cellular levels.[19] PET imaging is performed by intravenous injection of a radioisotope (e.g., ^{18}F) that binds, via various mechanisms, to its target tissue. In time, the radioisotope undergoes beta-decay and emits a positron (a positively charged electron) from the central nucleus of

the molecular structure. The emitted positron annihilates with free or loosely bound electrons resulting in the production of two photons: 511 keV each.[20] These photons travel in opposite directions and are simultaneously detected by PET detectors placed around the patient (Fig. 6.1), creating a line of response (LOR). The distribution of radioactivity within the body is determined by obtaining multiple LORs after a reconstruction of the images in three-dimension as well as corrections for attenuation, dead time, scatter, and random coincidences.[21]

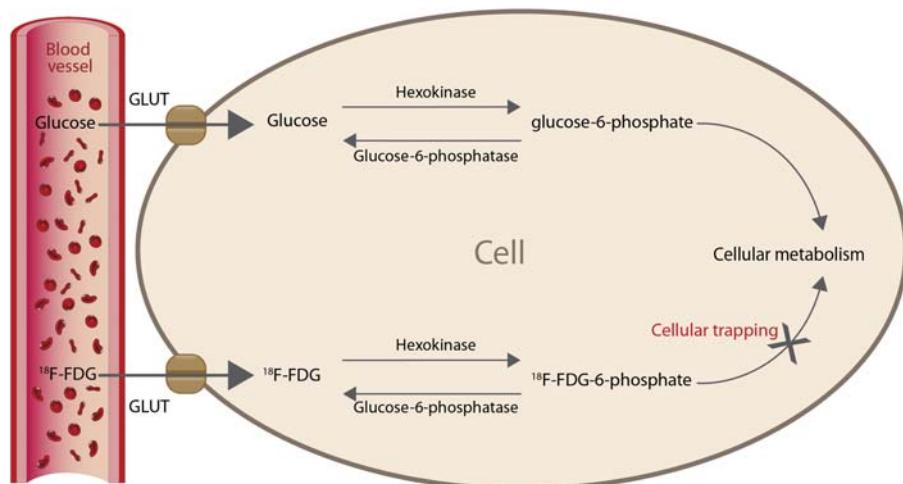
Positron emission tomography radionuclides

Many PET radionuclides have short half-lives that decay at predictable rates following administration. ^{18}F is the most frequently used PET nuclide in clinical practice and has a long half-life of 109 min, which allows for a higher positron yield and a short positron range, allowing for injection of lower dose of radioactivity, a higher spatial-temporal resolution in tissues, delayed imaging protocols, and for easy transportation over long distances.[20,22] Nuclides with

TABLE 6.1 Characteristics of typical positron emission tomography radionuclides with potential utility in vascular imaging.[23–25]

Nuclide	Decay (%)	Half-life	Maximum β^+ energy	γ energy (keV)	Examples of positron emission tomography radiotracers	Potential clinical applications
[11]C	β^+ (99.8) EC (0.2)	20.4 min	960 keV	511	^{11}C-choline[11]C-PK11195	Vascular inflammation[26,27]
[18]F	β^+ (97) EC (3)	109.8 min	635 keV	511	^{18}F-NaF ^{18}F-FDG	Vascular calcification, vascular inflammation
[64]Cu	β^+ (18) β^- (37) (45)	12.7 h	653 keV	511	^{64}Cu-TNP	Vascular inflammation[28]
[68]Ga	β^+ (90) EC (10)	68.3 min	1.9 MeV	511	^{68}Ga-DOTATATE; ^{68}Ga-NOTA-RGD	Vascular inflammation[29–31]
[89]Zr	β^+ (22.7) EC (77)	78.5 h	2.8 MeV	511 909	[89]Zr-DNP	Vascular inflammation[32]

[64]Cu, copper-64; *[64]Cu-TNP*, ^{64}Cu-tri-reporter nanoparticle; *[68]Ga*, gallium-68; *[68]Ga-NOTA-RDG*, ^{68}Ga-labeled 1,4,7- triazacyclononane-1,4,7-triacetic acid (NOTA) - Arg-Gly-Asp (RGD); *[89]Zr*, zirconium-89; *[89]Zr-DNP*, zirconium-89-labeled dextran nanoparticles; *DOTATATE*, Dodecanetetraacetic acid-DPhe1, Tyr3-octreotate.

significantly shorter half-lives, such as carbon-11 (^{11}C; 20 min), nitrogen-13 (^{13}N; 10 min), and oxygen-15 (^{15}O; 2 min) can also be used, but often require local availability of a cyclotron.[23,24] The characteristics of typical PET radionuclides with a potential role in vascular imaging are summarized in Table 6.1. Two ^{18}F-based radiotracers, ^{18}F-FDG and ^{18}F-NaF, are of significant interest in vascular imaging and are further described.


Positron emission tomography/computed tomography fusion imaging

A key advantage of PET over other molecular imaging modalities, including single-photon emission computerized tomography (SPECT), is its higher spatial resolution (4–5 vs. 10–16 mm for clinical PET vs. SPECT, respectively).[33] However, the 4–5 mm resolution is often insufficient to localize regions of small activity in the absence of established anatomical imaging tools.[34,35] Most modern PET scanners are combined with CT (PET/CT) or MRI (PET/MRI) to overcome this limitation, allowing same time-point acquisition of anatomical information.[21,36] These functional and anatomical images can be obtained simultaneously in a single study and automatically co-registered, allowing for more precise identification of PET tracer uptake by the multimodality scanners (PET/CT; PET/MRI).[36] This has revolutionized PET imaging both in oncological and CV medicine and is particularly useful in the identification of small, arterial regions of radiotracer activity.

[18]F-fluorodeoxyglucose positron emission tomography

Historical background and mechanisms

^{18}F-FDG is a radiolabeled analog of glucose which binds to glucose transporters (GLUT) to enter cells that use glucose as a source of energy.[37] This was first discovered by researchers at the University of Pennsylvania in the early 1970s who demonstrated that ^{14}C deoxyglucose (DG) crossed the blood–brain barrier and could be used to image brain's metabolic activity.[38] These investigators were the first to show that DG could be phosphorylated by hexokinase enzyme to DG-6-phosphate in a similar manner to glucose, as depicted in Fig. 6.2.[39] They observed that DG-6-phosphate could not undergo further metabolism, which made radiolabeled DG an attractive candidate for imaging of the brain metabolic activity. Further collaboration between the University of Pennsylvania and the Brookhaven National laboratory in 1973 led to a joint pursuit for radionuclides that could be used in humans, and by 1975, ^{18}F-FDG had been successfully synthesized at the Brookhaven National laboratory.[38] In a series of animal studies that followed, preferential ^{18}F-FDG uptake was demonstrated in animal models of malignant tumors.[37,40] It was later demonstrated that ^{18}F-FDG uptake correlated with the grade of tumor. In modern clinical practice, ^{18}F-FDG-PET has become a well-established modality for noninvasive imaging of cancer metastasis, prognostication, and for early detection of cancer recurrence after treatments.[38]

FIGURE 6.2   Mechanism of cellular ^{18}F-fluorodeoxyglucose (F-FDG) uptake and metabolism. Both glucose and [18]FDG enter metabolic cells via GLUT receptors. Upon entry, they both undergo phosphorylation by hexokinase to form glucose-6-phosphate and ^{18}F-FDG-6-phosphate, respectively. However, only glucose-6-phosphate undergoes further metabolism to its final products via glycolysis, whereas ^{18}F-FDG-6-phosphate becomes trapped within the cells.

Over a decade ago, it was observed that vascular areas with atherosclerotic disease had increased ^{18}F-FDG uptake compared to nonatherosclerotic segments.[41] This exciting discovery led to further exploration of this modality for potential imaging of vascular inflammation. In 2002, Rudd et al. performed the first prospective clinical study of ^{18}F-FDG-PET imaging in atherosclerosis, and demonstrated that ^{18}F-FDG accumulated in symptomatic atherosclerotic carotid artery disease compared to asymptomatic carotid lesions.[14] Since then, multiple retrospective and prospective studies have shown that ^{18}F-FDG uptake is a strong predictor of atherosclerotic plaque rupture and poor CV outcomes in atherosclerotic CVD.[18,42] ^{18}F-FDG-PET has become the most established molecular imaging modality used in atherosclerosis, although its use predominates in research settings. Its application to the imaging of aortic wall stiffness is still emerging.

Interpretation of ^{18}F-fluorodeoxyglucose signal

The rate of ^{18}F-FDG update tends to be proportional to the cells' metabolic activity and is increased in malignant tumors, brain tissue, myocytes, and inflammatory cells. This is in part due to the upregulation of GLUT receptors and enzymes involved in glucose metabolism owing to the cells' increased metabolic needs.[40,43] In inflammatory conditions such as atherosclerosis, increased ^{18}F-FDG uptake reflects accumulation of activated macrophages, which are the major driver of vascular inflammation.[21] However, the interpretation of vascular ^{18}F-FDG uptake can be challenging because other metabolically active cells such as neutrophils, lymphocytes, endothelial cells, and smooth muscle cells can also uptake glucose.[44,45] In

particular, smooth muscle cells and endothelial cells can markedly increase their glycolytic activity when exposed to proinflammatory cytokines.[45] Increased vascularity in atherosclerotic plaques may also result in increased ^{18}F-FDG uptake due to enhanced ^{18}F-FDG delivery to the resident cells.[21]

Furthermore, hypoxia has been shown to influence ^{18}F-FDG uptake through various mechanisms. While both M1 (proatherogenic) and M2 (atheroprotective and antiinflammatory) macrophages are observed in atherosclerotic plaques, M1 macrophages are the predominant subtype in the early stages of atherosclerosis and preferentially uptake ^{18}F-FDG.[46,47] *In vitro* studies have shown that increased ^{18}F-FDG uptake correlates with hypoxia-inducible factor 1α (*HIF1A*) gene expression, which may be related to an upregulation of GLUT receptors.[43,45,48] Hypoxia can also influence the polarization toward M1 macrophages and can stimulate glycolysis in M1 macrophages by stimulating overexpression of hexokinases.[43,47,49] Taken together, these factors complicate the interpretation of vascular ^{18}F-FDG uptake and may potentially reduce its specificity for imaging of inflammation. It remains unclear to what extent hypoxia rather than inflammation, influences ^{18}F-FDG uptake by macrophages.

Practical considerations in ^{18}F-fluorodeoxyglucose imaging

When studying arterial ^{18}F-FDG uptake, a pre-scan plasma glucose concentration ≤ 7 mmol/L (126 mg/dL) is recommended because higher blood glucose levels are associated with falsely low target-to-background ratios (TBRs) partly due to an increase in blood pool activity.[50] ^{18}F-FDG PET

imaging of the coronary arteries is particularly influenced by hyperglycemia because background myocardial uptake is often greater than ^{18}F-FDG signals originating from coronary plaques.[51]

Compared to ^{18}F-FDG PET imaging in oncology, longer ^{18}F-FDG circulation times of 2−3 h are also required in vascular imaging to allow enough time for ^{18}F-FDG accumulation into the arterial wall while permitting decay and excretion of background levels of ^{18}F-FDG before image acquisition. This is a critical step because a shorter time interval between ^{18}F-FDG injection and image acquisition will result in underestimation of arterial ^{18}F-FDG uptake.[50,52] When image acquisition is performed at 3 h after ^{18}F-FDG injection, the intensity of arterial ^{18}F-FDG uptake correlates with histological macrophage density.[52] Some experts believe that a circulation time of 2 h is likely to be sufficient and potentially more acceptable to patients.[53] Delaying image acquisition by >3 h does not offer any additional benefit.

The dose of ^{18}F-FDG required for imaging of aortic wall inflammation can be influenced by the sensitivity of the scanner, patient's body habitus, and the circulation time. It is recommended that the dose be minimized to reduce the exposure to ionizing radiation, particularly among patients undergoing serial ^{18}F-FDG PET imaging.[53] At least one study has previously demonstrated that a low ^{18}F-FDG dose does not significantly affect the image quality or quantification of ^{18}F-FDG uptake.[50] The recommended dose is between 3 and 4 MBq/kg body weight.[53]

[18]F-fluorodeoxyglucose positron emission tomography imaging of the arterial wall

^{18}F-FDG PET is a well-established modality for the imaging of vascular inflammation of the intimal wall in the context of atherosclerosis.[14,41] This reflects the pivotal role of ^{18}F-FDG in the detection of intimal macrophages, the key drivers in the inflammatory cascade of atherogenesis. This is further demonstrated in both ex vivo and in vivo studies in which ^{18}F-FDG accumulates in macrophage-dense areas of atherosclerotic plaques.[14,41] In patients with severe carotid stenosis, ^{18}F-FDG PET signal correlates strongly with macrophage staining on corresponding histologic sections after carotid endarterectomy.[52]

In contrast, the application of ^{18}F-FDG PET to the imaging of the medial layer of the arterial wall is less established, perhaps due to the differences in the histology between the tunica intima and the tunica media, and the pathophysiological differences between atherosclerosis and arteriosclerosis. Vascular smooth muscle cells (VSMCs) are the predominant cell types present in the avascular tunica media, and the balance between the proinflammatory and antiinflammatory properties of the VSMCs determines the extent and severity of medial arterial wall inflammation.[11]

While inflammation plays an essential role in the pathophysiology of atherosclerosis, LASt has a complex pathophysiology that differs from atherosclerosis, and involving elastic fragmentation and degradation, collagen deposition, collagen and elastin cross-linking, VSMC stiffening, endothelial dysfunction, medial calcification, and indeed, a component of inflammation.[4,5] The association between vascular inflammation and LASt is itself complex and multifaceted. On the one hand, the tunica media is considered an "immune-privileged" site, being spared of resident and infiltrating inflammatory cells in normal and atherosclerotic disease states.[11] On the other hand, medial immunoprivilege breakdown can be observed in the form of intense leukocyte infiltration associated with certain aortic aneurysms and vasculitides, which may result in loss of VSMCs, and destruction of the extracellular matrix architecture.[11] How this inflammation affects LASt is not well understood, but it may promote the trans-differentiation of VSMCs into an osteoblastic phenotype, resulting in active calcium deposition within the arterial media.[8,54,55] Vascular inflammation can also activate matrix metalloproteinases, resulting in degradation of elastin and collagen.[12]

Although LASt is mostly determined by factors affecting the medial arterial wall, it remains unclear whether medial arterial wall inflammation can be imaged in isolation because pathologies affecting any of the three layers of the arterial wall can result in aortic wall stiffness,[4] and differentiating these layers noninvasively is difficult.[9,56] Indeed, traditional CV risk factors and endothelial dysfunction which cause atherosclerosis are also associated with LASt.[4,57,58] Unsurprisingly, a recent study performed by Al-Mashhadi et al., demonstrated that arterial ^{18}F-FDG PET signal accumulates equally in intimal wall and other arterial wall tissues, including the arterial media,[56] supporting the notion that aortic wall inflammation may be associated with both atherosclerosis and arteriosclerosis.[9] It is theoretically possible that some of the ^{18}F-FDG uptake in the medial arterial wall may be mediated through VSMCs, rather than or in addition to the macrophages, because VSMCs can exhibit proinflammatory properties and have the ability to upregulate GLUT receptors under stress.[45,59] Detecting such processes would be possible with ^{18}F-FDG PET but would rely upon global methods of analysis whereby entire aortic ^{18}F-FDG burden would be of greater importance than localized regions of activity.[39,60]

While the mechanisms of inflammation in LASt remain poorly defined, many studies have shown that measures of aortic wall stiffness are associated with markers of active inflammation in patients with chronic inflammatory conditions such as rheumatoid diseases,[10] chronic obstructive pulmonary disease,[61,62] and vasculitides.[63] In a small study

of patients with rheumatoid arthritis (RA), Mäki-Petäjä et al. demonstrated an increased aortic wall stiffness in RA patients as determined by aortic PWV, which is strongly correlated with raised inflammatory markers.[10] In a cohort of patients with ANCA-associated small vessel vasculitis (systemic inflammation), Booth et al. showed that subjects with active inflammation had increased measures of aortic stiffness whereas PWV did not differ in individuals with disease in remission compared to control subjects.[63] The relationship between inflammation and LASt is discussed in detail in Chapter 20.

The potential utility of ^{18}F-FDG PET imaging in LASt can be observed in small studies of older patients and individuals with diabetes mellitus, and other CV risk factors. In a cohort of 44 patients with type 2 diabetes without established CV disease and who were not on hypoglycaemic medications, De Boer et al. found a significant independent correlation between subclinical arterial inflammation assessed with ^{18}F-FDG PET and arterial stiffness.[9] Furthermore, systemic low-grade inflammation exists among older individuals and is associated with aortic wall stiffness. In a study of 149 subjects who were stratified by age group, it was observed that the percentage of visible large artery segments with ^{18}F-FDG uptake increased with age (27% for the first decade, 38% for the second decade, 67% for the third decade, and 77% for the fourth decade).[64] In a cohort of 30 patients aged over 65 years with and without hypertension, Joly et al. observed a positive correlation between aortic ^{18}F-FDG uptake and aortic stiffness at the level of ascending aorta.[65] Stiffness was increased among individuals with raised inflammatory markers and this correlated well with ^{18}F-FDG uptake. Compared to older individuals who were normotensive, hypertensive older patients of matched age had higher thoracic aortic PWV and increased ^{18}F-FDG uptake.[65] Taken together, these early observations may suggest a role for ^{18}F-FDG PET imaging of the aortic wall to detect early markers of aortic stiffness, but further research is needed.

^{18}F-fluorodeoxyglucose positron emission tomography imaging in prognostic assessment

Increased vascular ^{18}F-FDG-PET activity may correlate with future clinical events, suggesting that it may have a role in the identification of a subset of patients who may benefit from intensive medical therapies.[52] Indeed, macrophages tend to accumulate in unstable atherosclerotic plaques, which are associated with a risk of rupture and future CV events.[14,42] In a cohort of cancer patients who were followed up for 29 months after undergoing a whole body ^{18}F-FDG-PET, Rominger et al. observed a strong correlation between ^{18}F-FDG uptake in large arteries and

subsequent vascular events.[18] Other studies have also demonstrated a prognostic value of ^{18}F-FDG PET imaging in predicting CV events.[42,66] Figueroa et al. evaluated whether arterial inflammation measured by ^{18}F-FDG-PET could predict CV events beyond traditional risk factors. In this study, 513 individuals with treated cancers and who had no history of CVD underwent ^{18}F-FDG-PET and were followed up for 4.2 years. The study demonstrated that TBR (quantified in the ascending aorta) was a strong and an independent predictor of subsequent CV events (incident stroke, transient ischaemic attack, acute coronary syndrome, revascularization, new-onset angina, peripheral arterial disease, heart failure, or CV-related death).[42] Furthermore, the addition of ^{18}F-FDG measurements to Framingham risk scores resulted in incremental improvement in ^{18}F-FDG-PET being able to predict future CVD events.

These findings suggest that increased vascular ^{18}F-FDG uptake is associated with active inflammation and is, at least in coronary atherosclerotic plaques, a predictor of plaque instability and increased risk of adverse CV events.[14,21] This is particularly relevant from a clinical standpoint because inflammation is now a key target for therapeutic interventions in CVD. The Canakinumab Antiinflammatory Thrombosis Outcome Study showed that antiinflammatory therapy targeting the interleukin-1β pathway with a fully humanized monoclonal antibody, canakinumab 150 mg every three months, significantly reduced the rate of recurrent CV events, among patients with previous myocardial infarction and a high-sensitivity C-reactive protein level.[67] However, this benefit occurred at the expense of increased risk of fatal infections, making Canakinumab a less desirable treatment option for coronary disease. In the low-dose colchicine for secondary prevention of CVD (LoDoCo and LoDoCo2 trials), colchicine 0.5 mg compared to placebo, significantly reduced the rates of CV events among patients with stable coronary disease.[68,69] The Colchicine Cardiovascular Outcomes Trial showed that colchicine compared to placebo was effective at preventing major adverse CV events after a myocardial infarction.[70] These results provide strong evidence for the potential benefits of antiinflammatory therapies in patients with coronary artery disease, perhaps by stabilizing atherosclerotic plaques.

The prognostic value of vascular ^{18}F-FDG uptake in relation to aortic stiffness and future CV events remains unclear. It is unlikely that high-risk plaques in the aorta are of great clinical importance, but global aortic inflammation, assessed with ^{18}F-FDG PET, may represent an increased propensity to develop further arterial disease (both intimal and medial) and subsequent CVD events.[18] Data from small studies indicate that both vascular inflammation and

aortic stiffness may be reduced by antitumor necrosis factor-α (anti-TNF) therapies,[10] but there is currently no direct evidence to suggest that this is associated with reduced CV events.

^{18}F-fluorodeoxyglucose positron emission tomography in translational research and clinical trials

There is substantial interest in using ^{18}F-FDG PET as a surrogate endpoint in clinical trials evaluating the treatment effects of anti-atherosclerotic and antiinflammatory drugs. It is expected that this tool may serve as a bridge between phase I/II and phase III clinical trials by providing early in vivo evidence of molecular benefits of new pharmaceuticals. Absence of improvement in ^{18}F-FDG uptake after treatment with a new pharmaceutical may indicate that the new drug is unlikely to have significant clinical effects and may argue against the need to embark on expensive and potentially futile phase III clinical trials.[71] However, these studies should be interpreted with caution since other factors such as duration of follow up, and methods of quantification of ^{18}F-FDG uptake are likely to influence the results.[71,72]

In the first randomized trial evaluating this concept, 43 patients undergoing ^{18}FDG-PET imaging for cancer screening and who had demonstrable ^{18}FDG uptakes in the thoracic aorta and/or the carotid arteries were randomized to either statin group receiving simvastatin (n = 21) or diet group receiving dietary management only. After 3 months of follow up, attenuated ^{18}F-FDG standardized uptake value (SUV) was observed among statin-treated individuals compared to the individuals in the diet control group, which paralleled improvement in lipid profiles.[73] In a study of Japanese adults with dyslipidaemia undergoing percutaneous coronary intervention for stable angina, Ishii et al. showed that 6 months of treatment with atorvastatin 20 mg compared to 5 mg was associated with a significant reduction in TBR in the ascending aorta and femoral artery, mirroring improvement in lipid profile and a decrease in inflammatory biomarkers.[74] Other trials have also shown improvement in ^{18}F-FDG uptake after statin treatment, which may be dose-dependent,[75] and correlates with improvement in inflammatory biomarkers.[76] In RA patients, Mäki-Petäjä et al. showed that anti-TNF therapy could reduce aortic inflammation, and this effect correlated with the decrease in aortic stiffness.[10] In this study, 17 patients with RA underwent ^{18}F-FDG PET before and after 8 weeks of anti-TNF therapy. Additional 34 patients with stable CVD were imaged concurrently and used as positive control at baseline. Both groups underwent assessment of aortic ^{18}F-FDG TBRs and aortic PWV. At baseline, RA patients had higher aortic TBRs than patients with CVD (2.02 ± 0.22 vs. 1.74 ± 0.22, P = .0001). At follow up, aortic TBR fell significantly to 1.90 ± 0.29, and the proportion of inflamed slices decreased from 50 ± 33% to 33 ± 27%. Furthermore, TBR in the most diseased segment of the aorta also improved. These improvements in TBR values after treatment with anti-TNF therapies correlated with reduction in aortic PWV. The results suggest that ^{18}F-FDG PET may be useful as surrogate endpoint in clinical trials of therapies for atherosclerosis and may potentially have a role in evaluation of therapies for aortic stiffness.

^{18}F-fluorodeoxyglucose uptake in aortic aneurysms and large vessel vasculitis

^{18}F-FDG PET is a very useful modality in certain aortic aneurysms and large vessel vasculitis where medial inflammation is typical.[77] Rupture of abdominal aortic aneurysmal (AAA) is associated with high mortality and although imaging modalities such as CT and ultrasound can be used to monitor for progression and risk of rupture, these modalities are imprecise and unable to provide information about biologic activity within the aortic wall. Aortic wall inflammation may be associated with an increased risk of aneurysmal rupture. Biopsy of aneurysmal walls with ^{18}F-FDG uptake has increased inflammatory cells, and a marked reduction of VSMCs in the medial wall compared with PET negative sites.[78] ^{18}F-FDG uptake in aneurysmal walls may also be associated with increased activity of matrix metallopeptidase 1 and 13, which could suggest active remodeling and a potential risk of rupture.[78] Ex vivo studies have shown an association between pre-rupture ^{18}F-FDG uptake on micro-PET imaging and inflammation in the ruptured AAA wall,[79] suggesting that it may be possible to use ^{18}F-FDG PET imaging to monitor inflammatory changes before AAA rupture. However, although these ex-vivo observations have been corroborated in small human studies, the results have been contradictory and there remains insufficient data to conclusively determine the association between aneurysm growth and rupture and ^{18}F-FDG uptake.[80]

Large vessel vasculitis (LVV), including Takayasu arteritis and giant cell arteritis are associated with intense aortic wall inflammation which may promote vascular calcification.[8] While ^{18}F-NaF remains an investigational tool in this context, ^{18}F-FDG PET can currently be used in clinical practice for assessment of suspected giant cell arteritis when the diagnosis cannot be excluded on basis of biomarkers, other imaging modalities, and temporal artery biopsy.[81] It may have a greater role in the diagnosis of extracranial vascular involvement in patients with LVV, but this is yet to be further elucidated in randomized clinical trials. If combined with CT angiography, ^{18}F-FDG PET may help to detect LVV-associated complications such as stenosis, aneurysmal formation, and dissection.[82] ^{18}F-FDG PET may also have a role in monitoring for therapeutic

response after treatment initiation for LVV although data to support this use are scarce.[81] At present, there is no internationally accepted definition of LVV based on ^{18}F-FDG uptake, but expert recommendations have been published.[82]

[18]F-sodium fluoride positron emission tomography

Historical background and mechanisms

[18]F-NaF is an established radiotracer that was first introduced and purposed for the detection of osteolytic and osteoblastic disease in the 1960s.[83] The radiotracer had limited clinical utility initially due to its high-energy nature and limited imaging modalities at the time and was subsequently superseded by 99 mTc—methylene diphosphonate scintigraphy.[84] However, recent improvements in molecular imaging, notably the evolution of PET, has seen the resurgence of ^{18}F-NaF as a bone-specific agent that has enhanced diagnostic accuracy in the detection of metastatic bony disease.[85] The improved image resolution of PET imaging occasioned the observation of nonosseous ^{18}F-NaF uptake, the most intriguing of such reflecting arterial calcification activity.[86] This has led to a growing interest in the role of this tracer for imaging of vascular calcification.

Upon intravenous injection, ^{18}F-NaF rapidly binds to hydroxyapatite $(Ca_{10}(PO_4)_6(OH)_2)$, the predominant mineral present in bone.[13] This involves the ^{18}F-ion exchanging for a hydroxyl group in the mineral matrix, thereby resulting in fluorapatite $(Ca_{10}(PO_4)_4F_2)$ formation.[87] This exchange process is rapid, reflecting the high affinity of this radiotracer for hydroxyapatite structures.[87,88] The ^{18}F-ion undergoes radioactive decay as previously described, and like ^{18}F-FDG, the resulting positron emission allows targeted identification of regions of radiotracer binding within the vascular and osseous structures.

Interpretation of ^{18}F-sodium fluoride- signal

The two major factors influencing the uptake of ^{18}F-NaF into vascular calcifications are (1) the surface area of hydroxyapatite available for binding and (2) the delivery of radiotracer to the area of binding. These features have been studied mostly in the setting of atherosclerotic calcification,[88] though similar principles are likely to apply to all types of calcification within the vasculature. Irkle et al. studied extracted carotid artery atherosclerotic specimens incubated with ^{18}F-NaF then imaged with spectroscopy, autoradiography, histology, and immunohistochemistry.[88] In the absence of calcification, no ^{18}F-accumulation was detected. ^{18}F-NaF radiotracer uptake was greater in the presence of microcalcifications (nodules <50 μm) more so than macrocalcification (nodules ≥ 50 μm). When carotid artery specimens were dissected prior incubation in ^{18}F-NaF, the radiotracer uptake was much higher than in specimens that were not dissected prior to incubation. These findings are secondary to the increase in surface area of hydroxyapatite available for ^{18}F-binding and ultimately translate to an increased signal intensity of such regions, on PET imaging.

The role of blood flow and delivery of radiotracer to hydroxyapatite crystals is surprisingly important, even in vascular calcification. In the study of carotid specimens interrogated by Irkle et al., the nondissected regions of carotid lesions had less radiotracer uptake, likely secondary to the inability for radiotracer to reach the inner core of the calcified plaque.[88] Therefore, delivery to the core of such plaques would likely increase radiotracer uptake in that region. Calcifications in close proximity to the vessel lumen may have a higher affinity for radiotracer activity, than those situated nearer to the adventitia, owing to the increased delivery of radiotracer to this area.[88,89] Regions of progressive atherosclerotic disease, of which calcification forms an important component, are often associated with the presence of microvessels, or vasa vasorum, that penetrate from the adventitia into the intima[90,91] and in atherosclerotic plaques with high ^{18}F-NaF binding, the presence of vasa vasorum is almost twice as much compared to ^{18}F-NaF negative arteries.[92] The presence of vasa vasorum may ultimately assist in the delivery of ^{18}F-NaF to regions of otherwise "walled off" calcification. While it is proposed that almost all of ^{18}F-NaF binds to regions of calcifications on first pass of blood,[93] it is very likely that regions of low blood flow may result in increased radiotracer binding capabilities because of pooling and a resulting increase in time to bind. This belief, albeit not entirely understood, may be of particular importance in aortic wall diseases including dissection, aneurysm, and coarctation.

In the pathophysiology of calcification within the vasculature, actively depositing calcifications often begin in the microscopic form, with high surface area available for binding and in the absence of locally impaired blood flow.[94] These key features promote increased binding of the ^{18}F-NaF radiotracer in the early and active stages of the disease process supporting its role in the detection of metabolically active disease. Furthermore, other histological and imaging data support the role of ^{18}F-NaF in the detection of calcification activity.

An ex-vivo analysis by Joshi et al. observed regions of radiotracer activity in explanted carotid specimens were positively associated with other histological and

immunological markers of calcification activity, increased alkaline phosphatase, osteocalcin, inflammation (CD68), necrotic core, and cell death.[95] A different study of carotid plaques also described an inverse relationship between ^{18}F-NaF activity and α-smooth muscle actin,[96] supporting a role for VSMC transdifferentiation,[55] or even apoptosis,[97] in the pathophysiological development of arterial calcification. In animal studies, ^{18}F-NaF binds to early intimal disease, perhaps even before the development of histologically identifiable macroaggregates of calcification.[98]

Imaging data from both prospective and retrospective studies have described the role of ^{18}F-NaF activity, detected using PET imaging, in predicting new CT-detectable calcification in the same anatomical location, years later. In the aortic valve, baseline ^{18}F-NaF activity is associated with the rate of change of calcification.[99] Within the femoral arteries, baseline ^{18}F-NaF activity is positively associated with the development of new calcifications after almost six months.[16] Within the aorta, retrospective studies have observed high radiotracer activity within the aortic wall go on to develop new calcifications in the same area.[100,101] Taken together, these observations support the role of ^{18}F-NaF PET in the detection of calcification activity within the vasculature. The utility of such an imaging tool is further described.

[18]F-sodium fluoride- positron emission tomography imaging of the aortic calcification activity

Intimal calcification activity

From a pathophysiological perspective, intimal aortic calcification differs greatly from medial arterial calcification. However, in severe intimal calcification, the functional impact on arterial wall stiffness is likely to be similar to that of medial arterial disease, at least at a local level.[7] Therefore, the prediction of severe intimal calcifications using ^{18}F-NaF PET is likely to be of great clinical importance when considering LASt. Within the aorta, calcified atherosclerotic plaque develops in a similar mechanism to other vascular territories; however, the prevalence of aortic calcification is generally lower than the coronary arteries.[17,102]

The role of ^{18}F-NaF imaging in intimal aortic calcifications is not well understood, though a significant proportion of our understanding can be extrapolated from invasive coronary imaging techniques. Atherosclerotic plaques with increased ^{18}F-NaF PET uptake display increased prevalence of positive remodeling, necrotic core and microcalcification, and vasa vasorum.[92,95] Additionally, ^{18}F-NaF positive plaques have a greater burden of atherosclerosis compared to ^{18}F-NaF negative plaques.[92] However, ^{18}F-NaF PET activity is higher in partially calcified plaques than fully calcified plaques, representing

its capacity to differentiate between active ongoing disease and burnt out, established calcifications.[103] In the coronary arteries, the role of this imaging modality may serve to function as a tool to identify high-risk plaques noninvasively, which may be associated with increased risk of CVD events. In the aorta, the role of high-risk plaque features is less clinically relevant and the ability to detect disease activity is of more importance. Increased aortic wall ^{18}F-NaF uptake can be observed many years before the onset of CT-detectable calcification,[104] which may subsequently precede the development of clinically relevant aortic wall stiffness.[7]

Intimal calcification activity within the aorta was first described by Derlin et al. in a retrospective analysis of patients undergoing ^{18}F-NaF PET imaging for oncological purposes.[86] In this study, the prevalence of thoracic aortic ^{18}F-NaF PET positive disease was 36%, and 48% in the abdominal aorta. In contrast, a different study of high CVD risk patients described ^{18}F-NaF PET positive disease in more than 90% of patients.[105] Though, it is important to recognize the difference in thresholds of ^{18}F-NaF PET positivity between different studies. Intimal aortic calcification activity is positively related to already established calcification burden,[106,107] but is inversely related to plaque density,[108] suggesting that densely calcified plaques have a reduced surface area for binding and probably represent burnt out, inactive sites. Retrospective studies have described the relationship between ^{18}F-NaF PET being more associated with the rate of change of CT calcium score than the baseline calcium score itself[100] and may be most predictive of disease processes at 1 year follow-up.[101] Prospective data have demonstrated a role of ^{18}F-NaF PET in predicting new calcifications.[109] This is of particular importance in the arterial media, whereby predicting calcification prior to its macroscopic development may identify those patients who go on to develop clinically significant LASt.

Medial arterial calcification activity

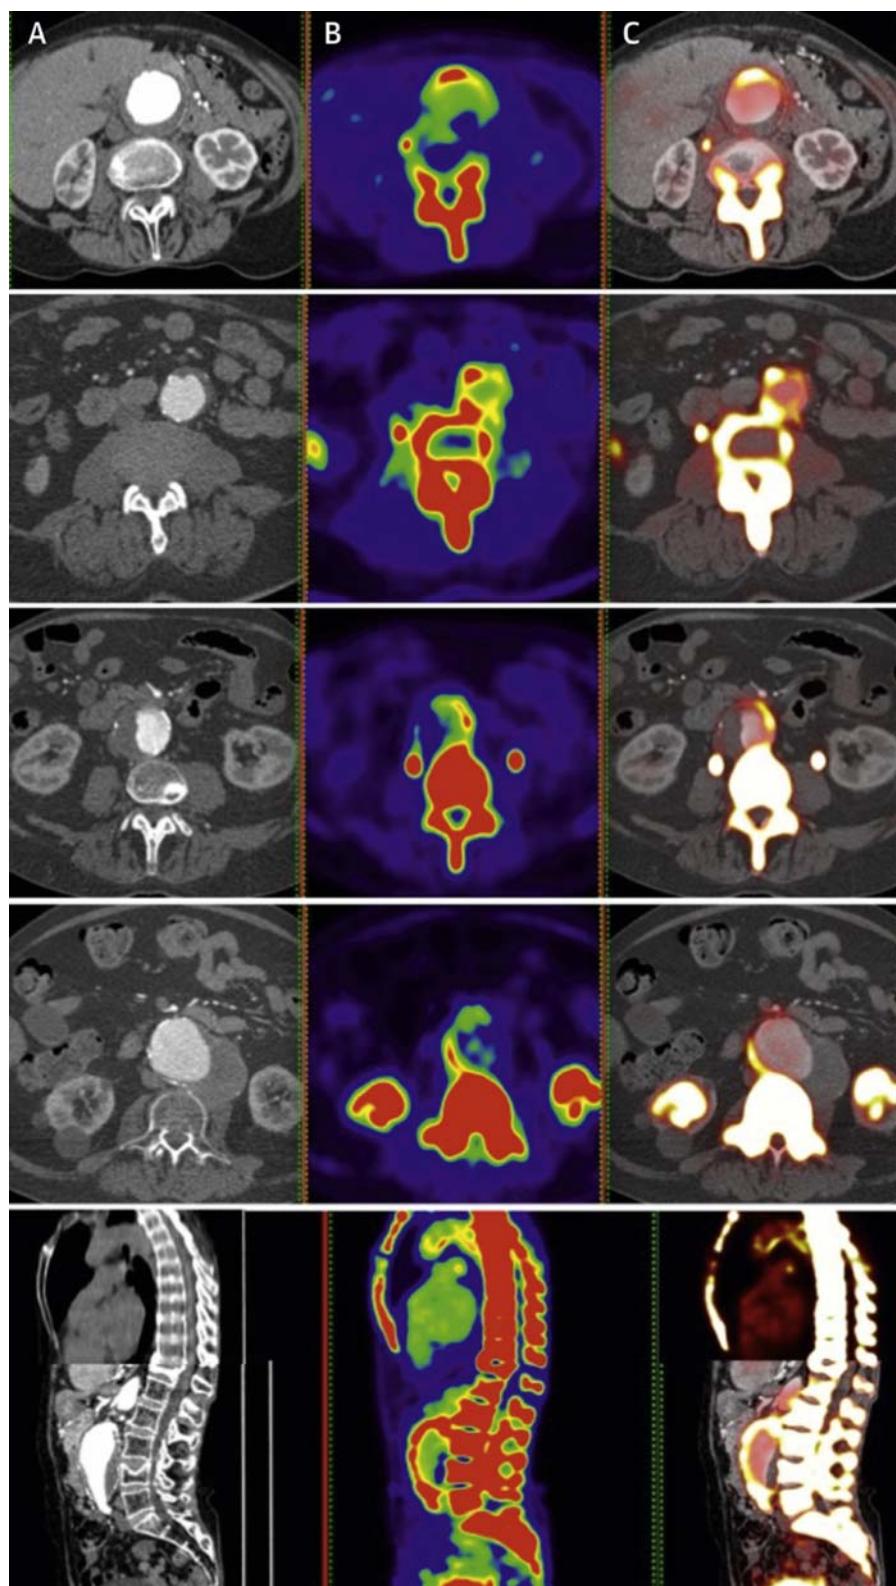
X-ray and CT imaging modalities have provided some insight into the differentiation between intimal and medial arterial disease using noninvasive imaging. X-ray imaging has described medial calcifications as uniform, linear "railroad track" like appearance and intimal calcifications as discrete, interrupted plaque-like lesions.[7,110]CT imaging has more recently established alternative quantitative methods to differentiate intimal from medial calcifications, using circularity, thickness, and morphology of the calcifications.[111] Translating these to ^{18}F-NaF PET is possible but must be considered in light of the reduced spatial resolution of the imaging technique.

Generally speaking, medial arterial calcifications are more common than intimal calcifications, in the lower

limbs.[112] In contrast, medial calcification is rare in the coronary arteries where intimal calcification predominates. In the aorta, the prevalence of medial calcifications is not well described, though the prevalence likely sits somewhere between the coronary arteries and the aorta will vary depending on age and other traditional CVD risk factors.[113,114] Medial arterial calcifications begin as fine, powdery deposits and can develop to severe calcifications containing osteocytes and features consistent with bone marrow formation.[55,115] Situated in the tunica media, often with sufficient supply of blood, early stages of these calcifications are likely to display great ^{18}F-NaF uptake. In comparison to their intimal counterparts, the effect of a heavily calcified "walled off" effect is probably less prominent.[88]

Imaging of medial arterial calcification with ^{18}F-NaF PET is possible when applying the X-ray and CT guided imaging principles to the interpretation. Indeed, the prevalence of medial calcification detected on ^{18}F-NaF PET is associated with hypertension, diabetes, and other clinical risk factors frequently associated with medial arterial calcification detected using CT and X-ray.[116,117] Indeed, medial arterial ^{18}F-NaF PET activity is positively associated with established medial arterial calcification burden detected using CT.[118] This is important, because using current technologies, the single biggest predictor of developing vascular calcifications is the burden of calcification at baseline[119] and any modality that can provide additional prognostic information is likely to be of good clinical utility. Interestingly, smoking is inversely associated with reduced medial arterial calcification activity detected with ^{18}F-NaF PET,[116] and this is a phenomenon witnessed in other vascular territories examining medial arterial calcification.[120,121]

Compared to intimal pathologies, the medial arterial wall is less influenced by inflammation[121] whereas the calcification of the medial arterial wall is a well-established process in medial arterial pathologies.[118] These differences have important implications both in the selection of appropriate imaging modalities and in the prognostic assessment. In prospective studies of heterogenous cohorts directly comparing ^{18}F-FDG and ^{18}F-NaF, aortic ^{18}F-NaF activity was strongly related to CV risk, while aortic ^{18}F-FDG activity was not.[106] However, as previously discussed, other studies have observed a strong relationship between aortic ^{18}F-FDG activity and increased CV risk.[14,21] This may be partly explained by the dynamic and temporal relationship between the pathophysiological mechanisms underlying inflammation and calcification, which may occur at different time points in a patient's disease progression, but still contributing to the development of CV risk.[8,10]

By detecting arterial calcification activity, ^{18}F-NaF PET may have an important role in CVD risk stratification, beyond its role in identifying early medial-specific arterial calcifications. Firstly, ^{18}F-NaF PET activity is related to traditional CVD risk factors; age,[15] gender,[122] diabetes mellitus,[123] hypercholesterolemia,[124] hypertension,[125] and Framingham risk score,[106,126] and may provide additional prognostic information over clinical risk scores. Secondly, in the abdominal aorta, calcification burden is a strong predictor of CV events,[127] even after adjusting for traditional CVD risk factors and current observations support the positive relationship between ^{18}F-NaF PET activity at baseline and subsequent aortic macrocalcification development.[100,101] Finally, the progression of aortic calcification, likely to be predicted by ^{18}F-NaF PET, is positively associated with the risk of incident coronary calcification development; the single best available independent predictor of CVD events.[102,128,129]


[18]F-sodium fluoride- positron emission tomography in aortic aneurysms, large vessel vasculitis, and other aortic pathologies

The interaction between aortic calcification and corresponding impairment in arterial compliance is becoming increasingly understood. However, the relationship between calcification and aortic-specific pathologies, such as aortic aneurysms is less well understood. Some suggest that calcification in the presence of an aortic aneurysm is protective in a nature.[130] This may particularly be the case if the calcifications exist on the outer medial-adventitia border thereby limiting the progression of arterial wall expansion.[131] It has also been proposed that the presence of calcification within the aortic wall may prevent the worsening proteolysis within the aortic wall, further preventing the degradation of arterial integrity and progression of disease.[131,132]

In contrast, some studies have suggested that the presence of calcification within the aortic wall is an important contributor to isolated disruption of already pathological wall stressors and may increase the risk of rupture of an existing aortic aneurysm.[133,134] The region at the edge of partially calcified aortic wall within an aorta is at specifically susceptible to failure.[135] Notably, the edges of partially calcified regions are likely susceptible active calcification processes which may therefore be detectable using ^{18}F-NaF PET imaging.

[18]F-NaF PET imaging provides unique biological information about the calcification activity developing within an already existent aneurysm and may subsequently serve to determine who may go on to be at risk of aneurysm rupture. While such prospective data are not yet available, ^{18}F-NaF PET activity appears to be positively associated with the rate of change of aortic aneurysm expansion and likelihood of aneurysmal repair (Fig. 6.3).[136] Furthermore, histological analyses of ^{18}F-NaF uptake within aortic regions correspond well with regions of

FIGURE 6.3 Positron emission tomographic and computed tomographic images of abdominal aortic aneurysms. (A) Structural image of computed tomographic angiography, (B)[18]F-sodium fluoride uptake on positron emission tomography, and (C) fused positron emission tomographic−computed tomographic images colocalizing ^{18}F-sodium fluoride uptake with the skeleton and abdominal aortic aneurysm. *Reproduced from Forsythe RO, Dweck MR, McBride OMB, et al. (18)F-sodium fluoride uptake in abdominal aortic aneurysms: the SoFIA(3) study.* J Am Coll Cardiol. *2018;71(5):513−523.*

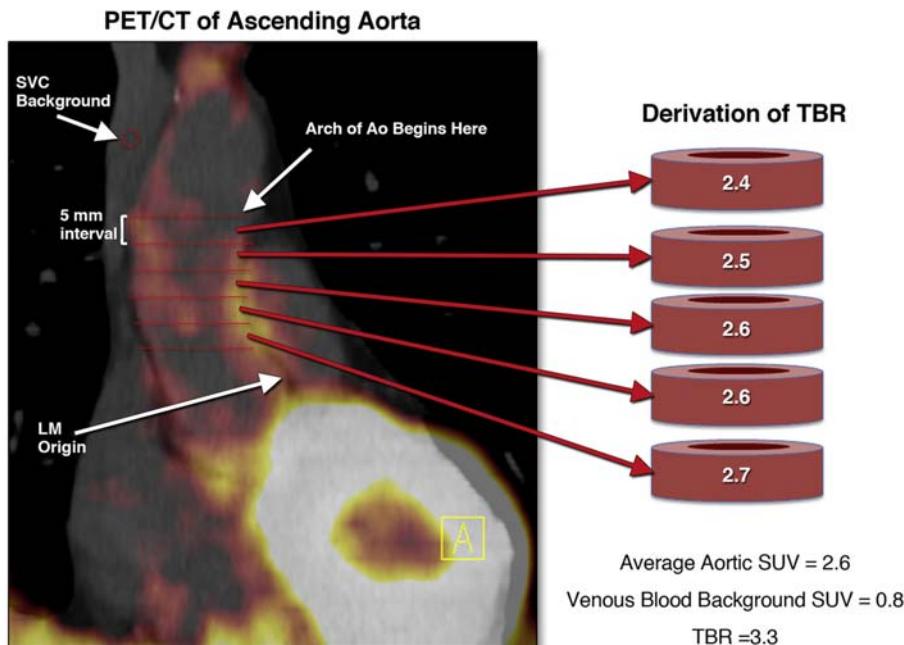
microcalcifications.[136] It is also possible that the presence of vasa vasorum, also associated with increased risk of aneurysm rupture, supplements ^{18}F-NaF delivery to the vessel media and results in increased ^{18}F-NaF signal intensity.[137]

The relationship between aortic calcification, stress, and subsequent impairment of arterial integrity is also relevant in the development of aortic dissections. Regions of intimal tearing, the initiating factor in an aortic dissection, appear to develop near to or just on regions of aortic calcification.[138] Coupled with computational fluid dynamics and traditional CT imaging, detecting early stages of this disease process may be possible with ^{18}F-NaF PET. Though, the low prevalence of the dissections and the high incidence of aortic calcifications, the positive predictive value of such a tool must be much higher than CT to have clinical utility. In high-risk subpopulations, ^{18}F-NaF PET may be more useful.

In patients with Marfan syndrome, early intervention of aortic aneurysms may be required.[139] The disease is characterized by impaired fibrillin formation and subsequently compromised elastin integrity. The presence of elastic fragmentation co-localizes with regions of aortic wall microcalcification deposition and this may further predispose to the development of structural aortic wall diseases.[12,140] It is possible that early detection of calcification activity with ^{18}F-NaF PET may discriminate between those who require more intensive monitoring, or even intervention, and those who can continue regular monitoring.

Other large vessel vascular diseases have a calcific component that may warrant dedicated imaging with ^{18}F-NaF PET. Pseudoxanthoma elasticum involves extensive calcification of elastic fibers in connective tissues of the vasculature and prognostication could be assisted with the use of metabolic imaging.[141] Though further research is needed to understand whether ^{18}F-NaF PET can guide novel therapies in this population.[142]

Patients with Takayasu arteritis experience granulomatous large vessel inflammation, and it is traditionally considered that the resulting calcification is a sequela of inflammation[8] and may present as the chronic component of the disease process.[139] ^{18}F-NaF PET can assist in identifying regions of metabolically active disease,[143] as opposed to metabolically indolent disease, and may perhaps further assist in identifying regions of the aorta at risk of life-threatening complications (i.e., Aneurysm formation or dissection).

Finally, it is possible that ^{18}F-NaF PET may be useful for the identification of those patients in whom interventional therapies, such as endovascular aneurysmal repair, are failing. In other vascular territories ^{18}F-NaF PET activity is related to the risk of in-stent complications[144] and prosthetic valvular complications.[145] However, in these settings, calcification may be more related to stenosis, which is less likely within the aorta.


Methods of analysis and limitations of positron emission tomography imaging

In vivo visualization of molecular and cellular processes is achievable with PET imaging but relies heavily on the availability of discriminating radiotracers that can be detected with high-resolution PET imaging hardware. The quantification of the signal emitted by radionuclides can be affected by signal-to-noise ratio, which necessitates that radionuclides exhibit good contrast against normal tissue surrounding the area of interest. This can be achieved by selecting radiotracers with a high specificity for its target (to minimize off-target effects), and a rapid clearance from nontarget tissues.[146] Ideal radiotracers should also be able to overcome biological barriers while exerting low toxicities to human tissues.[25]

Many techniques are used to quantify radiotracer uptake in PET imaging. A relatively common method involves the segmentation of a region of interest (ROI) and measurements or estimation of radiotracer uptake in the ROI to determine the mean and maximum SUV.[147] SUV is a dimensionless value and is calculated by dividing radiotracer uptake in a ROI by the injected dose per body weight. Maximal SUV (SUVmax) is the SUV of the most radiotracer-avid voxel within a ROI while mean SUV (SUVmean) is the mean SUV within the ROI.[53] SUV can also be normalized for lean body mass, known as SUL, which provides less variation in the calculated value. However, SUVmax is preferred in clinical practice due to its superior reproducibility.[60]

The accurate quantification of PET radiotracer uptake is very challenging particularly in the arterial system where lesions are of small sizes compared to the spatial resolution of PET.[147] While the SUV is commonly used for quantification of radiotracer uptake in oncology, it has many limitations when applied to vascular imaging. It can be markedly influenced by blood glucose in ^{18}F-FDG PET, the time between injection and image acquisition, spatial resolution of the PET scanner, partial volume effects, activity spill in and spill out, attenuation correction, and image reconstruction parameters.[147,148] PET imaging of the vasculature is particularly susceptible to partial volume effects which can significantly underestimate the true radiotracer uptake.[148]

TBR measurements are preferred in vascular inflammation as they have been shown to better correlate with macrophage density.[52] TBRmax corrects for blood pool uptake and is calculated by dividing SUVmax measured in an arterial vessel wall by the venous blood pool (Fig. 6.4).[42] TBR quantification of ^{18}F-FDG uptake in atherosclerotic plaques can be performed using three different approaches. In the assessment of global vascular inflammation (whole vessel analysis), the average TBR is measured in all the axial segments of the target vessel (TBRmax; TBRmean). This allows for signals to be

FIGURE 6.4 **Fluorodeoxyglucose (FDG) uptake measurement.** In this example, FDG uptake was evaluated within the wall of the aorta on axial images. At each axial section, a region of interest (ROI) was drawn around the wall of the aorta and the maximum standardized FDG uptake value (SUV_{max}) was recorded. The thickness of each axial slice was approximately 5 mm. Subsequently, the target-to-background ratio (TBR) was calculated by dividing the mean of all axial slice SUV_{max} (approximately six to eight slices per patient) by the venous blood SUV_{max} obtained from the superior vena cava (average of 10 ROIs) to correct for the blood compartment contribution. *Ao*, aorta; *LM*, left main artery; *SVC*, superior vena cava. *Reprinted With permission from Elsevier from Figueroa AL, Abdelbaky A, Truong QA, et al. Measurement of arterial activity on routine FDG PET/CT images improves prediction of risk of future CV events.* JACC Cardiovasc Imaging. *2013;6(12):1250−1259.*

averaged over many arterial segments and is therefore thought to be less sensitive to image noise and ^{18}F-FDG signal from surrounding structures.[60] The trade-off is reduced sensitivity for detecting small changes in ^{18}F-FDG uptake in focal areas of atherosclerotic plaques.[60,72] In contrast, the most diseased segment (MDR) approach measures the average TBR across a small segment of the index vessel and has been shown to be useful when assessing the degree of inflammation in a specific atherosclerotic plaque.[10,75] Finally, the active segment (AS) analysis is most useful in clinical trials where only lesions with increased ^{18}F-FDG uptake are monitored overtime to evaluate the effects of therapeutic interventions on ^{18}F-FDG uptake.[73]

Both TBRmax and TBRmean demonstrate excellent reproducibility and are less influenced by radiotracer circulation times, acquisition times, and reconstruction filters, which is of particular importance when analyzing radiotracer uptake within arterial structures where circulating radiotracer may influence readings.[60] However, factors that affect blood pool activity such as ^{18}F-FDG uptake in the circulating blood cells can significantly impact TBR measurements. Similarly, blood pool ^{18}F-NaF PET activity is a critical regulating factor in the analysis of vascular ^{18}F-NaF PET and is often adjusted for by taking measurements from

either within the vena cava or the right atria.[89] Not surprisingly, the dose of radiotracer injected and PET/CT imaging system used are important predictors of blood pool radiotracer activity and should be consistent in serial imaging, or in person−person comparisons.[149] Furthermore, the role of renal function is important, with a lower glomerular filtration rate being associated with a higher thoracic aortic ^{18}F-NaF activity.[149] This relationship is likely related to the clinical impact of renal failure on arterial calcification but should also be considered in its role in the possibly delayed excretion of radiotracer.[22,115]

In the analysis of aortic ^{18}F-NaF PET, the proximity of the aorta to the vertebra can cause significant disruption to the analysis of aortic activity, owing to the effect of radiotracer overspill from vertebral bone into the aortic lumen. This impairs the accuracy of aortic ^{18}F-NaF PET analysis, mostly owing to a reduced specificity of perceived aortic measurements. Approaches to improve analysis include the manual extraction of regions with vertebral overspill,[150] or semiautomated extraction of vertebral ^{18}F-NaF activity.[151] The former method is time consuming and highly dependent on clinician experience.

Finally, patient motion artifact is a significant limitation of all imaging modalities and may be particularly undesirable in the temporal acquisition techniques employed in

PET imaging. The risk of patient motion is likely higher in PET imaging due to prolonged acquisition times (up to 30 min) and may be influenced by breathing and the cardiac cycle. Several strategies are used to improve image quality, including motion-compensation techniques,[21] and software incorporating patient motion correction algorithms, which display considerable success.[152] Other prospective acquisition techniques, such as respiratory and cardiac gating may also be useful, although are likely to serve a greater utility in the analysis of the coronary arteries moreso than the aorta.[153]

Future directions

Various strategies are being pursued to improve the diagnostic utility of PET imaging, including the search for novel radiotracers with improved specificity for molecular targets, developments in whole body PET imaging, and ongoing research in automated data analysis technologies such as artificial intelligence.

Novel PET radiotracers in the current research pipeline are focused on assessment of atherosclerosis and seek to improve the specificity of vascular imaging by targeting specific receptors and proteins that are overexpressed by activated macrophages. This includes ^{68}Ga-DOTATATE, a novel PET tracer with specificity for somatostatin receptor 2, which is overexpressed by macrophages in response to inflammation.[29] Several studies have demonstrated its potential utility in PET imaging of vascular inflammation in atherosclerotic disease.[29,30] Other radiotracers that have shown promise in atherosclerotic imaging include ^{11}C-PK11195, a selective ligand of the translocator protein that is commonly used in PET imaging of neuro-inflammation but also shows promise in vascular inflammation.[26] Tracers that target tissue hypoxia such as ^{18}F-Fluoromisonadazole are also being studied,[154] and may be particularly helpful because hypoxia probably precedes and may promote vascular calcification.[155] PET imaging with ^{18}F-labeled fluoromethylcholine or ^{11}C-choline is used in cancer imaging but shows promise in atherosclerosis.[27] Choline is taken up by activated macrophages, phosphorylated by choline kinase, and is then incorporated into cell membranes after further metabolism to phosphatidylcholine.[156] ^{68}Ga-NOTA-RGD is a radiotracer that targets integrin $\alpha\nu\beta3$, expressed in angiogenic endothelial cells and macrophages.[31] PET imaging of neoangiogenesis using this tracer appears feasible in atherosclerotic disease and may be a useful marker of plaque vulnerability.[31] These novel radiotracers are still in research settings, and although their use in LASt is theoretically possible, there is currently no direct evidence of such utility and further research is needed.

Molecular targeting of the extracellular matrix such as elastin degradation and collagen deposition is a feasible future direction in LASt. This approach has been evaluated in the context of atherosclerosis[157] and in patients with lung and hepatic fibrosis[158]; however, its application to aortic wall stiffness remains to be seen. If validated for LASt, it could lead to imaging modalities specific for aortic fibrosis, which would be useful in both research and clinical settings.

Finally, whole body PET imaging techniques that are under development,[159] along with improved analysis techniques, incorporating manual and automated processes,[160] will further assist in the full utilization of PET imaging, allowing mass analysis of data to be extracted from single datasets, reducing the manual time required for analysis and improving accuracy.

Conclusion

Vascular inflammation and microcalcification occur in the earliest stages of vascular remodeling and often precede the development of detrimental LASt. Both processes are detectable using ^{18}F-FDG and ^{18}F-NaF PET imaging, respectively, though the direct role of each radiotracer in detecting the early stages of LASt needs further research. Most existing studies have assessed the utility of ^{18}F-FDG PET imaging of the aortic wall in the context of atherosclerosis and only a few small studies have examined the role of ^{18}F-FDG PET imaging in dedicated LASt. Because vascular inflammation tends to be associated with both arteriosclerosis and atherosclerosis and may indeed play a role in medial arterial calcification, it is reasonable to consider that ^{18}F-FDG PET could play an important role in the imaging of early LASt. In contrast, although ^{18}F-NaF remains primarily a research tool, it may serve a greater purpose in the imaging of LASt than ^{18}F-FDG PET, as calcification of the medial arterial wall is better understood than medial wall inflammation and its relationship with LASt is well established. ^{18}F-NaF PET has a unique capability to localize and quantify arterial calcification within the aortic wall, at an early stage in its development, prior to the established calcifications detectable on CT imaging.

Overall, PET imaging of the aortic wall could be used for CVD risk stratification and subsequent implementation of preventative therapies prior to irreversible disease development, in those patients with high disease activity. It may assist in determining response to established therapeutics or as a useful tool for the trial of novel therapeutics, reducing the time required to reach a comparable endpoint of CT-detectable changes or hard CV outcomes. Finally, PET imaging of the aortic wall can dramatically improve our understanding of the complex pathophysiological processes of aortic wall stiffness along with their associated clinical and physiological effects on the aorta.

Arterial wall stiffness: basic principles and methods of measurement in vivo

Patrick Segers[1] and Julio A. Chirinos[2, 3]

[1]Faculty of Biomedical Sciences, Institute of Biomedical Engineering and Technology, Ghent University, Ghent, Belgium; [2]University of Pennsylvania Perelman School of Medicine, Hospital of the University of Pennsylvania and Perelman Center for Advanced Medicine, Philadelphia, PA, United States; [3]Ghent University, Ghent, Belgium

Introduction

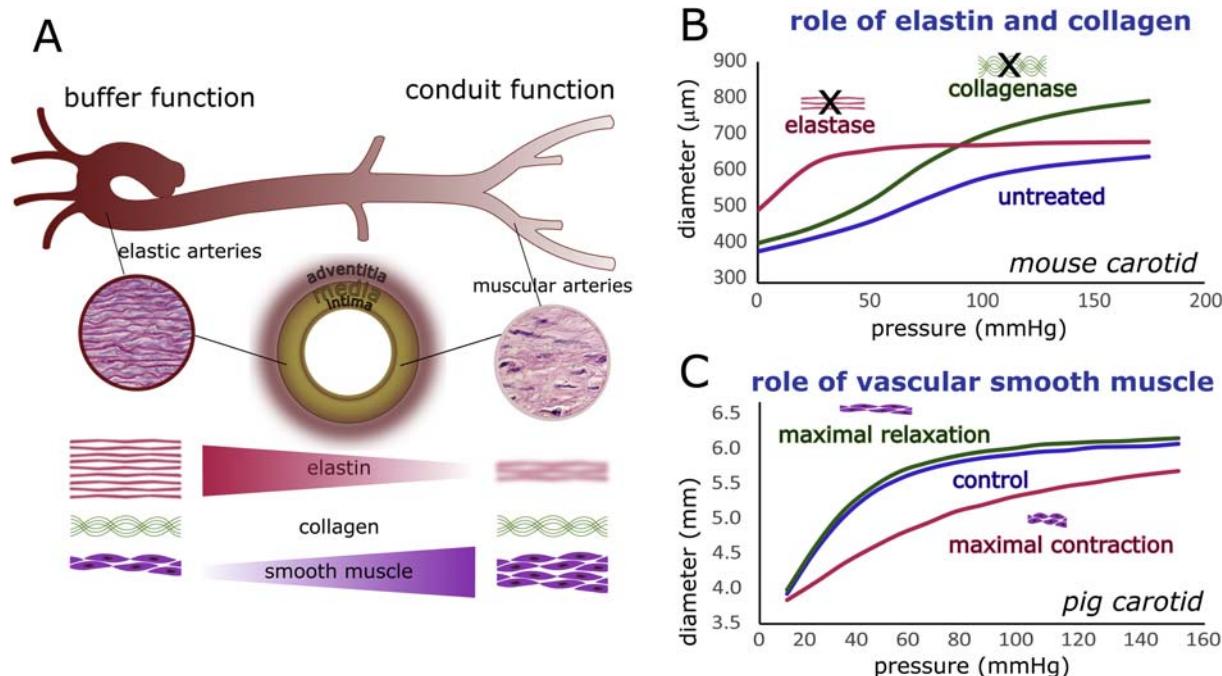
"Arterial stiffness" is an intuitive general term that refers to the arterial mechanical properties, particularly of large elastic arteries. In this chapter, we first cover the constitution of the arterial wall, and focus on the role of extracellular structural proteins and vascular smooth muscle cells (VSMCs) as drivers of the mechanical behavior of arteries. We briefly introduce concepts from material science and soft tissue biomechanics, highlighting the complexity in quantifying material properties of complex composite tissues as the arteries. In the in vivo setting, however, one often has to settle with functional indices that encompass material properties as well as the geometrical of the artery. To many, arterial stiffness may have become synonymous to pulse wave velocity (PWV), the speed at which the arterial pulse travels over the arterial wall. We outline how PWV relates to the pressure-area relation of the artery and cover transit-time methods to measure PWV in the clinical setting and briefly touch upon the strengths and weaknesses of more recent and emerging methods to assess arterial stiffness.

Arteries—what's inside?

The primary role of arteries is the transport of blood from the heart toward the organs and tissues (systemic circulation) or the lungs (pulmonary circulation). To that end, the arterial tree forms a magnificent branching network of progressively smaller yet more numerous vessels, encompassing the aorta/pulmonary artery with a diameter >2 cm close to the heart, down to capillaries measuring ∼8 μm in diameter inside the tissues where the exchange of nutrients and waste products takes place. With the exception of capillaries, all arteries exhibit a three-layer structure. In healthy arteries, the innermost layer—the intima—is a thin, confluent monolayer of endothelial cells on a basal membrane, forming the interface between the blood and the surrounding tissues.[1] Its physiological importance and biological function are vital, but the intima does not directly contribute to the mechanical properties of the healthy artery. The middle layer, the media, is delineated by the internal and external elastic membrane, with matrix proteins (collagen fibers oriented in different directions and elastic lamellae), VSMCs, and other matrix components such as glycosaminoglycans as major constituents. The outermost layer, called the adventitia, is mainly composed of connective tissue, and connects the artery to its surroundings. It is especially the collagen within the media and adventitia that provide the artery its mechanical strength, while elastin in the media provides its resilience and distensibility.

Besides simply distributing blood, the arterial system (together with the heart) also has a key role in active and passive blood pressure regulation. Mean arterial pressure (the average pressure over a heartbeat) is driven by cardiac output, on the one hand, and the total resistance that the viscous blood experiences because of friction as it pumped through the arterial network. It is known from Poiseuille's law that the flow resistance of a vessel with diameter D is proportional to $1/D^4$, so it is clear that arterial resistance is mainly driven by the smaller arteries. It is important to keep in mind that, as vessels bifurcate, they individually decrease in diameter but increase in number with an increase in the net cross-sectional area after each new vessel generation. In the circulation, it is the arterioles with diameters of 30−100 μm that play a role in controlling resistance and blood distribution through active

regulation of their diameters via contraction/relaxation of the vascular smooth muscle in the media. In addition to arteriolar constriction, microvascular rarefaction can significantly increase resistance in a given vascular bed.[2]

Pulse pressure (PP), the difference between systolic and diastolic pressure, on the other hand, is driven by the properties of the large central arteries that have the ability to distend when pressurized and to buffer part of the stroke volume (SV) with each cardiac contraction. Elastic energy is stored upon distension in systole, which is released to promote blood flow in diastole (the "windkessel" function).[3] The more blood stored locally in the proximal aorta, the less blood has to be transported over longer distances in systole. This limits the "inertial load," the required driving pressure (and energy demands for the heart) and limits the diastolic-systolic pressure differences.


The physiological function of arteries thus differs along the arterial tree, which also translates into gradual changes in their structure and composition along with their size (and the mechanical load acting on the artery). This difference in structure and composition is especially visible in the media as observed from histological images. The media of large central arteries is characterized by an ultrastructure of concentric elastic lamellae (up to 60—80 in the human ascending aorta), interdigitated by connective tissue layers that contain VSMCs. This layered microstructure gradually vanishes in peripheral vessels as the number of elastic lamellae decreases while the smooth muscle cell contents increases.[4] Arteries thus undergo a spatial central-to-peripheral transition from elastic to muscular arteries, in line with their functional transition of vessels contributing to buffering to conduit vessels contributing to pressure regulation.

Large artery stiffness and stiffening—a tale of elastin and collagen

As any organ and tissue in the human body, arteries are not immune to disease or effects of aging. In this chapter, we do not consider focal disease as atherosclerosis (that may lead to stenosis) or pathologies affecting locally the structural integrity of the artery (e.g., aortic aneurysm, aortic dissection), but rather focus on the consequences of diffuse processes affecting the overall arterial structure and function, particularly of large elastic arteries, leading to what is known as large artery stiffening. As a consequence of large artery stiffening, large arteries gradually lose their windkessel function with a widening of PP, imposing higher mechanical stress on the vessels and organs that may result in organ damage in the heart, kidney, brain, and other organs.[7] At the same time, peripheral arteries (possibly because of their much lower elastin content) are less susceptible to stiffening, and the "stiffness gradient" between the central and peripheral arteries decreases. These processes alter hemodynamics, affect the magnitude and timing of forward and backward traveling pressure and flow waves in the circulation, and the

physiological amplification of the pressure pulse from the heart to the periphery.[7,8] All in all, arterial stiffness is considered as a key biomarker of vascular health, believed to integrate the accumulated effect of aging and exposure of the arterial system to insults and mechanochemical stressors, and has repeatedly been demonstrated to predict cardiovascular mortality and morbidity above and beyond conventional cardiovascular risk factors.[9–11]

To understand the mechanical behavior of arteries, it is important to understand the role of the matrix proteins elastin and collagen. The distensibility of young, healthy arteries at physiological pressures arises first from the intrinsic distensibility of the vessel's elastin (having a Young elasticity modulus that increases with strain up to values of about 600 kPa[12]) and from the wavy, undulating nature of the stiffer collagen fiber families (Young modulus in the order of 10 MPa[12]) that helically spiral along the artery and allow for vessel expansion as intra-arterial pressure rises. It is then the elastic nature of elastin that provides resilience and allows for arterial recoil as pressure decreases. The undulation and dispersion of collagen fibers ensures that collagen is only progressively recruited with increasing pressure/stretch levels, ensuring smooth progressive functional stiffening of the artery at higher pressures (Fig. 7.1B, left panel). The Achilles heel of the artery, however, is elastin. In contrast to collagen—continuously degraded and deposited in a process of mechanobiological homeostasis[13]—elastin is believed to (a) be only deposited in the media of the arterial wall during fetal growth and infancy, without the ability to renew[14] and (b) degrade with a reported half-life of 40—50 years.[15] Both have important consequences for large artery function. With somatic growth, elastin within the arterial wall becomes progressively stretched, subjecting the elastic arteries to a permanent tensional load in the circumferential and longitudinal direction (explaining why the arterial wall retracts after surgical incision). Much like worn out rubber, elastin degradation in later life in arteries gradually relaxes arterial prestretch, leading to dilation, elongation, and increased tortuosity with age.[16] In the process, arteries progressively lose their low-stretch bearing component, shifting load from elastin to stiffer matrix components (collagen). Obviously, other constituents can contribute to or modulate arterial stiffness, including smooth muscle cell stiffness and tone, fibrosis, cross-linking of elastin and collagen, and calcification of the media, which interact with each other and with overarching pathways (such as inflammation and endothelial dysfunction). We refer to Reference 7 for an overview. Although stiffness is generally considered a "passive" property of an artery, smooth muscle tone does play a significant role in the mechanical behavior of the arterial wall, whereby the level of smooth muscle cell contraction seems to modulate the transition point at which collagen takes over the load bearing from elastin as demonstrated in pressure-inflation tests on perfused arterial

FIGURE 7.1 (A) There is a gradual transition in the composition of arteries along the arterial tree. Large elastic arteries, close to the heart, have the characteristic lamellar structure with layers of elastin interdigitated by layers of collagen and vascular smooth muscle. These arteries contribute to buffer function. Further away from the heart, arteries lose the elastic lamellar structure and evolve into muscular-type arteries with a decrease in elastin and increase in smooth muscle contents. (B) pressure-diameter relation of the untreated mouse carotid artery (dark blue) and after removal of elastin (red) or collagen (green). (C) pressure-diameter relation of the pig carotid under control conditions (dark blue) and after modulation of smooth muscle tone to maximal contraction (red) and relaxation (green). *(A, B) Reconstructed from Gabriela Espinosa M, Catalin Staiculescu M, Kim J, Marin E, Wagenseil JE. segments. This may lead to a perhaps unexpected behavior, with muscle contraction leading to a functionally more distensible artery than a vessel under normal tone in the higher pressure range. Indeed, complete muscle contraction shifts the elastin-collagen load-bearing transition to higher pressure levels, implying a more distensible artery as the contracted muscle becomes the dominant load-bearing component at lower pressure (Fig. 7.1C, right panel).
Mechanics of arterial tissues: bioengineering principles and perspective

In this section, we briefly discuss some bioengineering principles to characterize the mechanical behavior of materials and tissues. The main motivation is to sketch the complexity of arterial biomechanics and confront it with the prevalent simplistic approach of arterial stiffness characterization in vivo. Rather than formulating equations and mathematical expressions, we will attempt to illustrate principles and complexity making use of data that has been acquired from *ex-vivo* testing on arterial tissue.

Stress and strain—what's in a name?

We all have at least an intuitive notion of the concepts of stress and strain. Stress, with SI units N/m^2 (also called Pa), is generally defined as force divided by surface (noted here as σ). Strain (noted as ε) is the deformation of material relative to a reference state and is dimensionless.

In material science, materials are characterized from the relation between stress and strain, i.e., a constitutive relation describing the response of the material to a stimulus. The simplest example is a metal rod with unloaded length L_0 and cross-sectional area A_0 subjected to a force F (Fig. 7.2, panel A) that leads to small deformation (lengthening) of the rod, say 0.2%, to its new deformed length L (stretch $\lambda = L/L_0$) and cross-section A. Stress is then simply calculated as F/A, and strain ε (in this case, 0.2%) is calculated as $(L - L_0)/L_0 = \lambda - 1$. The relation between stress and strain is linear (the material is called linear elastic or Hookean) and the ratio of stress and strain is the Young elasticity modulus E (in Pa), such that $\sigma = E\varepsilon$. If the material is isotropic, i.e., its mechanical properties are the same in all directions, E fully characterizes the material (Fig. 7.2B).

FIGURE 7.2   (A) and (B) concepts from linear elasticity. (A) Definition of stress, strain, and stretch based on simple extension; (B) stress-strain plot for small deformations (much less than 1%) with the slope yielding the Young elasticity modulus. The area under the stress-strain curve is the elastic energy stored in the material. (C) in vivo loads acting on an arterial segment and resulting principal strains acting in the radial, circumferential and longitudinal direction. (D) and (E) concepts from arterial mechanics, characterized by large deformations with nonlinear stress-strain relations and appearance of hysteresis loops in loading-unloading experiments indicating viscoelasticity (D). The tissue is anisotropic, with much stiffer behavior when a load is applied along the fiber direction than across the fiber direction (E).

This simple example with uniaxial loading of an isotropic linear elastic material undergoing small deformations is, however, of little relevance when studying arterial mechanics, and the concepts of stress and strain become much more complex and ambiguous.

Stresses acting on the arterial wall

Let us approximate an arterial segment in the circulation as a cylinder with radius R and wall thickness h. The blood pressure, P, will induce stresses that, for a thin-walled cylinder ($h/R < 0.1$), are given by Laplace law yielding PR/h (tensile) in the circumferential and $-P/2$ (compressive) in the radial direction. In the arterial tree, however, the cylinder is not isolated and axial stresses of unknown magnitude will act on the segment due to axial prestretch (that can be as high as 1.6 or higher), effects of tethering, anchoring, or other factors (e.g., cardiac motion). Arterial pulsations induce diameter changes in the order of 10%, but these are superimposed on the much larger deformation that already exists at the diastolic blood pressure level. As such, to understand the effective stress and strain levels that the artery is subjected to, one should first consider the segment in its unloaded configuration (depressurized and disconnected from its surroundings). The stresses that are needed to deform the unloaded segment to its diastolic in vivo configuration are called the initial stresses. Assessing these initial stresses involves solving a complex inverse problem. Note that the unloaded arterial segment will generally not be totally stress-free: arterial remodeling will lead to the development of residual stresses that are evidenced when further cutting up the arterial segment in ring segments, cutting these ring segments that will typically open up to a certain angle.

The above demonstrates that (i) arterial tissue is simultaneously loaded in multiple directions; (ii) deformations are very large and approximations based on small deformation theory should be used with caution; (iii) initial stresses are present on which the diastolic-to-systolic loading is superimposed.

Arteries consist of anisotropic, viscoelastic, nonlinear tissue

Arterial biomechanics is further complicated by the composition of the artery, directing its mechanical behavior. The concentric layering of large elastic arteries and especially the specific orientation of different collagen fiber families render arterial tissue anisotropic, meaning that its behavior will depend on the loading direction. Also, loading the tissue in one direction will interfere with its behavior in another direction and induce a complex stress field with principal stresses in the circumferential, axial, and radial direction (Fig. 7.2C). The undulation, dispersion, and

progressive recruitment of collagen fibers as the artery is stretched will lead to a nonlinear relationship between stress and strain. Arteries will also exhibit some degree of viscoelasticity, which manifests itself in hysteresis (energy losses due to internal friction) in stress-strain plots of cyclic loading experiments (Fig. 7.2D),[17] but its effects on arterial hemodynamics are relatively small.[18] For ex vivo testing of arterial segments or tissue specimens to be relevant and insightful, it is important that experiments are conducted in line with the loading as experienced by the vessel in vivo. In particular, data from pressure-inflation tests on prestretched segments and multiaxial testing on tissue specimens have been instrumental for the arterial biomechanics community (Fig. 7.2E).

A glimpse on strain energy functions

It is clear that the complex behavior of arterial tissue cannot be described by the linear elasticity theory with the Young modulus as single material parameter. One has to rely on large deformation theory of nonlinear materials, simultaneously considering stress, strain, and stretch and their relations in all directions in a three-dimensional (3D) setting making use of tensor notations for stress and strain. It is also important to realize that different definitions for strain and stress exist, and that caution is warranted when interpreting stress-strain data (one can, however, always convert one into the other). The reader is referred to specialized literature on the topic for more details.[19−21] In (computational) soft tissue biomechanics, it is most common to express deformation using the Green−Lagrange strain tensor, **E**, and stress by the so-called second Piola Kirchhoff stress tensor, **S** (with **E** and **S** being 3×3 tensors with nine components).

What is still missing is a constitutive relation that relates **S** to **E**, thus describing the material behavior. In soft tissue biomechanics, that relation is typically expressed making use of a so-called "strain energy density" function Ψ, such that $\mathbf{S} = \frac{\partial \Psi}{\partial \mathbf{E}}$. The function Ψ yields a positive scalar value, representing the energy stored in the material for a given deformation status, and with value 0 in the undeformed state. As the material deforms, energy is stored (or, conversely, it requires a certain amount of energy to deform the material). Applying the concept to the example of the linear elastic rod loaded along its axis, $\Psi = \frac{1}{2}E\varepsilon^2$ such that $\sigma = \frac{\partial \Psi}{\partial \varepsilon} = E\varepsilon$. Ψ represents the area under the stress-strain curve (Fig. 7.2B).

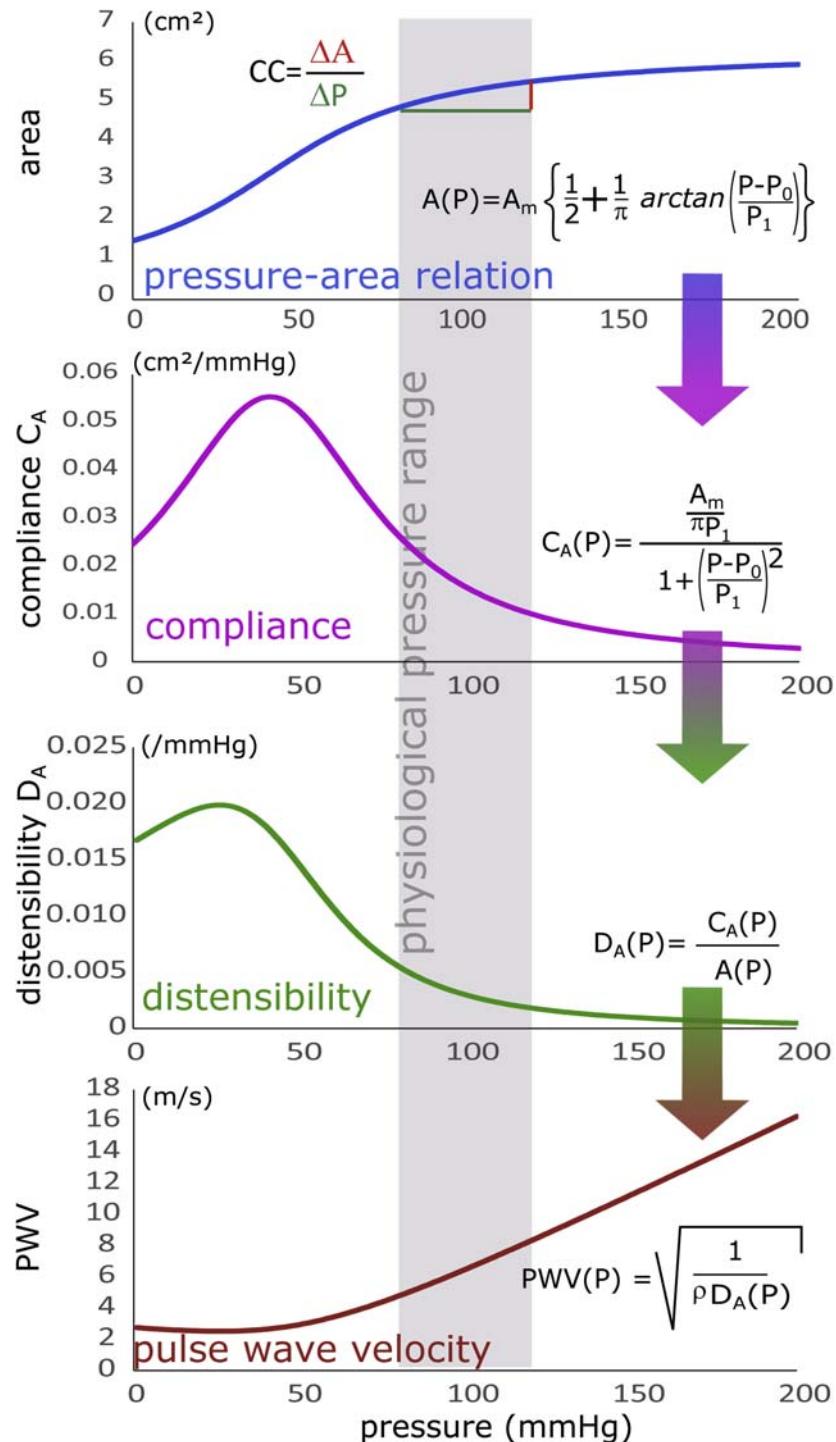
In arterial biomechanics, strain energy functions as the Holzapfel-Gasser-Ogden model (called after the researchers proposing the model) are probably most widely used, describing the anisotropic nonlinear behavior of arterial tissues, accounting for fiber orientation. Models are phenomenological in the sense that material constants are

derived after fitting the model to experimental data. As denoted in Chapter 9, it is essential that experimental data are acquired under conditions that are representative for the in-vivo loading.

Mechanics of arterial tissues: clinical/in vivo perspective

In the previous sections, we highlighted the complex architecture and microstructure of arterial tissue. Structural and mechanical properties of individual matrix constituents and smooth muscle cells, their 3D organization, interconnectivity, and smooth muscle tone drive the functional behavior of the artery. Ex-vivo experimentation on arteries have demonstrated nonlinear, nonisotropic properties (mainly induced by the orientation and distribution of collagen fiber families), with stress-strain relations that highly depend on the loading direction. Given the spatial variation of the size and composition of arteries throughout the arterial tree, and the permanent pathophysiological mechanobiological processes of matrix degradation and synthesis leading to arterial growth and remodeling, arterial properties vary from one location to another and are not constant in time. The mathematical formulation of the mechanical behavior of such materials is nontrivial and still mainly restricted to a phenomenological approach where the parameters of constitutive laws—under the form of strain energy functions—are determined by fitting data from experiments to these models.

To date, however, this biomechanical approach has been of little direct diagnostic or prognostic value to the clinical community. Conversely, the clinical community—besides being the provider of tissue samples—has been of relatively limited value to the biomechanical community (at least to those members of the community performing fundamental biomechanical research). This is regretful, as recent work in mouse models of arterial aging—with availability of in-vivo and ex-vivo testing—has demonstrated that concepts arising from a fundamental biomechanics approach can lead to important insights in the pathophysiology of arteries. In particular, stored elastic energy seems to be a sensitive biomarker of microstructural damage as demonstrated in fibulin-5 deficient mice. Advanced computational models also pinpoint an important role of perivascular tethering in arterial biomechanics.[22]

The fundamental problem that is faced when applying some of the more advanced biomechanical concepts in vivo is that the data that can be acquired in vivo are simply insufficient to reliably determine the parameters needed to feed into constitutive relations. Limiting factors are not so much imaging or measuring limitations, but rather the confined loading of the in vivo vessel. Indeed, the artery at interest is subjected to a given (unknown) level of axial prestretch, and deforms mainly in the radial direction under the pulsatile loading of blood pressure, varying between diastolic and systolic blood pressure. Typical datasets such as pressure-diameter relations over the in vivo pressure range are simply insufficient to reliably fit the multiple parameters of constitutive models without making stringent assumptions on the in situ configuration[23] and factors such as perivascular tissue and tethering and presence of unknown residual stresses that will have an effect on model fitting and the parameter values obtained.[24]


The clinical perspective on arterial stiffness, therefore, rather focusses on quantifying arterial function and assessing functional indices—biomarkers—that are, ideally, easy to measure with an acceptable accuracy and sensitivity that allows to discern pathology from normal physiology and carry prognostic information beyond standard clinical data (such as age, blood pressure, plasma lipids, etc). The remaining part of this chapter will focus on the in-vivo measurement of such functional indices. We will first cover *locally* measured functional indices that come closest to the biomechanical perspective—yet most often making abstraction of the continuum mechanics complexity. We will next discuss PWV as an elegant way to regionally phenotype arterial stiffness indices and conclude with methods that aim to quantify the buffering capacity of the entire arterial tree (or arterial territories) through measurement of (total) arterial compliance.

Local functional indices from pressure-area data: compliance and distensibility

As previously described, there is a nonlinear relation between intra-arterial pressure and lumen cross-sectional area (or diameter), which becomes particularly visible when testing arterial segments over a wide pressure range. This is best illustrated using seminal work done by Langewouters et al., who performed pressure-inflation tests on human excised, perfused thoracic, and abdominal aortic segments.[25] Testing over a 0−200 mmHg pressure range, they observed a typical nonlinear pressure (P)-area (A) relation that they analytically described using an arc-tangent relation as illustrated in the top panel of Fig. 7.3. We can now use this data-based analytical expression to study well-known functional indices as (area) compliance and distensibility.

(Area) compliance and distensibility

Area compliance, C_A, is defined as the ratio of the change in area, ∂A, in response to the change in pressure ∂P, C_A (in m2/Pa in SI units) is the local slope of the pressure-area curve. Using the arc-tangent relation, C_A is equally a function of pressure as illustrated in the second panel of Fig. 7.3. Normalizing C_A to cross-sectional are yields the

FIGURE 7.3 The top panel displays a pressure-area plot that is analytically described by an arc-tangent relation. A_m, P_0, and P_1 are obtained via curve-fitting on experimental data of the thoracic aorta of a 39-year old ($A_m = 6.4$ cm^2, $P_0 = 41.3$, and $P_1 = 36.8$ mmHg)[17]. A_m is the maximal cross-section at high pressures, P_0 the pressure corresponding to the inflection point of $A(P)$ where the vessel reaches its maximal compliance, and P_1 is a measure for the steepness of the pressure-area relation. The pressure-area relation forms the basis for the computation of compliance and distensibility, which can be converted into pulse wave velocity using the Bramwell–Hill equation[26].

distensibility, D_A (in Pa^{-1}), defined as $\partial A/A/\partial P$. It is the ratio of the relative change in cross-sectional area ($\partial A/A$) and change in pressure ∂P and is obtained as $C_A(P)/A(P)$.

Clearly, compliance is pressure-dependent and reaches its maximal value for infraphysiological pressures (at P_0). Within the physiological pressure range of 80–120 mmHg,

C_A is reduced by 62% when pressure increases from 80 to 120 mmHg, a phenomenon known as pressure-dependent stiffening. As C_A, distensibility is maximal at infraphysiological pressures, but not at the same pressure as C_A. Distensibility is reduced by 67% when pressure increases from 80 to 120 mmHg.

Compliance coefficient and distensibility coefficient

It is not uncommon in clinical studies to discard the pressure dependency of C_A and distensibility, and to calculate the compliance coefficient (CC) and distensibility coefficient (DC) from diastolic and systolic values differences in cross-sectional area (ΔA) and pressure (ΔP) as

$$CC = \frac{\Delta A}{\Delta P} \approx \frac{\pi D \Delta D}{2\Delta P}; \ DC = \frac{\Delta A/A}{\Delta P} \approx \frac{2\Delta D}{D\Delta P}$$

Cross-sectional area (change) is obviously easily derived from diameter (D) measurements and assuming circularity of the cross-sectional area. This approach implies a linearization of the pressure-area relation between diastolic and systolic pressure, with CC the slope of this line yielding a value in between the diastolic and systolic value (Fig. 7.3).

C_A and D_A (or CC and DC) quantify the functional mechanical properties of the blood vessel. They depend not only on intrinsic wall tissue properties but also on wall thickness and vessel dimensions (especially C_A). Indices are best calculated using local blood pressure, which may differ substantially from brachial cuff values due to pulse amplification as the pulse travels from the heart to the periphery.[27] Arterial area and diameter can be obtained using ultrasound for superficial vessels (typically the carotid and femoral arteries); magnetic resonance imaging (MRI) can in principle provide such data all along the systemic and pulmonary vasculature, but the spatial resolution sets limits in practice to the larger vessels where changes in area can still be measured with reasonable accuracy. Obviously, pulmonary artery pressure cannot be obtained in a noninvasive way. Of note is that in ultrasound, some algorithms (especially wall tracking algorithms) may measure the diameter using the media-to-adventitia transitions rather than lumen diameter. As this yields smaller ΔD and larger D, DC will be somewhat underestimated.[28]

Stiffness moduli

Although the bioengineering perspective provides many arguments against doing so, the linear elasticity theory (assuming infinitesimal changes in diameter) applied to a pressurized thin-walled (with thickness h) cylinder does

provide a Young elasticity modulus (E, SI units Pa) given as

$$E = \frac{\Delta P}{\Delta D} D^2 \frac{(1 - \nu^2)}{2h}$$

with ΔD the diameter variation corresponding the pressure variation ΔP, h wall thickness, and ν the Poisson ratio of the wall material (0.5 for biological tissue).[29]

A better approach, given the high nonlinearity of the vessel wall and the large deformations, is to use the "incremental" elasticity modulus E_{inc}, derived from stepwise variations of pressure (and diameter).[29] Assuming no external pressure, E_{inc} is given by:

$$E_{inc} = \frac{\Delta P}{\Delta D_o/D_o} \frac{2D_i^2(1 - \nu^2)}{D_o^2 - D_i^2}$$

with indices o and i for outer and inner wall, respectively. E_{inc} increases with intraluminal pressure; for a blood pressures of 100 mmHg, it is about 400 kPa for the aorta, while reaching 2000 kPa or more for peripheral arteries.[29]

Lastly, it is worth mentioning the sometimes reported Peterson incremental elasticity modulus E_P, which does not require knowledge of arterial wall thickness. It is defined as[30]:

$$E_P = \frac{\Delta P}{\Delta D_o/D_o}$$

The reader should, anyhow, be aware that none of the above indices should be seen as constitutive material parameters describing the intrinsic nonlinear mechanical properties of an artery. At best, they provide a single number quantification of the functional stiffness of the artery in the circumferential direction. The reader is referred to Chapter 9 for further advanced reading on this topic.

Shear wave elastography—an in-vivo bioengineering perspective?

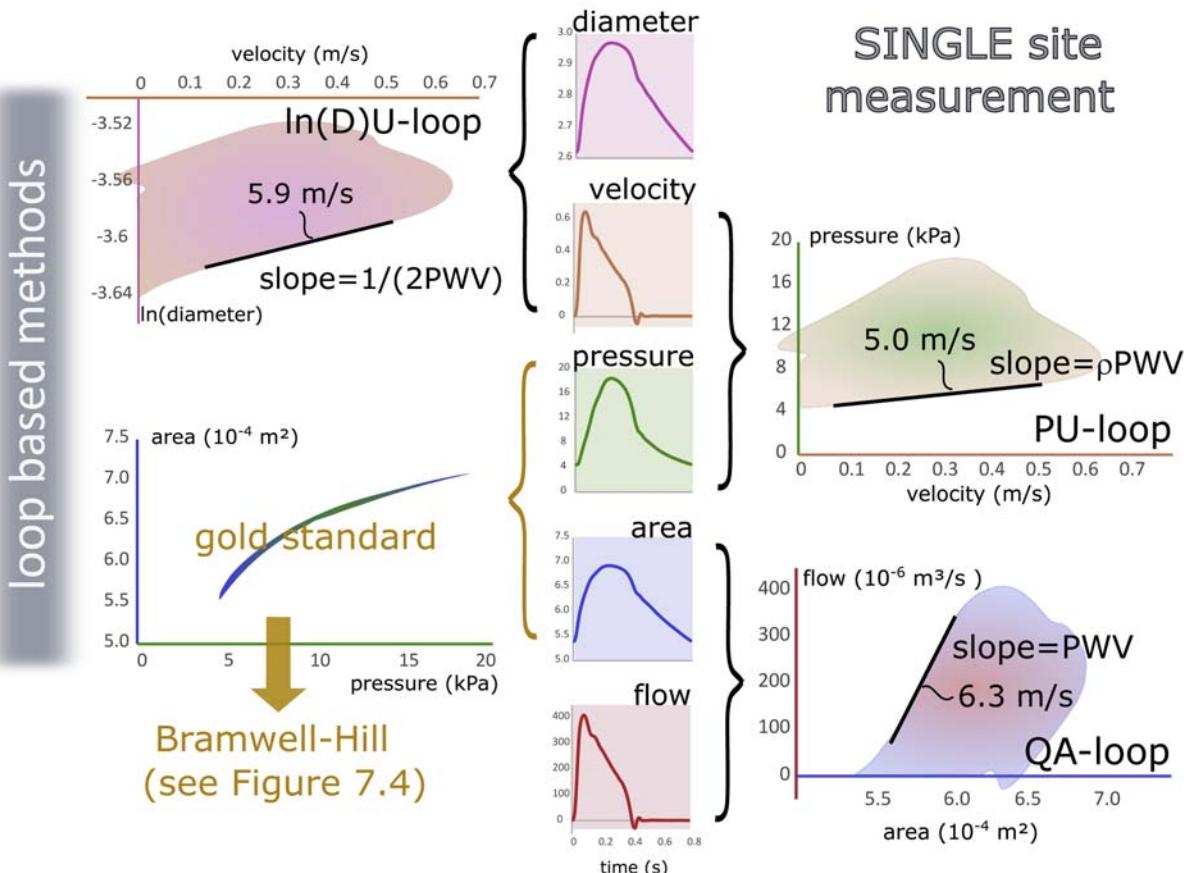
Shear wave elastography for soft tissue characterization is receiving a lot of attention in the ultrasound community[31] and may provide a clinically feasible way to effectively apply bioengineering principles in vivo. The working principle is that (i) small amplitude mechanical perturbations are induced locally within the tissue (typically micrometer displacements generated using mechanical energy from the focused ultrasound beam), and (ii) the propagation of the generated shear waves is tracked. As the shear wave speed is proportional to the stiffness of the tissue, shear wave elastography is potentially a direct stiffness measuring technique. Initially mainly used for liver fibrosis staging or breast tumor characterization, shear wave elastography is now fully being explored for the quantification of stiffness of the heart and arteries.[32] Methods are still under investigation,

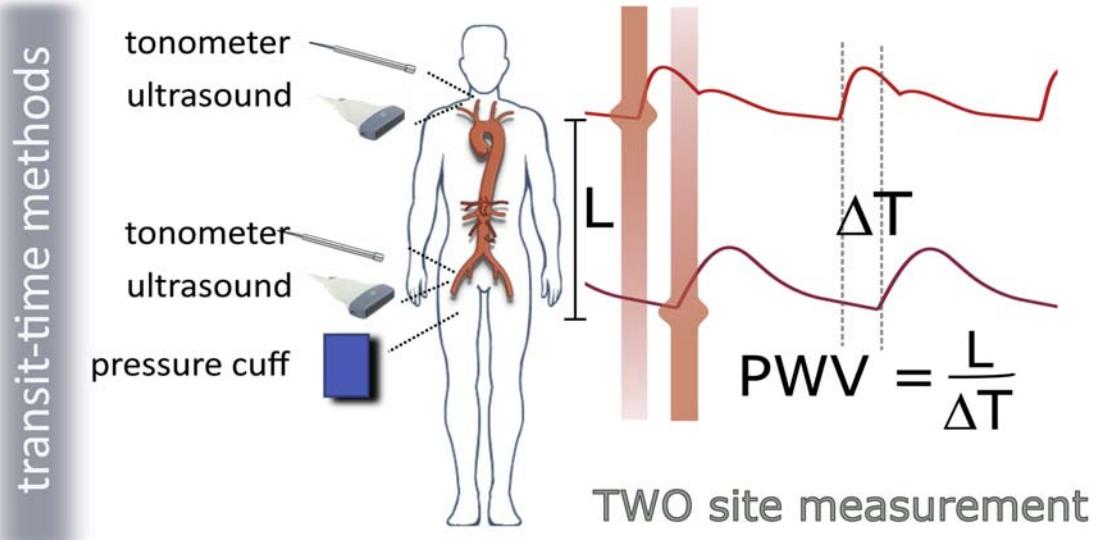
and the complex anisotropic and layered nature of the thin-walled tissues pose extra challenges, but initial results are highly promising.[33] In addition, given that shear waves can be tracked in 3D and propagation characteristics are sensitive to the tissues microstructure and anisotropy, shear wave elastography may provide in vivo assessment of arterial anisotropy.[34] Applications would be mainly directed toward the superficial carotid artery (whose properties may not always change in tandem with those of the aortic wall). Clearly, this technique is under development and any clinical and prognostic value remains to be established.

From local pressure-diameter to pulse wave velocity

Local stiffness measurements have the merit of phenotyping functional properties at a specific arterial site, but measurements and postprocessing—one has to combine pressure and diameter/area data—may be tedious and local properties not necessarily reflect the overall vascular health of a person. Above methods are therefore less frequently applied in clinical research whereby more global markers of vascular health may be more relevant. In the vast majority of these studies, PWV will be used as biomarker of arterial stiffness.

PWV is the speed at which the arterial pulse travels through the arterial tree, leading to easily observed time delays when the pulse is measured at two distinct locations (try, for instance, simultaneous palpation of the carotid and radial artery). The theoretical grounds that relate PWV to the stiffness of the distensible tube that the pulse travels in were established by Moens in 1877[35] and Korteweg in 1878[36] leading to the Moens–Korteweg equation $\text{PWV} = \sqrt{\frac{Eh}{\rho D}}$ with E the Young elasticity modulus, h wall thickness, ρ the density of the liquid inside the tube, and D the tube diameter. It were Bramwell and Hill in 1922, who reformulated this equation avoiding the necessity to measure E, h, and D into $\text{PWV} = \sqrt{\frac{V}{\rho}\frac{\partial P}{\partial V}}$ with V the volume within a tube segment of a given length.[37] Assuming a fixed length, one finds $\text{PWV} = \sqrt{\frac{A}{\rho}\frac{\partial P}{\partial A}}$ with ∂A the change in lumen area in response to a change in pressure ∂P. With $\frac{\partial A}{A\partial P}$ representing the distensibility (D_A) of the tube, $\text{PWV} = \sqrt{\frac{1}{\rho D_A}}$. High vessel stiffness (lower D_A) thus translates into a higher PWV. Note that, as the relation between pressure and area is nonlinear (as is the case in arteries), PWV will equally depend on operating pressure. As such, when using the foot of the wave as the fiducial point to assess transit time, one obtains PWV at diastolic pressure. The interrelations between the pressure-area diagram, distensibility, and PWV are illustrated in Fig. 7.3. It is important to realize that the

theoretical Moens–Korteweg and Bramwell–Hill relations hold for a uniform elastic tube, free of reflections (presumed infinitely long), which are conditions that not met in vivo, with arterial size and properties permanently changing across the arterial tree and with pressure and flow waves shaped by transmission and reflection. As such, despite generally considered the clinical gold standard to assess arterial stiffness, PWV may not be the most sensitive biomarker to detect changes in arterial wall material stiffness, as shown by modeling studies.[38]




Measuring (aortic) pulse wave velocity in vivo

Transit-time methods

In clinical practice, PWV is most commonly calculated as $\text{PWV} = \Delta L/\Delta T$, with ΔL the distance between two measuring sites, and ΔT the time it takes for the arterial pulse to travel from the proximal to the distal measuring site[42] (Fig. 7.4). With "pulse," we refer to measurable physiological signals that all propagate as a wave along the arterial tree at the same PWV such as pressure, flow or velocity waves, and arterial distension. With the aorta the largest elastic artery in the body, contributing to over 60% of the arterial buffer capacity,[43] most methods aim to measure aortic PWV which is ideally based on measurement locations within the aorta itself. The absolute reference is PWV from invasive pressure catheter recordings, but it is clear that such protocols are typically confined to technical validation studies (see e.g., Reference 44). More feasible, though probably not for large scale studies, is MRI which provides the 3D aorta and path length from anatomical imaging, while transit times can be assessed from flow measurements in specific cross-sections using phase contrast sequences.[45] Keep in mind, however, the temporal resolution of MRI which may not be sufficient to resolve transit times of a few tens of milliseconds, particularly when assessing regional PWV over shorter segments as the aortic arch.[46] Besides MRI, also two-dimensional ultrasound holds promise as a widely available technique to assess thoracic aortic PWV (from the aortic root to the diaphragmatic hiatus).[7]

To date, the closest proxy for aortic PWV is carotid-femoral PWV, with transit times assessed from "fiducial points" that are identified on signals measured at the carotid and femoral arteries.[42] These sites provide superficial arteries, still relatively close to the aorta, and accessible to measure pressure (applanation tonometry), flow velocity (ultrasound), arterial distension (ultrasound), or even skin-measured acceleration or vibrations (Fig. 7.4). These measuring techniques are embedded in commercially available systems such as Complior,[47] Sphygmocor,[48] Pulsepen,[49] and others, as well as custom-built data acquisition systems (as

FIGURE 7.4   Left: illustration of the concept of carotid-femoral pulse wave velocity. The transit-time time (ΔT) of the pulse from the carotid to femoral is measured, together with an estimated travel path length L. The ratio of L and ΔT yields PWV. Right: illustration of the various loop-based methods that have been proposed to estimate local pulse wave velocity. The PU-loop method was first introduced by Khir et al.,[39] who reformulated the method to the $ln(D)U$ method to avoid the use of pressure.[40] The QA method was introduced by Rabben et al.[41] The absolute reference and gold standard, however, is to use the pressure-area relation from which one can get PWV as a function of pressure as illustrated in Fig. 7.3. Methods have been shown susceptible to wave reflection (see text).

used in the Framingham[11] and Asklepios[50] population studies). Measurements are best performed simultaneously, but ECG-gated sequential measurements are common practice.[51] The availability of a large reference value database acquired from data across Europe[52] and studies demonstrating its prognostic power[10,53] have given carotid-femoral PWV a reference status of reference for clinical studies in Europe and the United States. The biomarker has, however, some important drawbacks as phenotype of large artery stiffness as the method bypasses the ascending aorta and part of the aortic arch, discarding the properties of the aortic section that contributes most its buffering function. Besides the difficulty in assessing the carotid-femoral pathlength (the current consensus being to simply calculate PWV using 0.8 times the distance between the carotid and femoral measuring site), there is ambiguity in its definition since the pulse does not directly travel along a single path from the carotid to the femoral measuring site. Also, computer modeling studies have shown that carotid-femoral PWV strongly correlates with, but differs substantially from theoretical PWV values derived from the Bramwell−Hill equation due to nonlinearities in arterial elasticity and the nonhomogeneity of the arterial tree.[54]

Several other devices have been developed over the past decades (see Reference 55 for a recent review), recording signals at more peripheral locations using cuffs at the brachial, ankle, and thigh or photoplethysmograph devices on the finger and toe.[56] As can be expected and confirmed by an invasive validation study, the further measuring sites move away from the aorta, the lesser the correlation and agreement with invasively measured aortic PWV.[44] Nonetheless, brachial-ankle PWV is frequently used in Asia, with large studies demonstrating the prognostic ability of this metric to assess cardiovascular risk.[57] The very large distance of the measuring sites to the aorta leads to an uninterpretable ambiguity in the path traveled by the wave along elastic and muscular arteries, making it virtually impossible to reconcile how derived values effectively relate to aortic PWV.[58] It may be more sensible to aim for heart-femoral PWV, detecting the time delay between closure of the aortic valve (detectable via a microphone) and arrival of the pressure wave picked up by a femoral cuff.

An index closely related to PWV is CAVI, the cardio-ankle vascular index. CAVI assumes a nonlinear (exponential) pressure-diameter relation[59] and provides a pressure-independent stiffness metric (after correcting the original formulation).[60] However, the arterial path used for the underlying measurement of PWV will largely impact its physiological meaning and interpretation.

As extensively discussed in a recent review,[58] we discourage the use of devices estimating PWV from a single brachial cuff pressure recording. It is physically impossible to *measure* PWV from only a pressure tracing at one single measuring site, and devices only provide some estimate that may or may not be based on legitimate underlying models, and involve algorithms trained on datasets to ensure that plausible PWV values are provided by the device.

Loop-based methods to measure local pulse wave velocity

An appealing class of methods to assess arterial stiffness are the so-called loop-based methods that exist in several formulations, depending on the combined signals (Fig. 7.4). All methods rely on the (reformulated) water hammer equations that state that—in a uniform elastic tube and in absence of wave reflections—changes in pressure (dP) and flow velocity (dU) relate as[61] $dP_\pm = \pm\rho\mathrm{PWV}dU_\pm$ with the $\pm$ sign indicating the direction of propagation of the wave, ρ the density of the liquid inside the tube (about 1050 kg/m^3 for blood), and PWV the local PWV. To illustrate: for an arterial segment with a PWV of 5 m/s, a step increase in flow velocity of 1 m/s would give rise to a step increase in pressure of 5250 Pa (36.4 mmHg).

Khir et al. demonstrated that, when plotting simultaneously measured and properly time-aligned in-vivo pressure as a function of flow velocity, a loop is obtained that will typically display a linear segment that corresponds in time with the first few tens of milliseconds in early systole.[39] As also discussed in Chapters 3 and 17, when describing a time-domain method to estimate characteristic impedance, it seems plausible that wave reflection is minimal during that particular window in time, which would fulfill the conditions of the water hammer equation. In other words, the slope of the linear segment of the PU-loop in early systole equals ρPWV from which PWV is directly calculated. Reformulations of the method have led to more easily noninvasively applicable methods such as the flow-area method (QA method[41]) and the $ln(D)U$ method, D being diameter.[40] Especially the QA-loop method is alluring as both variables are fairly easily measured with MRI and can also be applied to the pulmonary artery.[62]

The presence of a linear segment in the PU-loop (or QA or $ln(D)U$ loops), however, does not guarantee absence of reflections, and these most appealing methods have proven to be susceptible to error induced by wave reflections.[63] This has been demonstrated in hydraulic bench set-ups,[64] in silico[65,66] and in vivo.[66] The impact of reflections on the accuracy of the method is variable and differs from one location to the other.[65,67] In the vicinity of a reflection of the closed type as in the carotid artery, the PU loop tends to overestimate effective PWV, while the QA and $ln(D)U$ method tend to underestimate. The opposite happens in the vicinity of open-type reflections.[65,67] Attempts to correct for the error have been undertaken, but without real applicable success to date.

Pulse wave imaging

An interesting ultrasound technique that holds the middle between a transit time and a local PWV measurement is pulse wave imaging. The use of unfocused plane waves enables measurements with a temporal resolution of several kHz that are thus fast enough to monitor the propagation of a pulse within the artery over the width of the imaging window.[68] Pulse wave imaging visualizes the propagating wave front using spatiotemporal plots of wall displacement, velocity, or acceleration indeed, with PWV given by the slope of the propagating wave front.[69] The technique, applicable to superficial vessels as the carotid artery, captures PWV throughout time, and it is possible to track the wave front in early systole (PWV at diastolic pressure) as well as the wave front arising from aortic valve closure (at the dicrotic notch pressure).[33]

Total arterial compliance

As explained before, the "windkessel" function refers to the ability of the arterial tree to partly buffer SV in systole, keeping pressure pulsations within physiological limits preventing excessive systolic pressures as well as a steep pressure decline in diastole, preserving perfusion pressure. That overall function is best quantified by the total arterial compliance (C). C, defined as dV/dP with V intra-arterial volume and P pressure, is expressed in m^3/Pa in SI units (or in mL/mmHg). A simple estimate of total arterial compliance is the ratio of SV and PP.[70,71] SV/PP could be thought of as the total arterial compliance if the complete SV were buffered in the large elastic arteries in systole, without any peripheral outflow (and discarding, among others, wave reflection and viscoelastic effects). As there is a continuous run-off of blood, the volume increase during ejection is only a fraction of SV and SV/PP should overestimate true compliance.[72,73] The reader is referred to Chapter 3 (Essential Principles of Pulsatile Pressure-flow relations in the arterial tree) for windkessel model–based methods to estimate total arterial compliance.

Total arterial compliance versus arterial stiffness and pulse wave velocity

Despite the physiological significance of total arterial compliance, it is only seldomly used in clinical research. Besides the necessity to measure pressure and flow (SV), an important drawback of compliance is that it depends on stroke volume and pressure. While pressure can be assumed to be intrinsically independent of body height, SV clearly is not. This necessitates normalization, implies different values for men and women, and complicates comparison between groups. In addition, arterial aging encompasses changes in arterial stiffness and aortic enlargement, which

may compensate and lead to little changes in volume compliance, making it a rather insensitive biomarker to follow up on arterial changes. This stands in contrast with most (not all) aforementioned metrics of local stiffness and PWV which are insensitive to body size in humans and have similar values in mammals. This also facilitates translational research, with a straightforward adoption and translation of findings in animal models to the human setting.

Total arterial compliance versus effective arterial elastance

Effective arterial elastance (E_A), defined as the ratio of SV and end-systolic pressure, is a parameter frequently used in studies on ventriculo-arterial coupling. It is, however, occasionally reported as a measure of arterial stiffness. We have shown theoretically[74] and in vivo[75] that E_A is simply a function of systemic vascular resistance and heart rate and is negligibly influenced by (and insensitive to) changes in pulsatile afterload in humans. It should therefore not be used to quantify arterial stiffness or compliance.

Concluding remarks

Arterial stiffness (or rather the inverse, arterial distensibility) is a key physiological property of the organism which is, unfortunately, not easily quantified in a simple, tangible metric. The complex composite nature of the arterial wall yields a soft tissue with highly nonlinear anisotropic and viscoelastic properties that are site-dependent and further modulated by arterial tone and adaptations driven by mechanobiological interactions. It is therefore almost surprising that crude in vivo functional measurements as carotid-femoral PWV (and alternatives) have been proven such strong prognostic biomarkers. The urge for quick and easy assessment of stiffness (PWV) in larger (general) populations has stimulated the development of devices—some more trustworthy than others—though without really advancing the field or facilitating standardization. In the research setting, the further exploration of MRI for aortic assessment, and developments in ultrasound imaging may open up new, reliable methods for targeted functional phenotyping of the proximal aorta and large central arteries and material characterization using elastography. The further integration of imaging, advanced computational biomechanics, and most likely artificial intelligence, will, no doubt, further unravel the complex biomechanical axial-circumferential interactions in arteries and how these evolve in an aging aorta that dilates and elongates while being exposed to mechanical and biological/metabolic insults. At a macroscale, such studies should include the interaction of the aorta with its surroundings—the heart at its inlet, and its anchoring and

tethering. At the microscale, they should increase our understanding of mechanobiological interplay and the interaction of cells within the arterial wall and the extracellular matrix that it maintains and synthesizes. Ultimately, these insights should lead to novel methods for an easy assessment of vascular health in the general public, and to therapies for an optimal preservation of vascular health within an individual's lifetime.

Ambulatory 24-h measurement of brachial blood pressure and heart rate

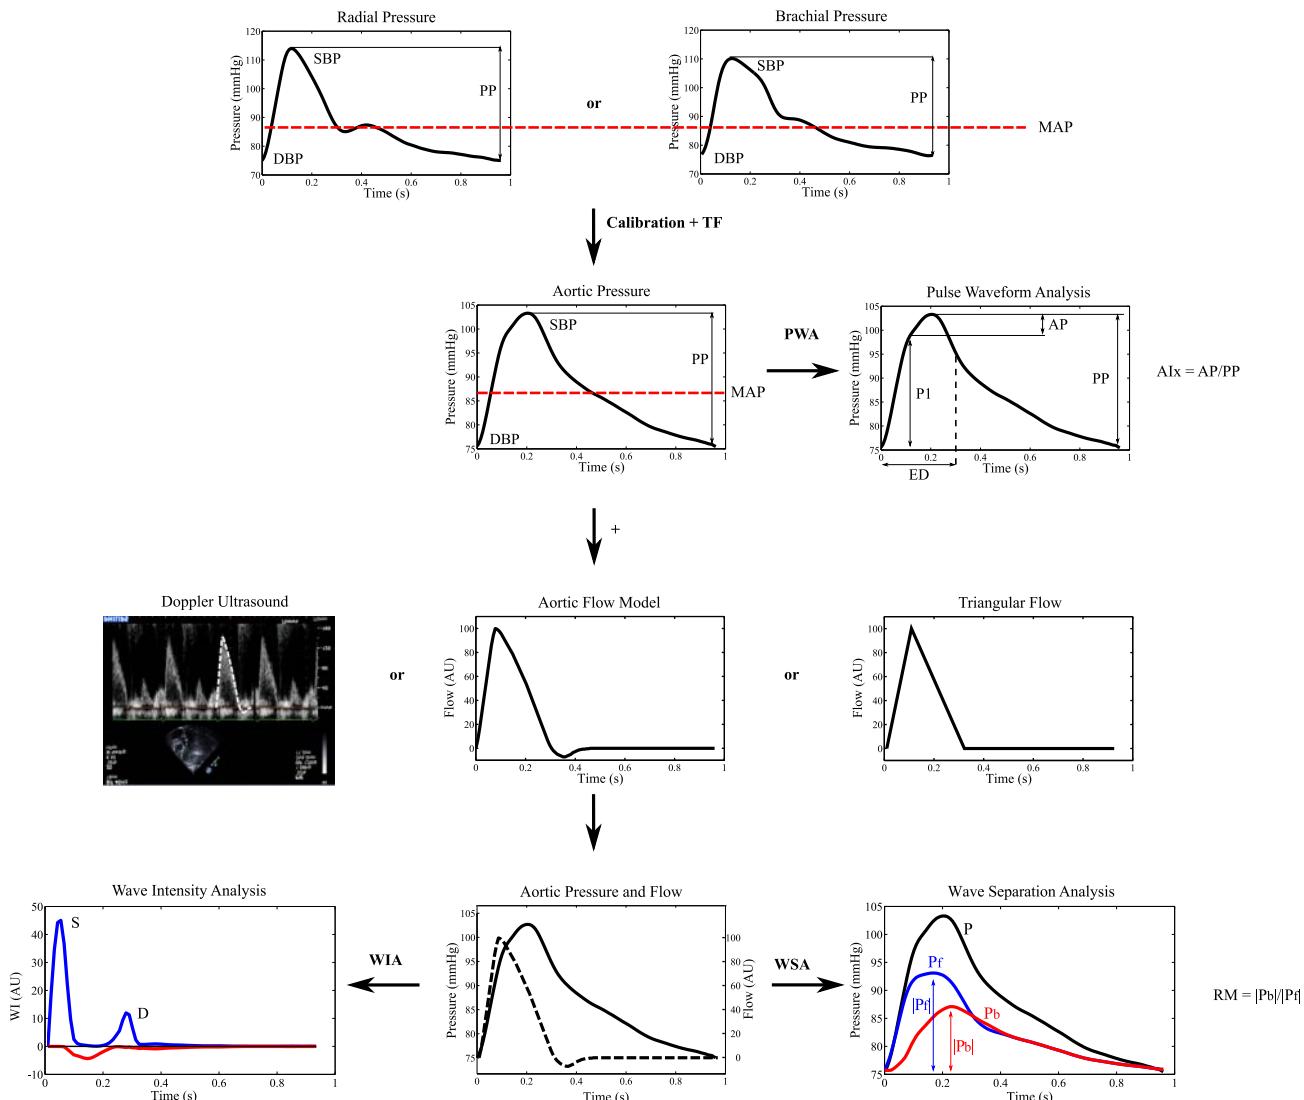
Although office blood pressure (BP), admittedly through its time-honored wealth of outcome data, particularly related to drug treatment of hypertension, is still the basis of the management of high BP,[1,2] out-of-office measurement of BP (24 h ambulatory BP monitoring—24 h ABPM and home BP monitoring) is increasingly recognized and recommended in current guidelines.[1,2] Compared to office BP, 24 h ABPM has numerous advantages,[3] including but not limited to the following: 24 h ABPM provides a much larger number of readings for a better assessment of an individual's BP level, with reproducible average 24 h, daytime and nighttime values, identifies white coat and masked phenomena in untreated and—less reproducible—in treated individuals,[4] provides a BP profile in the individual's usual daily environment, demonstrates nocturnal hypertension and dipping patterns, assesses BP variability over 24 h, and assesses the efficacy of antihypertensive drugs over 24 h. These benefits translate into a superior prognostic value of 24 h ABPM, as compared to office BP, as studies, beginning in the 1960s[5] and up to the present,[6] have repeatedly shown. Recently, an analysis of the International Database on Ambulatory Blood Pressure in Relation to Cardiovascular Outcome (IDACO), including 13 population studies in Europe, Asia, and South America and 11,135 participants,[6] provided compelling evidence that 24 h ABPM provides additive prognostic information to office BP, corroborating previous findings.[7] Accordingly, 24 h ABPM is recommended in the most recent versions of Guidelines on the Management of Hypertension globally, for instance, in Europe,[1] in the US,[2] and Japan.[8] Within this context, nocturnal BP and the daytime/nighttime ratio ("dipping") seems to be particularly important.[3,6,9] During healthy nocturnal sleep, a marked shift in autonomic balance occurs, with an increase in parasympathetic activity and a reduction in sympathetic cardiac/cardiovascular modulation, giving rise to a decrease in BP and heart rate by 10%−20% compared with daytime average.[3,10]

Although regularly assessed during 24 h ABPM, 24 h heart rate and daytime/nighttime ratio of heart rate have been investigated less often than BP. In an analysis from the IDACO registry,[11] 24 h and nighttime heart rate as well as night/day ratio of heart rate independently predicted all-cause mortality. The results regarding the prognostic relevance of heart rate "dipping" were confirmed in the Spanish ABPM registry on data from 56,901 patients.[12] Interestingly, in most studies investigating the prognostic role of 24 h ABPM, heart rate was not taken into consideration in the statistical models.[6,13,14]

Pulsatile and steady state hemodynamics

Due to the nature of the pump in the human circulation (the heart), pressure and flow in the arterial circulation are pulsatile, rather than steady. During the first decades of BP research, the focus was mean arterial pressure (MAP) and diastolic BP (DBP), with the very first successful trial in patients with high DBP (averaging 115−129 mm Hg) published in 1967.[15] At that time, hemodynamic phenomena were often simplified (ignoring atrial pressure) as "cardiac output = MAP/systemic vascular resistance

(SVR)," assuming a steady-state circulation. This approach is not only widely used in clinical medicine but also has a long track record in hypertension research,[16] up to recent years.[17]

However, for a more comprehensive view, one has to take the pulsatile phenomena, arising from the pulsatile pump and its interaction with the arterial system, into account. The simplest measurement is *brachial pulse pressure (bPP)*, the difference between brachial systolic (SBP) and DBP. bPP is convenient and available with every single BP measurement, but only a crude measurement of pulsatile hemodynamics. Brachial PP increases with age and with stiffening of the aorta and the large arteries, and with increasing wave reflections.[18] Brachial PP is more closely related to cardiovascular risk in middle-aged and elderly individuals than other BP components,[19] and can be used in the diagnostic workup of patients with unexplained exertional dyspnea.[20] Brachial PP > 60 mm Hg indicates asymptomatic hypertension-mediated organ damage in older people, according to the 2018 European Society of Hypertension (ESH)/European Society of Cardiology (ESC) guidelines for the management of arterial hypertension.[1] However, bPP has several limitations: it depends not only on arterial (PP increases with increased arterial stiffness/wave reflections) but also on cardiac function (PP decreases with severely impaired systolic function),[21] which leads to an inverse relationship (i.e., a lower PP is associated with a worse prognosis) with outcomes in patients with severely impaired systolic function[22]; PP measured at the brachial artery does not exactly reflect PP at the ascending aorta (*aortic = central PP—cPP*), with bPP being higher ("amplified") than aoPP in most people. The *pulse pressure amplification (PPA)*,[23] expressed as a difference or ratio between aoPP and bPP, depends among other factors on aortic stiffness, cardiac function, heart rate, and arterial geometry, as discussed below.


More sophisticated measurements of pulsatile hemodynamics beyond brachial and central pressures (cSBP, cPP) have become available, e.g., estimates of forward and reflected waves, and measures of arterial stiffness. A wide array of more complex models of the circulation are discussed in depth in other chapters of this book and elsewhere,[24] but below we focus on measurements available from current 24 h ABPM techniques.

The classical theory of pulsatile hemodynamics, i.e., the Windkessel model, fails to take into consideration the concept of pressure wave reflections, which is essential for the understanding of the peripheral circulation. Indeed, whereas *cSBP* and *cPP* are lower than their brachial counterparts (by anywhere up to 30+ mm Hg),[25] MAP and DBP decrease by only 1−2 mm Hg from the aorta to peripheral arteries.[24] As a consequence, cSBP and cPP are—compared to bSBP and bPP—more relevant to vital organs like the heart, brain, and kidney, and have been

closer associated with cardiovascular outcomes in some,[26,27] but not all studies.[28,29] These are direct consequences of the fact that pressure and flow waves, which are generated with each heartbeat and propagate toward peripheral sites, are also reflected backwards (toward the heart) for a combination of reasons (impedance mismatch, stiffness gradient, presence of bifurcations, abrupt diameter gradient in arterioles). Reflected waves merge with the antegrade waves at various phases during the cardiac cycle,[24] with pressure waves adding to the antegrade wave, and flow waves subtracting from the incident wave.[24] With aging, waves travel faster due to an increase in arterial stiffness. With vasoconstriction, the amplitude of the reflected pressure waves increases. As a net result of both of these processes, cardiac load and oxygen consumption is increased, resulting in an imbalance toward myocardial ischemia and an impairment of (mainly diastolic) left ventricular function.[30]

Wave reflection can be quantified from pressure waveforms (pulse waveform analysis—PWA), or from simultaneous analysis of pressure and flow waves (wave separation analysis—WSA)—Fig. 8.1. The technique of PWA is based on the mathematical identification of an inflection point on the pressure waveform, which is thought to represent the beginning of the arrival of reflected waves at the ascending aorta.[24] The pressure rise from the inflection point to the systolic peak of the pressure curve is named "*Pressure Augmentation—AP*," and the ratio AP/cPP is named "*Augmentation Index—AIx*." Thus, AP and AIx are thought to reflect and quantify the influence of wave reflection on the central aortic waveform. Using WSA, the amplitudes of the *forward wave* (*Pf*; the pressure wave generated by the heart) and the *backward wave* (*Pb*; the reflected pressure wave) can be derived, as well as their ratio (*Reflection Magnitude RM*; Pb/Pf).

Arterial stiffness (particularly *aortic stiffness*) can be measured in vivo because the speed of propagation of pulse waves (pressure or flow or distension) in an artery is directly related to the mechanical properties of the vessel (the stiffer the vessel, the higher the velocity).[31] Therefore, when the time delay between the arrival of a pulse wave at two locations (commonly the carotid artery and the femoral artery), and the distance between both locations are measured, *pulse wave velocity (PWV)* as the most robust measure of arterial stiffness[31] can easily be calculated. As the effects of the aging process (i.e., loss of elasticity, increased stiffening) are most pronounced in the human aorta as opposed to the muscular arteries,[32] the aortic pathway should be included in the measurement. In addition, the prognostic value is largely limited to pathways including the aorta,[33] such as carotid-femoral PWV (cfPWV). cfPWV is a strong independent predictor of cardiovascular events in different groups of high and low-risk patients and in the general population.[34] Obviously,

FIGURE 8.1 Methods to quantify pulsatile hemodynamics. *Top line*: recording of signal-averaged radial or brachial pressure waveforms with tonometry or brachial cuff. *Second line*: following calibration with brachial pressures, aortic waveforms are calculated with a TF. Pulse waveform analysis, based on pressure signals alone, yields measures of the first (P1) and second (P2) systolic peaks for computation of augmented pressure and augmentation index (AP, AIx). *Third line*: flow waveforms are obtained, either with Doppler recording of LV outflow (which equals aortic inflow), or as model-driven flow or triangular flow as a proxy. *Bottom line*: combined and time-aligned analysis of a pressure-flow pair is used for wave separation analysis, wave intensity analysis, and other analytical approaches. *AIx*, augmentation index; *AP*, augmented pressure; *DBP*, diastolic blood pressure; *MAP*, mean arterial pressure; *Pb*, amplitude backward wave; *Pf*, amplitude forward wave; *PP*, pulse pressure; *PWA*, pulse waveform analysis; *RM*, reflection magnitude; *SBP*, systolic blood pressure; *TF*, transfer function; *WIA*, wave intensity analysis; *WSA*, wave separation analysis. 24 h ambulatory measurement of cfPWV is not feasible. Technical[35,36] and mathematical[37] solutions to provide estimates of aortic PWV, based on brachial cuff recordings, have been developed. Although smaller preliminary studies in patients with chronic kidney disease, showing a relationship with cardiovascular events,[38,39] are promising, there is no consensus regarding the potential value of these aoPWV estimates at present.[40]

Techniques and devices for 24-h ambulatory measurement of pulsatile (and steady state) hemodynamics

For office measurements of cBP and wave reflections, most often brachial or radial tonometry was the basis (Fig. 8.1) of the next steps (calibration, transfer functions, PWA, WSA, etc). In one study, the daytime variability of parameters

related to wave reflection has been assessed with tonometry,[41] and shown that it is the main cause of circadian variability of PPA.[42] However, in general, the feasibility of tonometry for ambulatory recordings is quite limited. Therefore, alternatives have been developed, which rely on acquisition of waveforms with a brachial cuff[35,43–45] or with a wrist-watch like tonometer.[46] Table 8.1 provides an overview of current devices.

24-h variability ("dipping") of pulsatile and steady state hemodynamics

Brachial BP and heart rate in healthy individuals are higher during daytime and decrease during nocturnal sleep ("dipping").[47] Circadian variations in steady-state hemodynamics have been repeatedly assessed, using invasive[48–50] and noninvasive[51–54] methods, in healthy individuals,[49,52,54] in patients with so-called essential hypertension,[48–51,53] and in patients with chronic kidney disease.[54] In general, it was observed that SBP, DBP, MAP, and heart rate decreased during nighttime.[48–54] CO decreased during nighttime in most studies,[48,50,52,54] and was unchanged in some.[49,53,54] Results

for SVR were more variable and showed an increase,[51,52] a decrease,[48,49,53,54] or no consistent changes[54] with a peak value at 08.00 a.m.[50]. These differences may be related to measurement techniques or the influence of disease.[54]

Most interestingly, the diurnal variability, i.e., "dipping," of bSBP and cSBP are different to a smaller or larger amount. Using the BPro device, in a trial of two different drugs for BP lowering,[55] 24 h curves for bSBP and cSBP were largely parallel with preserved nocturnal dipping. However, the amount of nocturnal dip in SBP was 8.2% for bSBP and 6.9% for cSBP, respectively. Adjustment for the nocturnal change in heart rate attenuated the difference. In a trial in normotensives and hypertensives, using the same device, the nocturnal decrease of amplification (the difference between cSBP and bSBP) was mainly driven by the day-night difference in heart rate.[56] Similar results were obtained with the BPLab device in a multicenter registry,[57] with SBP amplification being 11.6 mm Hg at daytime and 8.8 mm Hg at nighttime.

When the Mobilograph device is used, a particular technical aspect needs to be taken into account: for calibration of the initially acquired waveforms, brachial BP is used. Due to the well-established systematic underestimation

TABLE 8.1 Commercially available device for 24 h measurement of central hemodynamics.

Name of device	Manufacturer	Type of device	Algorithms used	Parameters displayed (selection) and technical validation studies	FDA 510(k) clearance
Arteriograph 24	Tensiomed, Budapest, Hungary	Brachial cuff	Suprasystolic signals	Brachial SBP and DBP, heart rate,[88] MAP, central SBP,[89] central PP, AIx,[90,91] aoPWV[35]	No

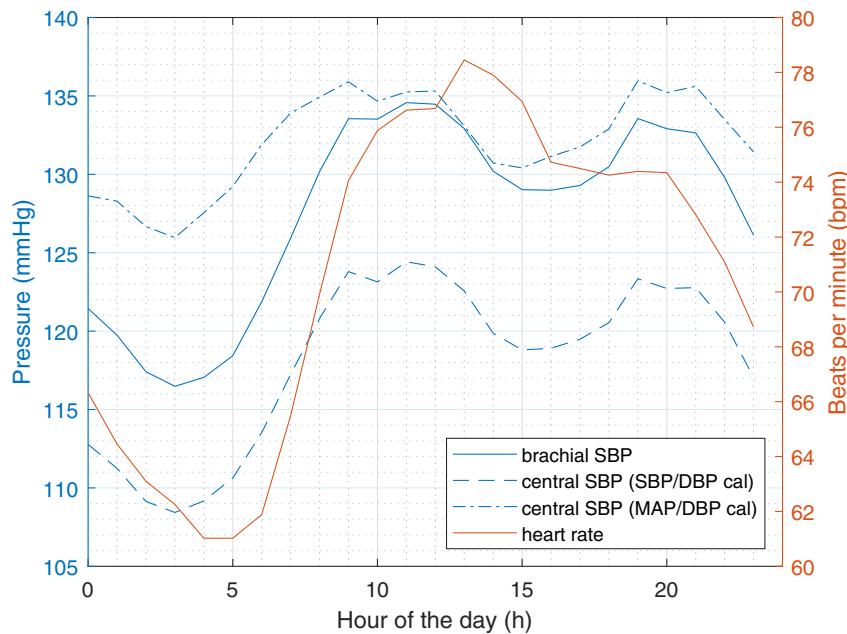
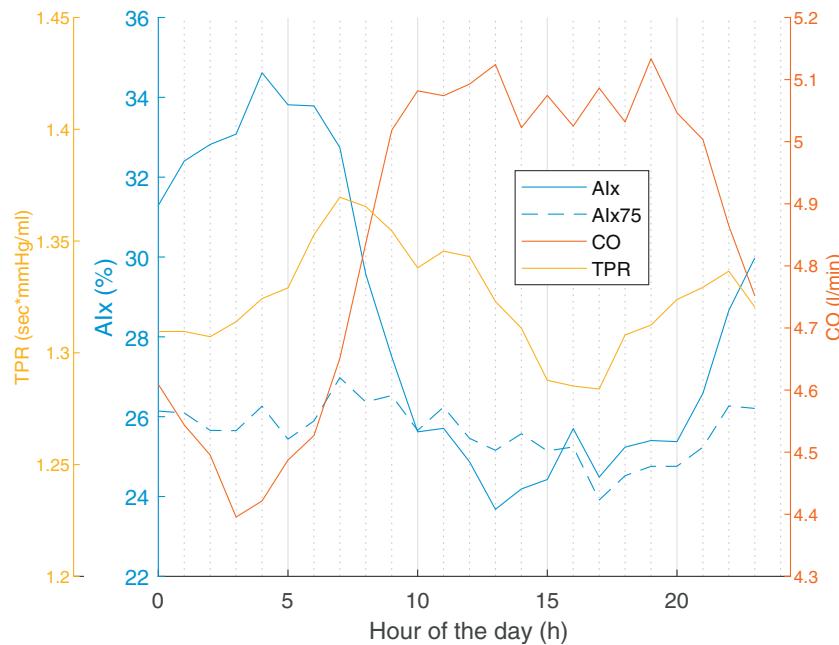
of true (i.e., invasive) bSBP by noninvasive cuff-based measurement,[25] waveform calibration with noninvasive bSBP will most often result in underestimation of cSBP, as compared to true (invasively measured) cSBP, whereas SBP and PP amplification will be preserved. In contrast, MAP can be determined directly with oscillometry as the point of maximal oscillations of cuff pressure during gradual cuff deflation.[43,58,59] As a consequence, waveform calibration with MAP (and DBP) may result in a better estimate of true (=invasive) cSBP.[60–62] With MAP/DBP calibration, the true level of SBP amplification can be *apparently* distorted (i.e., negative/inverse) because usually cuff-measured bSBP (and not invasive bSBP) is the comparator. In other words, the apparent inverse amplification is the result of a correct measurement of cSBP and an underestimation of bSBP by cuff measurement.[60] Theoretically, true (=invasive) bSBP can be calculated from MAP/DBP calibrated cSBP and SBP/DBP calibrated amplification,[63] but this approach has never been tested clinically. Preliminary results suggest that this technical issue translates into clinical outcomes (see below), favoring MAP/DBP calibration. It has to be acknowledged, however, that the concept does not hold for all cuff-based devices.[64]

Data from the SAFAR study, using the Mobilograph device and SBP/DBP calibration, show that SBP amplification is higher during daytime, as compared to nighttime.[65] In a random sample of 167 participants from Uruguay, the difference between bSBP and cSBP was 14 mm Hg at daytime and 9.7 mm Hg at nighttime.[66] In 136 untreated adolescents and young adults from Greece,[67] virtually the same results were obtained, with a difference between bSBP and cSBP of 16.3 mm Hg at daytime and 10.5 mm Hg at nighttime. In the same population, also the results of MAP/DBP calibration were reported: due to the different calibration, cSBP was apparently *higher* than bSBP, particularly during nighttime, and dipping of cSBP (MAP/DBP) was absent (even slightly reversed). In a preliminary analysis[68] from a global academic research consortium (international 24 h aortic BP consortium—i24abc), based on measurements in more than 2500 healthy individuals from 20 centers in 14 countries, analysis of nocturnal "dipping" was stratified across age groups. For bSBP, daytime-nighttime difference was between 10% and 20% in the youngest age group (i.e., normal[3]), and smaller in the oldest age groups. In contrast, cSBP (MAP/DBP calibration) displayed only minor daytime-nighttime changes. Fig. 8.2 shows 24 h profiles of bSBP and cSBP in a random sample of 500 individuals from the authors' institutions.

Apart from SBP, most other hemodynamic parameters exhibit circadian variability. Using the Mobilograph device, Boggia et al. were among the first to describe diurnal profiles of pulsatile hemodynamics, using a sample of 167 middle-aged and elderly Latin Americans. During nighttime, a decrease of cSBP, DBP, heart rate, and PPA, and an increase


of cPP and AIx were observed. These findings were later verified and further extended by data published from the SAFAR study.[69] Moreover, in 136 adolescents and young adults from Greece, Ntineri et al.[67] confirmed the results for pulsatile hemodynamics, and extended them to steady-state hemodynamics: they observed an increase in SV and a decrease on SVR and CO at nighttime. Fig. 8.3 shows 24 h profiles of selected steady-state and pulsatile hemodynamics in a random sample of 500 individuals from the authors' institutions.

As the change in body position is one of the obvious differences between daytime and nighttime, the changes in 24 h ABPM profiles are contrasted to those during active standing[70] and head-up tilt test.[71] It appears that daytime-nighttime variability of most hemodynamic measures indeed mirrors changes induced by active or passive (tilt-test) standing—Table 8.2. These results were confirmed and extended in a randomized cross over study with assessment of bBP and aortic pressure waveforms in the sitting and supine position in randomized order in 61 subjects. Whereas MAP did not change upon changing of body position, bPP, cPP, AIx, and AIx75 significantly increased in the supine position, whereas PPA decreased. The decrease in PPA was mainly driven by changes in pressure wave reflections.[72]


24-h ambulatory measurement of pulsatile (and steady state) hemodynamics—clinical studies

Regarding office-based measurements, a recent meta-analysis suggested that cBP is more strongly related to hypertension-mediated organ damage (left ventricular mass, carotid intima media thickness, and PWV) than bBP.[73] Along the same lines, 24 h cSBP was more closely associated with left ventricular mass and left ventricular hypertrophy in the SAFAR study (a single center study from Greece)[65] and in a multicenter study,[74] performed in seven European centers, as compared to brachial office and brachial 24 h SBP. The same trend, albeit without reaching statistical significance, was available in another small single center study from Spain.[75] In all studies, the same device (Mobilograph), has been used, and in all three studies, the superiority of 24 h cSBP was dependent on a technical issue, i.e., MAP/DBP calibration. Virtually the same results (a closer association with 24 h cSBP, as compared to 24 h bSBP; the results are confined to the MAP/DBP calibration method) have been obtained for left ventricular diastolic dysfunction.[76] Moreover, central BP variability, investigated with the Mobilograph device, has been shown to be superior to brachial BP variability in terms of association either with cardiac[77] or carotid[78] damage. In a multicenter registry using the BPLab device,[79] 24 h cSBP and cPP

FIGURE 8.2 24-h profiles of brachial and central systolic blood pressure as well as heart rate in a random sample of 500 adults. Daytime-nighttime difference ("dipping") can be easily seen for brachial systolic blood pressure (SBP) and heart rate. Central SBP (systolic-diastolic BP calibration) by and large parallels brachial SBP, whereas "dipping" is much smaller for central SBP (mean-diastolic BP calibration).

FIGURE 8.3 24-h profiles of steady-state and pulsatile hemodynamics in a random sample of 500 adults. During nighttime, there is a clear increase in AIx, a small increase in AIx75, and a decrease in CO, as compared to daytime. There are no consistant daytime-nighttime changes for TPR, with peak values in the morning hours. *AIx*, Augmentation Index; *AIx75*, Augmentation Index, normalized for heart rate 75; *CO*, cardiac output; *TPR*, total peripheral resistance.

showed a numerically closer association with LV hypertrophy, as compared to 24 h bSBP and bPP.

In patients with end-stage renal disease undergoing hemodialysis, ambulatory 48 h aoPWV, estimated with a nonlinear regression which includes age, central SBP, and waveform characteristics, was an independent predictor of cardiovascular events and all-cause mortality.[39] These results were confirmed in another small study in dialysis patients.[38]

24-h ambulatory measurement of pulsatile (and steady state) hemodynamics—drug trials

Office-based studies successfully demonstrated that drug-induced changes in cSBP may be different from changes in bSBP.[80−82] For 24 h cBP, such results are currently missing. Changes in 24 h cSBP in most trials paralleled

TABLE 8.2 Comparison of hemodynamic changes (brachial and central blood pressure, steady-state and pulsatile hemodynamics) during 24 h ambulatory monitoring, passive (tilt table test[71]) and active standing.[70]

changes in bSBP, for instance, in a study comparing Sacubitril/Valsartan and Olmesartan in elderly patients with isolated systolic hypertension,[83] in a study comparing Nebivolol and Olmesartan in patients with acute ischemic stroke,[84] or in a study comparing the hemodynamic effects of Empagliflozin with placebo in patients with type 2 diabetes mellitus.[85]

Summary and outlook

Recent advances in technology enable 24 h measurement not only of brachial BP and heart rate but also of steady-state and pulsatile hemodynamics, the latter including central hemodynamics, antegrade and reflected waves. With technical validation rapidly progressing, these measurements can be performed in daily routine and even under unusual conditions, like long-term space flights.[86] 24 h hemodynamics may find their way into physiological, pharmacological, and clinical research and, finally, clinical routine, if important prerequisites can be fulfilled: (1) proof of (added) prognostic value; (2) establishment of reference values, which are currently only available for office-based measurements[87]; (3) development of treatment strategies, based on the 24 h ambulatory hemodynamic measurements (personalized medicine); and (4) proof of medical and economic superiority of these strategies.

Chapter 9

Animal models and methods to study arterial stiffness

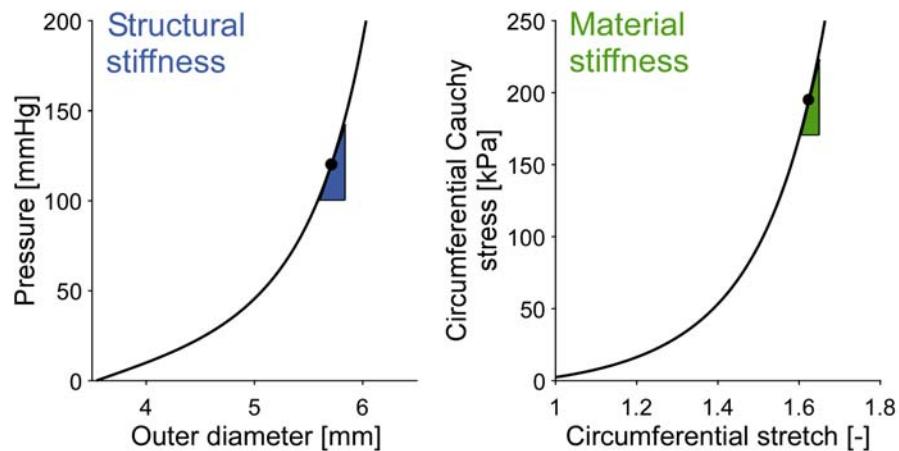
Bart Spronck[1,2] and Jay D. Humphrey[1,3]

[1]*Department of Biomedical Engineering, School of Engineering and Applied Science, Yale University, New Haven, CT, United States;* [2]*Department of Biomedical Engineering, CARIM School for Cardiovascular Diseases, Maastricht University, Maastricht, the Netherlands;* [3]*Vascular Biology and Therapeutics Program, Yale School of Medicine, New Haven, CT, United States*

Introduction

As emphasized throughout this textbook, increased arterial stiffness is an initiator and indicator of diverse cardiovascular, renovascular, and neurovascular conditions, and thus all-cause mortality. It is increasingly important, therefore, to measure arterial stiffness in at-risk patients, though typically such measurements are limited to in vivo metrics. Complementary studies in animal models therefore remain important for identifying the underlying molecular and mechanical mechanisms of arterial stiffening. These preclinical studies can also be useful for evaluating new measurement methods as well as potential drug efficacy. In this chapter, we first review key mechanical concepts related to arterial stiffness and its measurement, including common in vivo and ex vivo methods. We then discuss representative mouse models and conclude with a comparison of techniques and a set of brief recommendations.

Mechanical concepts

As discussed in Chapter 7 and various other sections of this textbook, pulse wave velocity (PWV)—the speed at which the blood pressure wave travels along a vascular path—has come to be regarded as the gold standard metric for arterial stiffness in the clinical setting. A much broader range of measurements and metrics are possible in animal studies, however, and an overall standard in animal models has yet to emerge. Toward this end, it is important to remember that the different metrics have different meanings, and thus different utilities.[1]


Briefly, stiffness is a measure of the change in loading needed to cause a particular deformation; compliance is the inverse of stiffness. The different metrics of stiffness thus emerge depending on the definitions of "load" and "deformation" as well as the conditions of loading. Importantly, material stiffness refers to an intrinsic property of the material; structural stiffness depends on both the material stiffness and geometry (Box 9.1). As an example, if the deformation is taken as an in vivo change in luminal cross-sectional area over the cardiac cycle and the load is the corresponding change in blood pressure, one obtains a structural measure of compliance—the coefficient $CC = (A_s - A_d)/(P_s - P_d)$, with A_s and A_d the systolic and diastolic luminal cross-sectional area, and P_s and P_d the systolic and diastolic blood pressure, respectively. An overview of different metrics of arterial stiffness commonly used in animal research is given in Table 9.1, which delineates structural and material metrics.

Measurements of arterial stiffness thus depend strongly on the loading conditions.[1] The most variable loading determinant in vivo is the blood pressure at the time of measurement, followed by heart rate (Box 9.2). In vivo, an artery is also subjected to a significant degree of axial stretch that is induced largely during somatic growth; it helps to ensure that the artery does not bend during blood pressure fluctuations. In addition, this *axial* stretch influences the *circumferential* stiffness of the arterial tissue. Whereas the axial stretch of an artery is dictated by the prevalent physiologic conditions in vivo, it is highly modifiable ex vivo, though often not reported or emphasized. For an ex vivo measure of stiffness to mimic in vivo conditions, the artery should be stretched axially to its in vivo length, as well as pressurized to its in vivo value. Box 9.3 illustrates some effects of different ex vivo loading conditions on stiffness measurements.

BOX 9.1 Arterial stiffness—material versus structural

Metrics of arterial stiffness can be divided into *structural* and *material* (Fig. 9.1). Metrics of structural stiffness quantify the stiffness of the artery as a whole, that is, as a structure. Examples include pulse wave velocity (PWV), compliance coefficient (CC), and distensibility coefficient (DC) (equations in Table 9.1). Metrics of material stiffness, on the other hand, quantify the intrinsic stiffness of the wall material, reflecting its composition, which is necessarily defined at a point. Examples include the incremental Young's modulus (E_{inc})[14] and the small-on-large metric $C_{\theta\theta\theta\theta}$.[49] Differences between structural and material metrics can be appreciated through an illustrative example of vascular hypertrophy. Suppose, for example, that the arterial wall begins to thicken in incident hypertension. If this thickening occurs via deposition of the same type of material as was already present, the *material* stiffness does not change although the thickening necessarily increases the *structural* stiffness.

- Structural property
- Geometry-**dependent**
- Changes when material changes (e.g. collagen cross-linking) and/or when geometry changes (e.g. wall thickening)
- (conceptually) the slope of the pressure-diameter curve
- Typical metrics: PWV, CC, DC

- Material property
- Geometry-**independent**
- Changes when material changes (e.g. collagen cross-linking); **not** when geometry changes

- (conceptually) the slope of the stress-strech curve
- Typical metrics: E_{inc}, $C_{\theta\theta\theta\theta}$

FIGURE 9.1 Structural versus material stiffness. *Source data from Spronck B, Humphrey J. Arterial stiffness: different metrics, different meanings.* **J Biomech Eng**. *2019.*

Finally, as can be seen from the Moens–Korteweg equation, PWV (a structural metric) incorporates both material (through E_{inc}) and geometric (wall thickness h and internal radius r_i) information:

$$\mathrm{PWV} = \sqrt{\frac{E_{inc} \cdot h}{2 \cdot \rho \cdot r_i}},$$ (9.1)

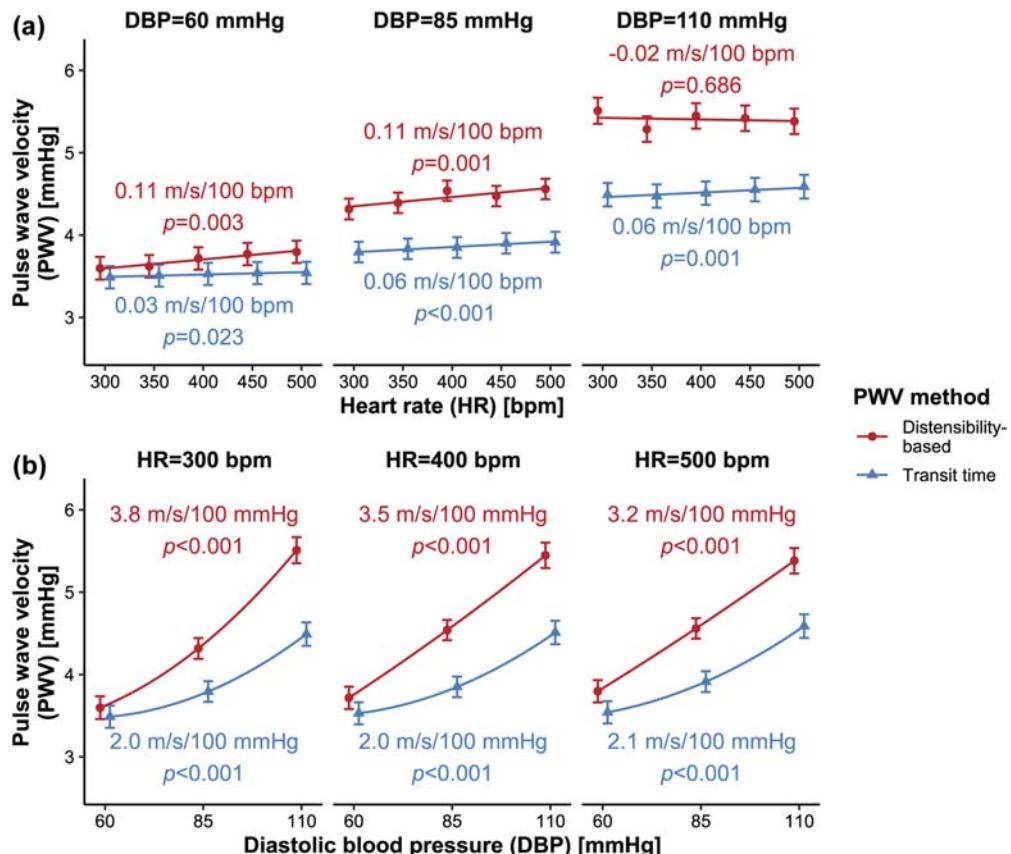
with ρ the mass density of the fluid, namely blood in vivo. It is thus structural metrics of stiffness that dictate the hemodynamics. By contrast, material metrics are important to the local mechanobiology, that is, the response of the cells to changes in their local mechanical environment.


TABLE 9.1 Overview of commonly used formulas for arterial stiffness calculation in animal research.

Name	Equation	Eq.	Structural/ material?	Description
Compliance coefficient (CC)	$CC = \frac{A_s - A_d}{SBP - DBP}$	(9.2)	Structural	Absolute change in area for a given change in intraluminal pressure
Distensibility coefficient (DC)	$DC = \frac{A_s - A_d}{(SBP - DBP) \cdot A_d} = \frac{CC}{A_d}$	(9.3)	Structural	Relative change in area for a given change in intraluminal pressure
Pulse wave velocity (PWV)	$PWV = \frac{\Delta s}{TT}$	(9.4)	Structural	Propagation speed of the blood pressure wave along the arterial tree
	$PWV = \sqrt{\frac{1}{\rho \cdot DC}}$	(9.5)	Structural	
Incremental (circumferential) Young's modulus (E_{inc})*	$E_{inc} = \frac{2 \cdot \rho \cdot r_i \cdot PWV^2}{h}$	(9.6)	Material	Linearized, approximate increase in Cauchy stress per unit increase in stretch*
	$E_{inc} = \frac{d\sigma_{\vartheta\vartheta}}{d\lambda_{\vartheta}}$	(9.7)	Material	
Small-on-large material stiffness ($\mathbb{C}$) *,**	$\mathbb{C}_{ijkl} = \delta_{ik}\widehat{t}_{lj}^{\,o} + \widehat{t}_{il}^{\,o}\delta_{jk} + 4F_{iA}^{o}F_{jB}^{o}F_{kP}^{o}F_{lQ}^{o}\frac{\partial^2 W}{\partial C_{AB}\partial C_{PQ}}\Big|_{\mathbf{C}^o}$	(9.8)	Material	Linearized increase in Cauchy stress per unit increase in strain*
Referential material stiffness (**K**)*	$\mathbf{K} = \frac{\partial \mathbf{S}}{\partial \mathbf{E}} = \frac{\partial^2 W}{\partial \mathbf{E}\partial \mathbf{E}} = 4\frac{\partial^2 W}{\partial \mathbf{C}\partial \mathbf{C}}$	(9.9)	Material	Increase in second Piola—Kirchhoff stress per unit increase in Green—Lagrange strain*

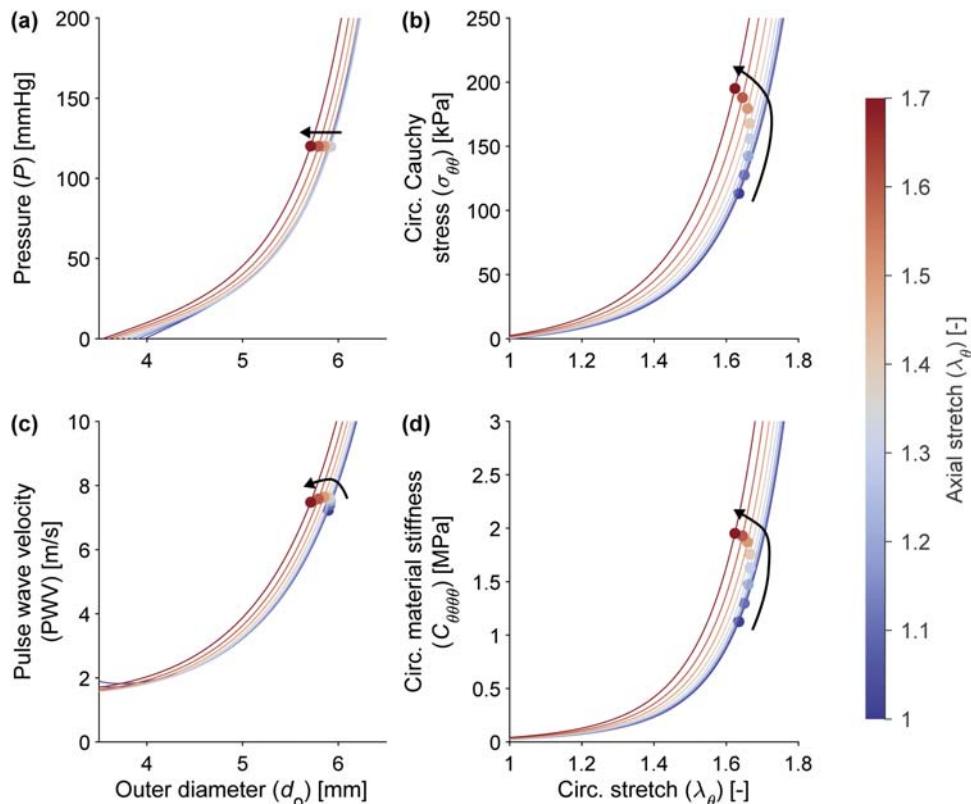
A_s and A_d, systolic and diastolic cross-sectional area; SBP and DBP, systolic and diastolic blood pressures; Δs, transit distance; TT, transit time; ρ, blood mass density; r_i, inner radius; h wall thickness; $\sigma_{\vartheta\vartheta}$, circumferential Cauchy stress; λ_{ϑ}, circumferential stretch; **F**, deformation gradient tensor; W, stored strain energy function; $\widehat{t}$, extra (deformation-dependent) part of Cauchy stress tensor; δ, Kronecker tensor; **S**, second Piola—Kirchhoff tensor; **E**, Green—Lagrange strain tensor; and **C**, right Cauchy-Green tensor (**C** = $\mathbf{F}^{\mathsf{T}}\mathbf{F}$). * for more details on material stiffness metrics and their differences, see Box 9.5. ** a detailed derivation of $\mathbb{C}$ can be found in Reference 49.

BOX 9.2 Effect of loading conditions: in vivo

The nonlinear material behavior of the artery wall renders measurements of arterial stiffness strongly dependent on the loading conditions, especially transmural pressure (Fig. 9.2). These dependences are of particular relevance during in vivo studies due to changes in blood pressure and heart rate, which are highly variable in rodents; emotional stress due to handling quickly raises blood pressure while anesthesia decreases heart rate and blood pressure. Therefore, when reporting arterial stiffness metrics measured in vivo, the blood pressure at which those measurements were taken should always be reported.

FIGURE 9.2   Influence of heart rate (HR, A) and diastolic blood pressure (DBP, B) on pulse wave velocity (PWV) measurements in rats.[10] Numbers in red/blue denote average HR and BP dependencies, respectively. BP dependencies are calculated for DBP = 85 mmHg. Distensibility-based measurements are derived from ultrasound echotracking-based measurement of diameter and catheter-based measurement of blood pressure. Transit time PWVs are derived from the time difference between two catheter-based measurements taken simultaneously a fixed distance apart. *Figure reproduced from Spronck B, Tan I, Reesink KD, et al. Heart rate and blood pressure dependence of aortic distensibility in rats: comparison of measured and calculated pulse wave velocity.* **J Hypertens**. *2020, with permission.*

In vivo methods to study arterial stiffness

In principle, most methods for measuring arterial stiffness in vivo in humans (discussed in detail in Chapter 7) can be used in animals. In some cases, however, size/resolution


may be a limiting factor. We will therefore review the most appropriate methods.

Blood pressure measurements

Blood pressure is a strong determinant of the measured value of arterial stiffness (Box 9.2). Therefore, ideally,

BOX 9.3 Effect of loading conditions: ex vivo

The influence of loading conditions on measurements of arterial stiffness is not limited to the in vivo case (Box 9.2). While an artery is (by definition) at its in vivo length/stretch in the body, the researcher is free to stretch the artery to any length ex vivo. Fig. 9.3 illustrates the influence of axial stretch on a structural (PWV) and a material (small-on-large stiffness, $C_{\theta\theta\theta\theta}$) metric of stiffness (see Table 9.1).

FIGURE 9.3 Effects of pressure and axial stretch on arterial stiffness ex vivo. Panels a and b show typical arterial pressure-diameter (structural) and circumferential (circ.) stress-stretch (material) curves. Individual lines correspond to values of axial stretch (λ_z), increasing from $\lambda_z = 1$ to $\lambda_z = 1.7$ in steps of 0.1. Dots correspond to a pressure of 120 mmHg. Panels c and d illustrate effects of increasing λ_z on pulse wave velocity and small-on-large material stiffness, typical structural and material stiffness metrics, respectively. *Source data from Spronck B, Humphrey J. Arterial stiffness: different metrics, different meanings.* J Biomech Eng. 2019. *A theoretical analysis of the PWV can be found elsewhere Demiray H. Wave propagation through a viscous fluid contained in a prestressed thin elastic tube.* **Int J Eng Sci**. 1992; 30:1607−1620.

every in vivo study measuring arterial stiffness should also measure (or estimate) blood pressure at the site(s) of interest. Methods have been developed, for example, to transform peripheral measurements (e.g., via sphygmomanometer) to central measurements. In mice, peripheral blood pressure can be measured similarly using a tail-cuff device, as well as invasively using a catheter, either indwelling or during a surgical procedure. Both fluid-filled and (solid state) pressure-tip catheters are used, though given the fast heart rate and correspondingly high-frequency content of the mouse blood pressure signal, pressure-tip catheters are preferable. When measured by acute catheterization, it is important to remember that anesthesia generally reduces blood pressure from its ambulatory value.[2,3] By contrast, when measured by telemetry, with the pressure catheters connected to a radio

transmitter that is implanted under the skin, one measures ambulatory pressures under conscious conditions—currently considered the gold standard. Nevertheless, due to the small size of the mouse vasculature, catheterization can alter blood flow and pressure.[4] Whereas the tail-cuff measurement does not affect the blood flow and pressure directly, the required animal restraint can result in highly variable results in mice due to differences in emotional distress.[5]

Invasive blood pressure to measure arterial stiffness by transit time

If blood pressure is measured invasively and simultaneously at two locations along the arterial tree in mice, a diastolic foot-to-foot transit time can be obtained which, given a distance measurement, yields a transit time PWV (Eq. (9.4), Table 9.1).[3,6] Distance can be measured by leaving both catheters in place after euthanasia, dissecting the (intact) artery free, and measuring the distance using a small suture or, when straight, directly with a ruler or caliper.[7] This technique can also be performed using a single, dual-tip catheter, which removes the necessity to measure the distance between measurement sites and thus removes any measurement error in such distance measurement. Alternatively, when an ECG is recorded together with the BP signal, the time difference between the R-wave on the ECG and the diastolic foot on the BP signal can be obtained. By performing this in duplicate, for two BP measurement locations, one also obtains a transit time.

Different methods are available to determine the time difference between two blood pressure waves. Similar to the human case, the diastolic foot of the waveform provides a reliable fiducial point for transit time determination in murine models.[8] Both second derivative−based and intersecting tangent−based methods provide robust foot detection.[9,10]

High-resolution ultrasound

Several other methods exist for measuring structural stiffness in mice.[11] Ultrasound tracking of arterial wall motion can be used to measure in vivo changes in diameter. Together with pressure measurements, this yields the structural stiffness metrics of compliance and distensibility, the latter of which can be converted into a *local* estimate of PWV (Eqs. (9.2), (9.3), and (9.5), Table 9.1), for a given artery (e.g., carotid). Alternatively, ultrasound can be used to obtain *regional*, point-to-point (over finite lengths) PWVs by measuring the velocity waveform at two points along the artery and determining the time difference between those points. Division of the effective distance between these points by the transit time yields a transit time PWV (Eq. (9.4), Table 9.1). Because PWV varies along the

arterial tree, such transit time PWV represents a regionally averaged metric.

Applanation tonometry

In humans, transit time PWV is commonly estimated using applanation tonometry, where a tonometer is pressed against (superficial) arteries, typically at the carotid and femoral locations. This approach is also feasible in mice.[12] As with all in vivo methods for measuring stiffness in rodents, the animal has to be sedated, thus potentially influencing blood pressure (Box 9.2) and, thereby, the measured PWV.

Ex vivo methods to study arterial stiffness

In vivo measurements of arterial stiffness are necessarily limited to in vivo loading conditions, namely, with blood pressure fluctuating but axial stretch fixed. In contrast, ex vivo measurements offer much greater experimental control, and thus freedom, to test a sample over a wide range of loading conditions. Yet, the choice of these loading conditions has important consequences for the obtained results.[13]

Atomic force microscopy

Atomic force microscopy (AFM) allows measurement of material stiffness (Box 9.1) at the nano- and microscales, thus enabling stiffness to be inferred for individual components of the arterial wall (e.g., cells, elastic laminae, and collagen fibrils) or locally. Typically, the AFM tip is used to indent (i.e., push into) an otherwise unloaded sample while measuring the indentation depth and corresponding force. In this mode, AFM yields a (radial) *compressive* stiffness under nearly unloaded conditions (near the traction-free state, implying no external forces acting upon the sample) typically inferred as an (estimated) Young's modulus.[14] In contrast, physiologically, the dominant relevant loads within the arterial wall are typically *tensile*, oriented in the circumferential and axial directions. These differences in loading, radial compression rather than in-plane tensile, leads to Young's moduli that typically differ by multiple orders of magnitude between AFM and the in vivo loading state (Table 9.2).[1] Other methodological confounders are the indenter tip size and diameter, and the algorithm/model (e.g., Hertz) used to convert measured data into a Young's modulus.

Wire myography

Wire myography involves the circumferential stretching of a short arterial ring between two wires while

TABLE 9.2 Values of aortic stiffness (mouse) depend strongly on methodology.

simultaneously measuring the associated force (Fig. 9.4). Wire myography is typically performed with the artery at a physiological level of circumferential stretch, but the axial direction is left unloaded, allowing it to move freely during testing and thus shorten via a Poisson effect (the phenomenon in which a material tends to compress in directions perpendicular to the direction of extension, and vice versa). In vivo, however, arteries are typically tethered axially and *prestretched* (elongated). The effect of axial stretch on circumferential mechanics is elaborated in Box 9.3. For a more detailed review about wire myography, the reader is referred to Reference 7.

Pressure myography

In pressure myography, an arterial segment (preferred length ∼5 times its unloaded diameter) is mounted between cannulae and pressurized, which necessitates that

all side branches are ligated (Fig. 9.4). The artery is typically maintained at a fixed length, which is often chosen as the minimum length at which the vessel does not buckle visually during inflation. Yet, the length (axial stretch) at which the artery is distended influences its circumferential behavior (Box 9.3). Hence, the artery should be mounted at its in vivo length, thus ensuring that the loading conditions mimic those in vivo. This can be accomplished for some arteries by measuring the length in situ prior to excision. Identifying the proper in situ length can be difficult for many arteries, however, including the ascending aorta and coronary arteries (which change length over a cardiac cycle), the common carotids (if the neck is extended to enable the requisite cut-down), and smaller arteries (which have significant adherent perivascular tissue).

Some pressure myographs allow measurement of axial force. If such measurement is available, the in vivo length of the artery can be estimated without measuring an actual in situ length. This method exploits the observation that the axial force remains approximately constant when an artery is pressurized at its in vivo length.[15] When held at a greater or shorter length, the force increases or decreases, respectively, with increased pressure. Using this knowledge, one can estimate the axial stretch that corresponds to the in vivo situation by repeatedly inflating/deflating an artery while measuring axial force.

Biaxial biomechanical testing

Biaxial biomechanical testing is similar to pressure myography. These two techniques differ, however, in that a biaxial test does not only involve distension (while keeping the artery at a fixed *length* or axial *force*) but also extension (while keeping the artery at a fixed *diameter* or *pressure*; Fig. 9.4). By combining these two loading modes, biaxial testing assesses arterial behavior along the two primary directions or axes.[16,17] Hence, one can quantify both the circumferential and the axial material stiffness, thus revealing potentially coupled behaviors (Box 9.3). Although beyond the current scope, such biaxial data allow one to quantify the nonlinear anisotropic behavior in terms of appropriate constitutive relations.[18]

Digital image correlation

Panoramic digital image correlation (pDIC) is a relatively new technique that provides spatially resolved material properties under biaxially loaded conditions.[19,20] For pDIC, the artery is typically first tested biaxially (see previous paragraph) to estimate the in vivo axial stretch and to determine the bulk biaxial properties. Optical coherence tomography (OCT) can also be used to measure local wall thickness for the full sample. Thereafter, a speckle pattern is created on the sample, which is then mounted vertically within a conical mirror (Fig. 9.4). Imaging via this mirror from the top yields the full surface deformation pattern,

which is repeated for different pressures and axial stretches. The OCT and pDIC data can then be used together to identify constitutive properties locally, which can be particularly important in cases of complex geometry, such as aneurysms.

Mouse models to study arterial stiffness

Many different animal models continue to contribute to our understanding of arterial stiffening, both its presentation and potential reversal. Nevertheless, the mouse has emerged as the model of choice for multiple reasons. The many different genetically modified mouse models available allow one to delineate effects of individual cell phenotypes, proteins, receptors, etc., on overall vascular structure, function, and properties. The many different surgical models enable one to focus on the effects that altered hemodynamics have on subsequent vascular and cardiac changes. The many different possible pharmacological interventions allow one to study both disease progression and its treatment. Perhaps most importantly, technological advances now allow one to collect extensive cell biological, biomechanical, and physiological data that, in turn, can be correlated with (immuno)histological information given the many antibodies available in the mouse. Finally, the short gestational period, the ease of handling, and the lower cost of mice are particularly advantageous for performing longitudinal studies over periods of weeks or months. Box 9.4 discusses key differences and similarities between the mouse and human aorta. In the following sections, we briefly discuss a few studies representative of the large number of papers available on arterial stiffness in diverse mouse models.

Aging

Among others, Sir William Osler, one of the four founding fathers of Johns Hopkins Medicine, remarked at the beginning of the 20th century that we (humans) are as old as our arteries. Natural aging is now a well-known contributor to arterial stiffening and thus a strong, inevitable risk factor for many cardiovascular diseases. In humans, extreme aging results in many vascular changes, including endothelial cell dysfunction, increased inflammation, and fibrosis. Importantly, aging also results in progressive decreases in elastic fiber integrity, since functional elastic fibers are only deposited early in life, though with a normal half-life in the order of 50 years. In mice, with much shorter lifespans than humans, the elastic lamellar structure appears to change little with natural aging. If the effects of reduced elastic fiber integrity are of interest in a particular study, mice deficient in the elastin-associated glycoprotein fibulin-5 can be useful, which mechanically phenocopy human aging,[21] enabling their use, for example, in studies on the combined effects of

aging and hypertension.[22] Despite the minor changes in elastic lamellar structure in mice, other effects of aging do manifest therein. Careful measurements of blood flow and pressure reveal changes in characteristic impedance in aged mice,[23] thus reflecting underlying stiffening. At least in some mice, such age-induced stiffening associates with arterial inflammation and adventitial fibrosis, which is partially reversible with aerobic exercise.[24] Again remembering the different definitions and metrics, such stiffening appears to be due primarily to changes in wall thickness, due to increased accumulation of fibrillar collagen and glycosaminoglycans, rather than marked changes in material stiffness[21] (that is, it is the structural stiffness that increases). Similarly, a paradoxical increase in arterial stiffness, and thus PWV, emerges in progeria, an extremely rare, highly accelerated aging disorder. In this condition, decreases in material stiffness are far outweighed by increases in wall thickness, again due to accumulating collagen and especially glycosaminoglycans, thus increasing structural stiffness and PWV.[25] These changes can be slightly greater in the abdominal than in the thoracic aorta, causing regional differences in PWV, but nevertheless augmenting central pulse pressures as would be expected of aortic stiffening.

Connective tissue disorders

Marfan syndrome results from a mutation in the *Fbn1* (mouse) gene, which codes for the elastin-associated glycoprotein fibrillin-1. This syndrome affects many different tissues, though aortic root aneurysms are the most common cause of morbidity. In addition to aneurysms, Marfan syndrome results in a stiffening of many central arteries, as first inferred via measurements of PWV.[26] In mice, Marfan syndrome is also associated with endothelial cell dysfunction and compromised nitric oxide signaling, which can have myriad effects on wall composition and thus properties.[27] Biaxial mechanical testing reveals further that it is an increase in material stiffness in the thoracic aorta that associates with Marfan syndrome in the $Fbn1^{mgR/mgR}$ mouse model,[28] consistent with a reduced ability of the smooth muscle cells to mechanosense and mechanoregulate wall stiffness in genetically predisposed thoracic aortopathies.[29] Material stiffness otherwise appears to be mechanoregulated well in many cases,[30] hence suggesting that measurements of intrinsic stiffness are also important indicators of the ability of the intramural cells to sense and regulate their local mechanical environment, which is crucial for maintaining proper structure and function via mechanical homeostasis.[31] Although most findings herein derive from mouse studies, the mouse and human aorta are, despite their size difference, structurally very similar. Controversy, however, exists about the role of smooth muscle tone in the human aorta, whereas this is well established in the mouse aorta (Box 9.4).

BOX 9.4 The mouse aorta versus the human aorta

When choosing the mouse as a model animal for arterial stiffness research, one should be aware that, necessarily, differences exist between murine and human large arteries. Table 9.3 lists key structural and functional metrics for both species. Most structural metrics come from the seminal work by Wolinsky and Glagov,[56] in which they showed that, despite major size differences across species from mouse to human, the medial lamellar unit is remarkably well conserved. Indeed, though the number of lamellar units in the human aorta is ∼12 times that of the mouse, lamellar thickness and especially tension per unit is similar across species.

TABLE 9.3 Structural and functional metrics for mouse and human aortas.

Metric		Mouse	Human	References
Diameter (loaded) (mm)		1.2	17	56
Medial thickness (mm)		0.03	1.1	56
Number of lamellar units		5	60	56

Typical murine and human body weights are 30 and 75,000 g, respectively.[56]
*cfPWV: carotid-femoral PWV from applanation tonometry. Murine measurements were performed in ∼5.5-month old mice under sevoflurane anesthesia.[12] Human values are for 30−39 year old normotensives.[58] **Varies with age/disease.

The human aorta is often said to possess little vascular tone, in contrast to the murine aorta which contracts strongly to vasoactive substances.[62] Despite these claims, direct measurements (e.g., myography) of human aortic contractility remain wanting. "Indirect" evidence suggests, however, some vascular tone in the human aorta. Stefanadis et al., for example, showed a shift in the aortic pressure-diameter *relationship* shortly after smoking, suggesting involvement of vascular tone.[63] In addition, several studies investigated effects of sympathetic activation on PWV with disparate results, which may be attributable to the concomitant changes in blood pressure that often occur with sympathetic stimulation[64−68] (review in Reference 69). To overcome this limitation, Nardone et al. used lower-body pressure changes to elicit sympathetic activation, and showed significant increases in carotid-femoral PWV after mild lower-body negative pressure, without changes in blood pressure.[70]

When arteries distal to the aorta are studied, the influence of vascular tone becomes stronger and clearer. Vascular tone is well known to modulate human brachial artery diameter, as used in flow-mediated dilation measurements.[71] In addition, transit time PWV measurements that (also) involve more distal arteries have shown a vascular tone dependency.[72,73] Finally, cardio-ankle PWV as used in cardio-ankle vascular index (CAVI)/CAVI$_0$ changes markedly with alpha-1 adrenergic receptor blockade,[74,75] independent of blood pressure.

Diabetes and obesity

Obesity and diabetes are increasingly responsible for many sequelae, including cardiovascular disease. They also have significant effects on large artery stiffness. Importantly, it was shown that increases in arterial stiffness, as inferred via the PWV, in obese mice can precede the development of hypertension,[32] consistent with general findings in humans.[33] That is, it is now clear that increased large artery stiffness can be both a cause and consequence of

hypertension, thus revealing potentially insidious positive feedback loops that drive disease.[34,35] Recent data also indicate a bidirectional relationship between diabetes and large artery stiffness, since the latter can predict new-onset diabetes[36] and conversely, diabetes increases arterial stiffness, largely via fibrosis,[37] though also via changes in advanced glycation end-products.[38] We are reminded, therefore, that it is both changes in arterial wall composition and organization that dictate the material stiffness. Indeed, increasing evidence points to a critical role of tissue transglutaminases in arterial stiffening, which are important in matrix cross-linking.[39,40] The reader is also referred to a study that showed that obesity-induced arterial stiffening can be prevented with low-dose mineralocorticoid receptor blockage in mice, with arterial stiffness assessed using ultrasound (in vivo) as well as pressure myography and AFM (in vitro), hence emphasizing the different metrics having different meanings, though with overall consistent implications.[41]

Hypertension

Uncontrolled hypertension is one of the most common risk factors for myriad cardiovascular diseases; it, too, associates with marked increases in arterial stiffness. There are many different ways to induce hypertension in mice, including salt-loading, blocking endothelial-derived nitric oxide synthase using N(G)-Nitro-L-arginine methyl ester (L-NAME), surgically introducing constrictions, and chronic infusion of angiotensin II (AngII) or norepinephrine. Each model provides important, complementary insights. The so-called transverse aortic constriction model is particularly useful for it introduces proximal hypertension mainly via a mechanical perturbation. Nevertheless, it elicits infiltration of inflammatory cells and engages a local AngII response, both contributing to a structural stiffening of the wall.[42,43] Because of the central role of the renin-angiotensin system, chronic infusion of AngII is very common, with diverse arterial phenotypes being possible.[44] Again emphasizing the importance of matrix cross-linking in arterial stiffness, blocking the effects of lysyl oxidase (using β-amino-propionitrile, BAPN) in AngII-induced hypertension prevents the expected increase in PWV in mice.[45] The important dependence of mechanosensing in hypertensive arterial remodeling was demonstrated directly by showing attenuated remodeling in mice lacking the α1-integrin subunit[46]; integrins are, of course, key components of mechanotransduction in arteries. At least in the AngII-infused model, aortic stiffening depends both on elevated pressure-induced wall stress and inflammatory cell burden, which was demonstrated clearly using mice deficient in T-cells or interleukin 17a.[47] Again, however, it was structural, not material, stiffening that emerged,[48] suggesting yet again that the intramural cells try to mechanoregulate material stiffness. It is, nonetheless, the structural stiffness that affects the hemodynamics (see Eq. (9.1), Box 9.1), hence

reinforcing the importance of measurements of wall thickness, though this should ideally be total wall thickness, not just intimal-medial thickness, since adventitial fibrosis is evident in many cases of arterial stiffening, ranging from aging to hypertension.

Comparison of methods

In the preceding sections, we reviewed the primary methods available for measuring arterial stiffness, both in vivo and ex vivo, and illustrated their use via brief discussions of diverse mouse models. As elaborated in Boxes 9.2 and 9.3, loading conditions significantly influence such measurements.[1] Table 9.2 illustrates how differences in loading conditions and methodologies can potentially lead to large differences in calculated values of stiffness for the mouse aorta. As an example, note that reported values of material stiffness obtained from AFM (radial compressive in the traction-free state) and biaxial testing (circumferential and axial tensile in the in vivo stressed state) can differ by three *orders of magnitude* (i.e., 1000×). Clearly, such metrics cannot be compared directly. Although we did not detail appropriate constitutive relations, they are essential to the interpretation of measurements. Given that the arterial wall exhibits strongly nonlinear, anisotropic behaviors over finite deformations, appropriate theoretical frameworks should be employed.[18] We emphasize further that the associated reference state should be chosen carefully noting that stress-free (approximated via a series of judicious cuts), traction-free (in the absence of applied loads), and in vivo (e.g., in vivo value of axial stretch and diastolic pressure) can each be appropriate, indeed convenient, depending on the metric of interest. When using the in vivo state as a reference, however, one must ensure that the state of "prestress" is accounted for appropriately, which can be achieved in different ways depending on the application. As an example, our group has used three different approaches simply when considering the in vivo reference, with applications to quantifying the hemodynamics, the mechanobiological state, or a reference for complex subject-specific geometries.[49–51] One approach is not necessarily better than another, they are simply different with different utilities.

Recommendations

In this section, we offer a few recommendations for choosing an appropriate method to study arterial stiffness. First, if a direct comparison/translation is to be made to human studies, in vivo measurement of PWV may be an appropriate choice. We emphasize again, however, the importance of the associated loading conditions: blood pressure at the time of measurement strongly influences the value of the calculated in vivo stiffness. Therefore, care must be taken to ensure that measured effects are not due to anesthesia and/or emotional stress influencing blood

pressure. Another potential factor that mandates in vivo studies is the requirement for follow-up measurements. If follow-up measurements are not required and excised tissue can be obtained, ex vivo measurements—not affected by the large confounding influence of blood pressure—may be more appropriate. Importantly, PWV can be approximated from ex vivo measurements of pressure and diameter (when performed under loading conditions similar to in vivo) using the Bramwell—Hill equation (Eqs. (9.3) and (9.5), Table 9.1),[10,52] without the need to take into account the effects of anesthesia or emotional stress, while allowing direct comparisons between in vivo and ex vivo. In this regard, note that perivascular tissue typically exerts a radial load on the adventitial surface, thus affecting the transmural pressure that distends the wall. Such perivascular effects can be significant and should be accounted for.[53]

Ex vivo methods come in many varieties. Indentation methods such as AFM provide extremely detailed maps ("images") of spatially resolved stiffness values. Yet, often performed as an indentation test, AFM measures compressive—not tensile—stiffness, often in the excised traction-free state. Hence, translation of such measurements to whole-artery, in vivo—relevant arterial stiffness values is cumbersome.

Myography has become a well-established method to functionally test arterial responses to vasoactive stimuli. In particular, wire myography (requiring only small ring-like samples) allows simultaneously testing of responses to various stimuli. Wire myography also has the advantage that side branches, if present, do not have to be ligated (pressure myography does require this, in order for the artery under test to hold pressure). Smooth muscle

---

BOX 9.5 Different material stiffness metrics

Many different metrics of material stiffness are used in arterial stiffness research. Often encountered is Young's modulus (E), a measure of the extensional stiffness (i.e., change of stress with respect to strain) of a material, which can be inferred by plotting normal stress versus extensional strain in a *uniaxial* stress test.[76] E is defined for LEHI (linear, elastic, homogeneous, isotropic) material behavior. The artery wall material, however, is strongly nonlinear and anisotropic, limiting the appropriateness of E in arterial mechanics.

The linearity assumption of E is commonly "overcome" by estimating an *incremental* Young's modulus (E_{inc}) as the local tangent of the circumferential Cauchy stress-stretch curve obtained during inflation (Eq. (9.7), Table 9.1). However, such loading is not uniaxial but rather biaxial (with lateral contraction due to a Poisson effect in standard "uniaxial" tests and, with strong biaxial coupling present due to the axial (pre)stretch in pressurized vessels (Box 9.3). The local tangent, hence, is influenced by both circumferential and axial behaviors and cannot be interpreted as an "independent," circumferential, material stiffness.

Strictly speaking, (material) stiffness is defined as a change in stress with respect to a change in conjugate strain (or stretch).[76] Common stress-strain pairs are given in Table 9.4, below. Note that E_{inc} when obtained from Cauchy stress and stretch ratio (a component of the deformation gradient or the left stretch tensor), violates this definition.

TABLE 9.4 Conjugate stress-strain measures.

Stress measure	Conjugate strain measure	Volume	Integral of stress-strain product over volume
Cauchy ($\boldsymbol{\sigma}$)	—	Deformed/current	—
First Piola—Kirchhoff ($\mathbf{P}$)	Deformation gradient ($\mathbf{F}$)[a]	Original/material	Stored energy
Second Piola—Kirchhoff ($\mathbf{S}$)	Green—Lagrange ($\mathbf{E}$)	Original/material	Stored energy

[a]*which has stretch ratios λ on diagonal in the absence of rigid body rotations.*

Commonly observed (circumferential) stiffness metrics that obey conjugacy are $\partial P_{\theta\theta}/\partial\lambda_\theta$ and $\partial S_{\theta\theta}/\partial E_{\theta\theta}$. Both, however, are defined with respect to the original volume. Typically, one wants a (material) stiffness metric to reflect how a material will deform if it is loaded in the *current* configuration. Baek et al. invoked the theory of small-on-large to arrive at such a metric that is useful in fluid—solid interaction simulations over a cardiac cycle ($\mathbb{C}$; Eq. (9.8), Table 9.1),[49] which has the advantage that it can be intuitively used to directly operate on a small strain tensor ($\boldsymbol{\varepsilon}$; the *small* strain in small-on-large theory), yielding the associated change in Cauchy stress ($\boldsymbol{\sigma} = \mathbb{C} : \boldsymbol{\varepsilon}$).

contraction in wire myography occurs under non-physiological axial loading, however, and may not be directly comparable to the physiological case.[54] This issue is resolved in pressure myography, where the artery can be held at its in vivo length. When the main study of interest is to quantify structural stiffness (Box 9.1) under reproducible, in vivo relevant conditions, pressure myography is a good compromise. When constitutive behavior and material stiffness (Box 9.1) are of particular interest, biaxial testing has a clear advantage.

Biaxial testing enables parameterization of an anisotropic *constitutive* model of the arterial wall material. Such a constitutive model enables calculation of true material stiffness parameters (Box 9.5), which have been shown to be particularly relevant in aneurysm mechanobiology,[28] and which are essential in informing finite element formulations.[49] pDIC, finally, extends biaxial testing to account for nontubular/nonuniform geometries. This is also particularly relevant in aneurysm research, yielding detailed maps of material parameters along the entire aneurysmal surface. As such, it allows properties to be compared, as, for example, at the neck and in the dome regions of an aneurysm. pDIC is, however, a highly specialized technique, typically requiring the combination of three measurement modalities ("normal" biaxial testing, OCT, and pDIC imaging) as well as inverse finite element modeling. As such, its use is practically limited to dedicated engineering labs.

Chapter 10

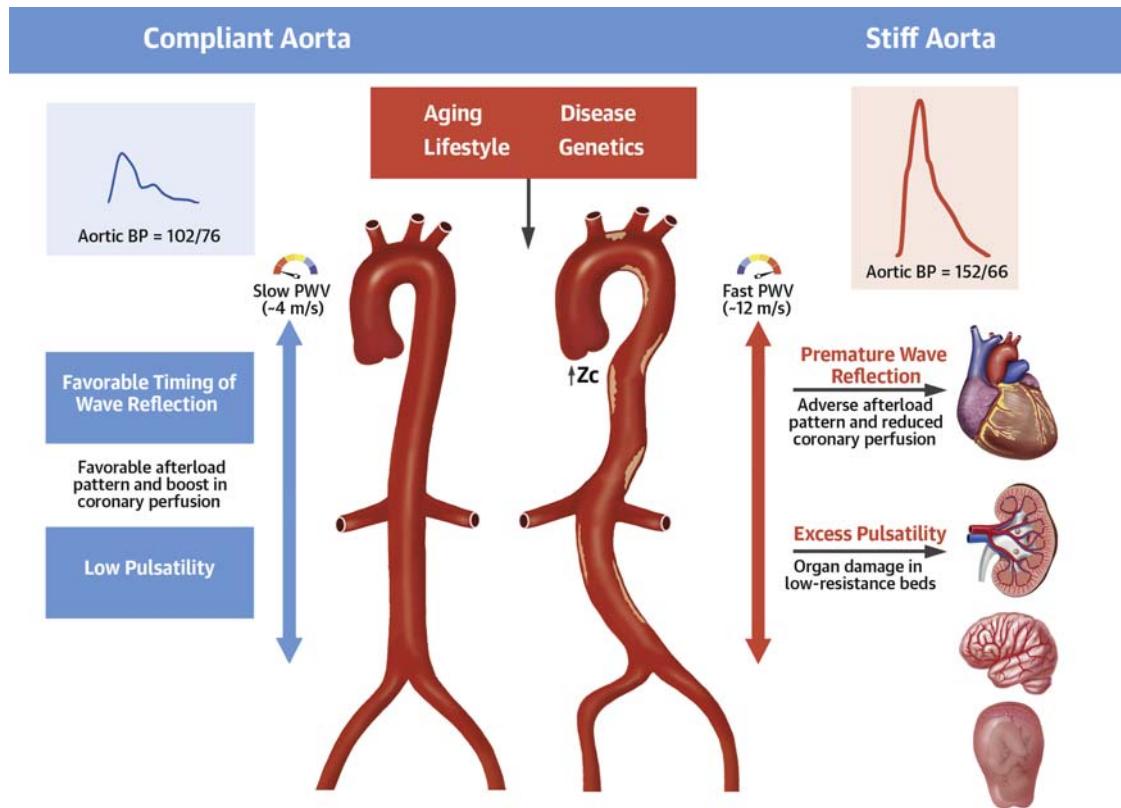
Hemodynamic role of the aorta

Julio A. Chirinos[1,2]

[1]University of Pennsylvania Perelman School of Medicine, Hospital of the University of Pennsylvania and Perelman Center for Advanced Medicine, Philadelphia, PA, United States; [2]Ghent University, Ghent, Belgium

Introduction

The aorta, a large elastic artery, exerts important hemodynamic role beyond its conduit function. A healthy aorta exerts a powerful cushioning function, contributing to the delivery of nearly steady flow to the microvasculature despite the intermittent left ventricular (LV) ejection. Increased large artery stiffness (LAS), which occurs with aging and various disease states, causes an impairment in this cushioning function, leading to multiple deleterious consequences on pulsatile arterial hemodynamics, and ultimately on target organs (Fig. 10.1). LAS causes isolated systolic hypertension,[1] an endemic condition characterized by increased systolic blood pressure with normal or low diastolic blood pressure (i.e., increased pulse pressure [PP]), responsible for a large proportion of the global burden of cardiovascular morbidity and mortality. Second, LAS reduces coronary perfusion pressure and increases LV afterload, promoting LV remodeling, dysfunction, and failure, as discussed in Chapters 15, 16, 17 and 36.[2] Third, by promoting increased arterial pressure and flow pulsatility, LAS leads to increased penetration of pulsatile energy into the microvasculature of target organs, particularly those that require high blood flow and therefore must operate at low arteriolar resistance.[3] Interestingly, target organ failure (such as chronic kidney disease and diabetes) can lead to further arterial stiffening,[4] creating a vicious cycle of hemodynamic dysfunction that ultimately contributes to the pathogenesis of heart failure (HF), impaired coronary perfusion, kidney disease, and cerebrovascular disease. Recent data also support a potential role for LAS in metabolic dysfunction and diabetes. Consistent with the central role of LAS in human health, measures of LAS (such as carotid-femoral pulse wave velocity, CF-PWV) independently predict the risk of incident cardiovascular

events in various populations including clinical and community-based cohorts.[5-7]


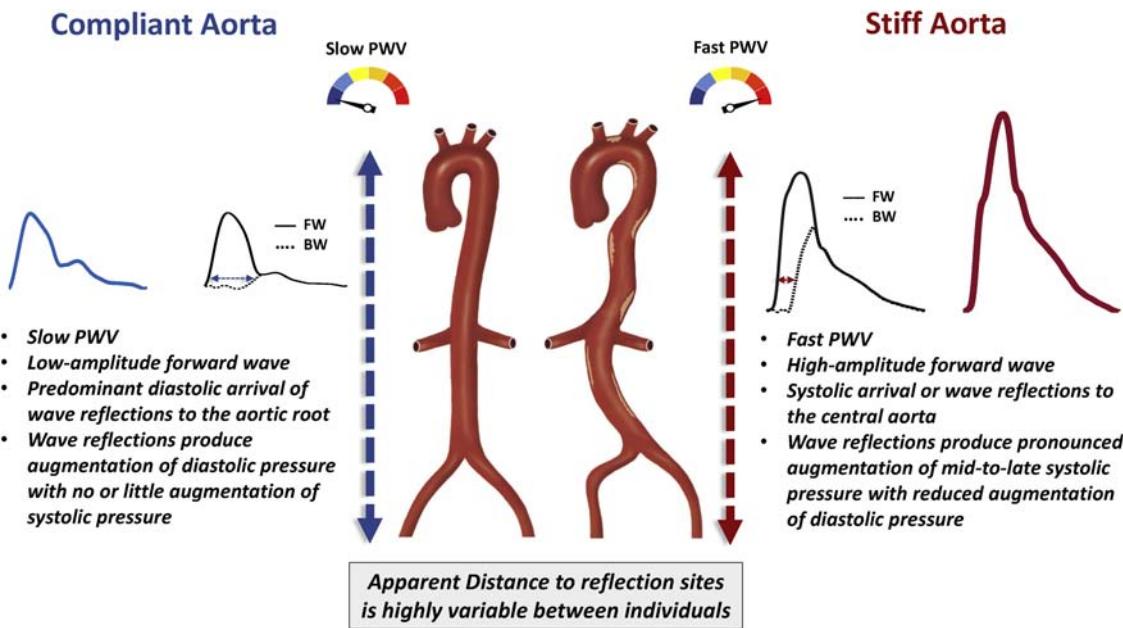
This chapter, largely based on a recent review of aortic stiffness by the author and collaborators,[7] provides an overview of key principles related to the hemodynamic role of the aorta, the impact of aortic stiffening on target organs. Specific aspects of the hemodynamic role of the aorta will be developed in dedicated chapters throughout this textbook. This chapter also provides a brief description of key mechanisms leading to aortic stiffening, which are developed in detail in subsequent chapters.

Hemodynamic consequences of large artery stiffness

The hemodynamic consequences of LAS are variable and relatively complex, but can be conceptually described from: (1) The effects of LAS on the early aortic systolic pressure rise; (2) The effects of LAS on the speed at which the cardiac pulse travels in the arterial wall[2,8]; (3) The effects of LAS on wave reflections at first-order bifurcations.

Effect on the early systolic aortic pulse pressure rise

As described in detail in Chapters 1 and 3, at the beginning of each cardiac cycle, the left ventricle generates a forward-traveling pulse that increases pressure and flow in the proximal aorta. The amount of pressure increase required to push the pulse flow through the aortic root in early systole depends on the local impedance offered by the proximal aorta. This local impedance, called the *characteristic impedance* (Zc), is a measurable property that increases due to aortic root wall stiffening, a small aortic cross-sectional area, or both.[2] Interestingly, Zc is much more sensitive to size (i.e., cross-

FIGURE 10.1   Role of large artery stiffness in health and disease. In young healthy adults, a compliant aorta: (A) effectively buffers excess pulsatility due to the intermittent left ventricular ejection; (B) exhibits a slow pulse wave velocity (PWV), which allows pulse wave reflections to arrive to the heart during diastole, effectively increasing diastolic coronary perfusion pressure but not systolic ventricular load. A number of factors increase aortic wall stiffness, which leads to several adverse hemodynamic consequences. Aortic stiffening leads to increased forward wave amplitude on one hand and premature arrival of wave reflections to the heart on the other. This leads to increased pulsatile load to the left ventricle in systole and a reduced coronary perfusion pressure in diastole, ultimately promoting myocardial remodeling, dysfunction, failure, and a reduced perfusion reserve (even in the absence of epicardial coronary disease). This adverse hemodynamic pattern also results in excessive pulsatility in the aorta, which is transmitted preferentially to low-resistance vascular beds (such as the kidney, placenta and brain), because in these organs, microvascular pressure is more directly coupled with aortic artery pressure and flow fluctuations. *Reproduced from Chirinos JA, Segers P, Hughes T, Townsend R., Large-artery stiffness in health and disease: JACC state-of-the-art review. **J Am Coll Cardiol**. 2019; 74(9):1237−1263, with permission from Elsevier.*


sectional area) than to the stiffness of the aortic wall material. Therefore, aortic dilation may partially overcome the hemodynamic consequences of aortic root stiffening, and conversely, wall stiffening in the absence of eccentric remodeling of the root can have particularly pronounced effects on PP. However, excessive aortic dilation with aneurysm formation is clearly deleterious and associated with a risk of aortic rupture. Although the physical principles governing PP are well understood, the causal interrelationships between aortic dilation, aortic wall stiffening, and pressure pulsatility are likely multidirectional and incompletely understood from a biologic standpoint.

Effect on wave speed (Fig. 10.2)

As discussed in detail in Chapter 11, the energy wave generated by the LV (incident wave) is transmitted by conduit vessels and partially reflected at innumerable sites of impedance mismatch throughout the arterial tree, including

points of change in wall diameter, change in material properties along the artery wall, and points of branching. A myriad of scattered tiny reflections from individual reflection sites are conducted back to the proximal aorta and merge into a net reflected wave. The timing of arrival of reflected waves to the proximal aorta is strongly influenced by the pulse wave velocity (PWV) of conduit vessels, particularly the aorta, which transmits both forward and backward traveling waves. Stiffer aortas conduct waves at greater PWV, and therefore promote an earlier arrival of the reflected waves for any given distance to reflection sites.

In the presence of a slow PWV, as occurs in young, healthy adults with elastic aortas, wave reflections arrive at the aorta predominantly during diastole, augmenting diastolic pressure. In contrast, when PWV increases due to aortic wall stiffening, wave reflections return to the proximal aorta in mid-to-late systole, producing systolic pressure augmentation, with loss of diastolic pressure augmentation and widening of the aortic PP (Fig. 10.2).

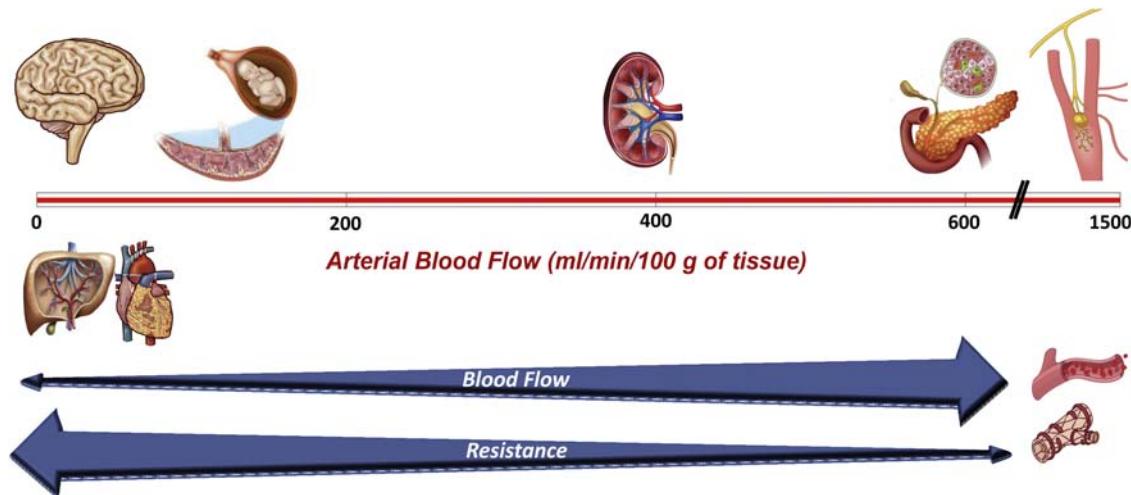
FIGURE 10.2   Consequences of increased aortic stiffness on the central pressure waveform. The left side represents what occurs with a highly compliant aorta, as occurs in young healthy adults; the right side represents a very stiff aorta, as occurs in the elderly and/or in the presence of various disease states. A stiff aorta is associated with a high-amplitude forward wave and a faster pulse wave velocity (PWV), determining a faster forward and backward (reflected) wave speeds. This determines an earlier arrival of wave reflections to the aorta, with progressive loss of diastolic pressure augmentation and increased late systolic augmentation. The figure illustrates two rather extreme situations, with most people falling "in between." Moreover, it should be emphasized that the apparent distance to reflection sites is highly variable between individuals and may become a dominant determinant of the timing of wave reflections in populations that exhibit stiff aortas or in the setting of hypertension. The term "apparent" is used because reflection sites can modify the morphology of reflected waves making it appear "shifted" in time (i.e., a shift to the right appears as if a reflection site is further away from the heart, for any given PWV). *BW*, backward wave; *FW*, forward wave. *Reproduced from Chirinos JA, Segers P, Hughes T, Townsend R., Large-artery stiffness in health and disease: JACC state-of-the-art review.* **J Am Coll Cardiol**. *2019; 74(9):1237−1263, with permission from Elsevier.*

Interestingly, this phenomenon cannot be measured via brachial PP measurements because the reflected wave tends to augment central systolic pressure to a greater degree than brachial pressure. Moreover, even at the central aorta, the reflected wave not only increases central peak pressure but also has a predominant effect on the morphology of the pressure waveform, with a pronounced mid-to-late systolic component relative to early systolic and diastolic pressure. Therefore, individuals with identical central PP values can have markedly different central pressure profiles and for any given absolute blood pressure level, late systolic loading from wave reflections determines abnormal ventricular−vascular interactions and an adverse LV loading sequence,[9−11] as will be discussed in detail in Chapter 16.

Although forward and backward traveling waves are often seen as having different determinants, they are in fact highly interrelated. First, the amplitude of the reflected wave is highly dependent on the amplitude of the forward wave. In turn, wave reflections can re-reflect at the LV, becoming rectified and thus contributing to the amplitude of the forward wave.[12] In the presence of very high PWV, as occurs with advanced age and/or disease, multiple reflections and re-reflections occur in a single cardiac cycle, and forward and backward waves are highly dependent on each other.

Some caveats to the simplified description above are worth mentioning. First, although the reflected wave appears discrete and is often referred as a single wave, it is important to keep in mind that the net reflected wave measured in at the aortic root is the net sum of innumerable tiny reflections. Accordingly, the reflected wave does not arise from a single reflection site, and the concept of the "effective" length of the arterial tree (i.e., distance to the reflection site) is an unrealistic concept. As discussed in detail in Chapter 11, given the highly distributed nature of wave reflections, individual reflection sites have little importance relative to the bulk of reflections originating elsewhere (except for strong reflection sites in specific conditions, such as aortic coarctation or complete distal aortic occlusion). Finally, it is important to note that wave reflections and arterial stiffness do not necessarily vary in the same direction. In general, arterial stiffness *modulates* the effects of wave reflections on the central pressure profile by affecting the timing of their arrival to the proximal aorta. However, wave reflections also vary independently

of arterial stiffness due to modulation of muscular artery stiffness and size,[13] as well as microvascular tone. Although the timing of wave reflections is correlated with aortic PWV, there is also great variability in the distance to reflection sites, such that this relationship is not perfect. Moreover, the variability in the distance to reflection sites can become the dominant determinant of the timing of wave reflections within patient populations that in general exhibit stiff aortas (such as older, diseased populations), in the setting of hypertension or in the setting of specific pharmacologic interventions that modulate muscular artery properties.[13]

Effect of aortic stiffness on wave reflections in first-order bifurcations


In young adults, aortic PWV is much lower than the PWV of intermediate-sized muscular arteries. With aging, aortic PWV increases and matches the PWV of these more distal segments. This has led to the controversial proposition that increased PWV with aging produces "impedance matching" with the stiffer muscular arterial segments, reducing wave reflections at first-order bifurcations (such as the aortic-femoral or aortic-carotid interfaces).[14] This principle has been extended to propose protective reflections at first-order branches of target organs such as the brain and the kidney. Several aspects of this concept are inconsistent with physiologic considerations. First, wave reflections at the inlet of target organs amplify the PP, and thus increase it in daughter branches to a much greater degree than they prevent energy penetration. This is because PP amplification into the branches is linearly related to the local reflection coefficient, whereas prevention of energy penetration is related to its square root; for example, a local reflection coefficient at the aortic-carotid interface of 0.10 would prevent only 1% of energy penetration but would increase carotid PP by 10%. Second, *impedance matching* does not equal *PWV matching* between parent and daughter vessels, but largely depends on vessel size (specifically, the ratio of the area of the parent vessels to the sum of the areas of the daughter vessels). This is due to the fact that characteristic impedance of a vessel is much more dependent on its caliber than on its stiffness. The geometry of vessels at first-order bifurcations tends to be already optimized for forward energy transmission,[15] such that impedances are relatively well-matched even before the aorta stiffens with age. Third, due to this matched geometry, reflections at single bifurcations are rather small relative to the composite reflected wave arising from the sum of innumerable tiny reflections elsewhere. For example, reflection coefficients as small as 0−0.15 have been reported for the aorta-carotid interface,[14] which would prevent only up to ~2.25% of energy transmission into the carotid artery. This contrasts with systemic reflection coefficients of ~0.5 or higher,

which in sum return as much as ~25% of the energy contained in the pulse to the central aorta. Fourth, the bulk of reflections originating outside the target organs (such as the brain and kidney) and returning to the aorta, penetrate these organs as forward waves. This may be particularly important for reflected wave returning from the lower body and traveling up the carotid arteries as forward waves into the brain vasculature. Moreover, arteries upstream of the carotid appear to be more effective at attenuating high-frequency flow pulsations (such as those produced by the initial cardiac contraction) than low-frequency oscillations (contained in the reflected wave from the lower body),[16] suggesting that the latter wave more effectively penetrates the cerebral microvasculature. Therefore, a protective effect of wave reflections at the inlet of target organs is not substantiated from a theoretical standpoint, not clearly demonstrated from a clinical standpoint, and its quantitative importance remains to be determined by rigorous studies that account for the complexity of whole-system hemodynamics. Clearly, further work is required regarding this important issue, which has implications for common disease states such as age-related dementias and chronic kidney disease. The reader is also referred to discussions of this topic with somewhat different points of view by various experts in Chapters 11, 17, and 40.

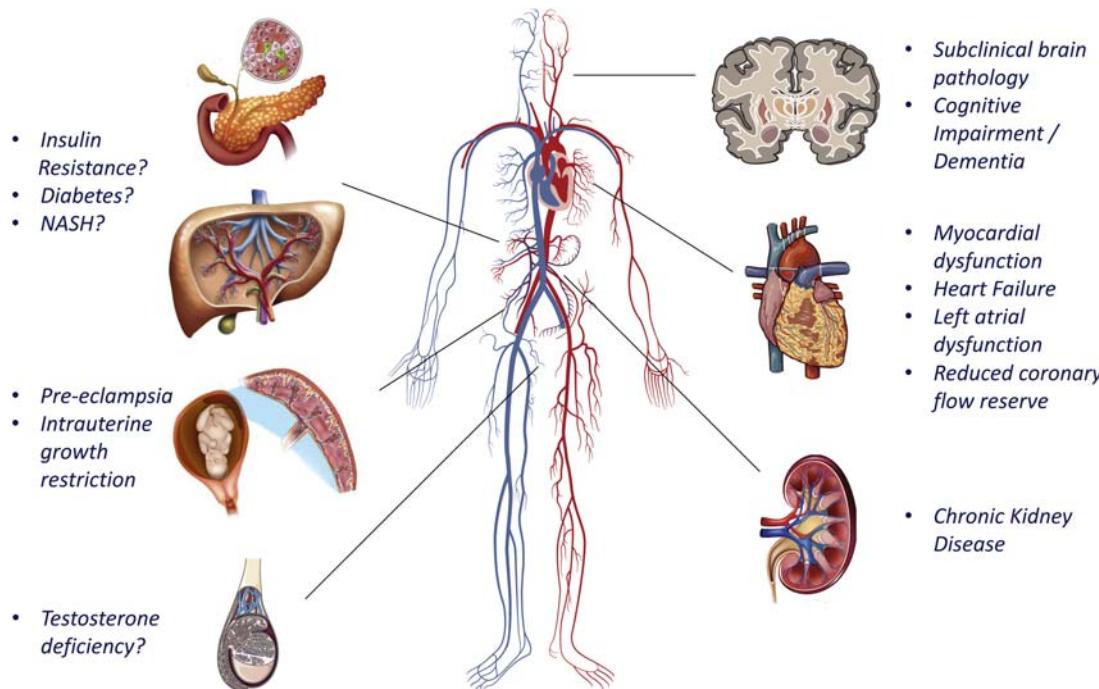
Aortic stiffening and its role in target organ damage

When aortic stiffness increases, the resulting increase in arterial pressure and flow pulsatility can exert deleterious effects in various systemic organs, particularly those that exhibit richly perfused low-resistance vascular beds such as the kidney, the placenta, and the brain (Fig. 10.3). Both increased pulsatile pressure (barotrauma) and pulsatile flow (with excessive shear forces from increased pulsatile flow velocity) can result in microvascular damage in these organs. Similarly, pancreatic islets are characterized by a low-resistance, torrential flow, dense glomerular vascular network. Through effects on pancreatic islets and the liver, increased LAS may also contribute to metabolic dysfunction, and accumulating evidence links increased LAS to incident new-onset diabetes. Although myocardial vessels also exhibit low resistance, but are protected during systole by the myocardial contraction, which extrinsically compresses intramyocardial blood vessels.

However, increased LAS does result in increased pulsatile load to the left ventricle (which directly interacts with the pulsatile load imposed by aorta and downstream wave reflections) and a reduction in diastolic perfusion pressure. It is useful to discuss the cardiac consequences of arterial stiffening (derived from its effects on load and the diastolic pressure decay) separately from consequences in peripheral high-flow, low-resistance target organs. A list of potential

FIGURE 10.3   Arterial blood flow per unit of tissue mass in various organs. The kidney, placenta-fetal unit, heart, brain, pancreatic islets, liver, and testicle are shown. Although liver blood flow is much higher than shown, most of it is from the portal vein (not accounted for in the graph, which represents only arterial flow). For the pancreas, flow rates represent islet blood flow, rather than combined endocrine and exocrine pancreatic blood flow. *Modified from Chirinos JA, Segers P, Hughes T, Townsend R. Large-artery stiffness in health and disease: JACC state-of-the-art review.* **J Am Coll Cardiol***. 2019; 74(9):1237−1263, with permission from Elsevier.*

consequences of arterial stiffening on various target organs is shown in Fig. 10.4.

Arterial stiffness and the heart


The adverse consequences of aortic stiffening and abnormal pulsatile hemodynamics on the heart are discussed in detail in Chapters 13−18. Only a brief description will be provided here. The aorta affects ventricular−arterial interactions via: (1) Its impact on the early systolic pressure rise, which is a key determinant of peak myocardial wall stress in early systole; (2) Its impact on the timing of arrival of wave reflections to the LV, which increases late systolic load, promoting LV remodeling, fibrosis, diastolic dysfunction, and reduces coronary perfusion pressure in diastole.[9]

During early ejection, the characteristic impedance of the proximal aorta (Zc) governs the aortic and LV pressure rise for any given blood flow from the LV into the aorta. Peak myocardial wall stress occurs in early systole, when systolic pressure coexists with quasi-diastolic LV geometry (thinner wall and larger cavity), consistent with Laplace's law.[17] Therefore, aortic Zc impacts peak myocardial wall stress in early systole. Interestingly, although absolute levels of wall stress in early systole are high, in the absence of ischemia, the LV myocardium seems to adapt relatively well to increased load during this early period of contraction.[18] However, peak myocardial wall stress is a key determinant of myocardial oxygen consumption,[19] implying that a high aortic root characteristic impedance increases myocardial oxygen demand.

As discussed above, another important consequence of aortic stiffening is an increase in aortic PWV, which favors an earlier arrival of reflected waves to the heart. Wave reflections arriving at the heart during mid-to-late systole rather than diastole determine an increase in mid-to-late systolic load on one hand, and a reduction in the area under the pressure curve in diastole (i.e., coronary perfusion pressure) on the other (Figs. 10.1 and 10.2).

As discussed in detail in Chapter 16, pulsatile afterload during mid- and late-systole has adverse consequences on LV remodeling and function.[9,20,21] A prohypertrophic and profibrotic effect of late systolic load has been demonstrated in experimental studies in animal models,[20] and is also supported by human studies[22−24] Similarly, experimental animal data demonstrate that late systolic load has a profound effect on LV relaxation and systolic−diastolic coupling,[21] which is supported by human studies demonstrating that late systolic load is independently associated with diastolic dysfunction in clinical and community-based cohorts[25−27] and strongly predicts new-onset HF in the general population.[28,29] Late systolic load is also associated with atrial dysfunction[30] and independently predicts the risk of atrial fibrillation.[31] Interestingly, adverse consequences of impaired pulsatile hemodynamics on the LV seem to be more directly related to late systolic load and the timing of wave reflections to the proximal aorta, rather than to aortic stiffness per se. Hence, measures of LAS (such as CF-PWV) predicted incident HF in some studies,[6,32] but not others,[33] whereas measures of late systolic hypertension seem to be more robustly associated with adverse left heart quantitative phenotypes, incident HF, and incident atrial fibrillation. It should be noted that the timing of wave reflection is not only dependent on aortic PWV but also on muscular artery function, which can impact the apparent distance to reflection sites. In general, direct measurements

FIGURE 10.4   Potential consequences of large artery stiffness on target organs. LAS can impact the heart through effects on afterload (particularly, modulation of the timing of wave reflections) and may damage low-resistance organs via excess arterial pulsatility. Importantly, not all these potential consequences are similarly well-established. In general, there is a large body of evidence supporting deleterious effects on the kidney and heart, moderate evidence for the brain and the placenta, and early/limited evidence for the pancreas, liver, and testicles (see text for details). *ASH*, Nonalcoholic steatohepatitis. *Modified from Chirinos JA, Segers P, Hughes T, Townsend R. Large-artery stiffness in health and disease: JACC state-of-the-art review.* **J Am Coll Cardiol**. *2019; 74(9):1237−1263, with permission from Elsevier.*

of LV pulsatile afterload and late systolic load (which can be accomplished with analyses of time-resolved aortic pressure and flow waveforms),[9] rather than measurements of LAS per se, appear to most informative for the assessment of ventricular afterload, ventricular−arterial interactions, and for predicting incident HF and atrial fibrillation. The assessment of ventricular−arterial interactions is discussed in detail in Chapters 15−17.

A premature arrival of wave reflections to the proximal aorta also determines a loss of diastolic pressure augmentation by wave reflections (Figs. 10.1 and 10.2). The reduction in aortic compliance by aortic stiffness along with premature wave reflections determines a steep diastolic pressure decay, reducing coronary perfusion pressure.[34] The increase in systolic load along with the reduction in coronary perfusion pressure induced by aortic stiffening and premature wave reflections adversely impact myocardial supply/demand, which may partially exhaust the coronary perfusion reserve at rest, particularly in women.[35] This has implications exercise tolerance due to impaired coronary perfusion even in the absence of epicardial coronary stenoses, a topic that requires further research in specific populations.

Arterial stiffness and the kidney

The relationship between the aorta and the kidney is bidirectional. On one hand, aortic stiffness may promote progressive declines in kidney function due to glomerular damage, whereas established kidney disease promotes further aortic stiffening.

The kidney exhibits high-flow, low-resistance arterial physiology, rendering glomerular capillaries susceptible to trauma from pulsatile pressure and blood flow.[36] Therefore, aortic stiffness may contribute to the pathogenesis of albuminuria and reduced glomerular filtration capacity over time.

Patients with established chronic kidney disease (CKD) (particularly diabetic CKD) exhibit increased CF-PWV, which worsens as kidney function declines.[37,38] Once established, CKD enhances aortic stiffening due to several mechanisms, including dysregulated bone and mineral metabolism with vascular calcification,[39−41] inflammation,[42] neurohormonal dysregulation, (including increased renin-angiotensin-aldosterone axis activation),[43] and sympathetic hyperactivity.[44] LAS independently predicts adverse cardiovascular outcomes in CKD patients, including incident hospitalized HF,[6] progression to end-stage

kidney disease, and all-cause death, independent of office blood pressure.[45] LAS is also predictive of all-cause death among patients with end-stage kidney disease on hemodialysis.[46] The relationship between arterial stiffness, pulsatile hemodynamics, and renal disease is discussed in detail in Chapter 40.

Arterial stiffness and the brain

Given its high metabolic demand, the brain also exhibits low-resistance, high-flow physiology,[47] thus being susceptible to pulsatile microvascular trauma.[3] Although on average, the brain receives a lower blood flow per gram of tissue compared to the kidney, activation of specific areas of the brain are associated with sharp regional increases in blood flow. Therefore, the fine regulation of regional arteriolar resistance is a key aspect of neurovascular function.

Maintaining consistent and well-regulated cerebral perfusion is essential for proper cognitive and physical function, and abnormalities in regional perfusion may be key for the progression of cognitive impairment and dementia. Microvascular dysfunction in the brain may lead to impaired neurovascular coupling and regional hypoperfusion, particularly in the white matter, which receives less perfusion than the gray matter. An increased LAS with consequent increased pulsatility in the cerebral circulation may promote brain microvascular remodeling, impaired oxygen delivery, and impaired blood flow autoregulation (a multifactorial process of the cerebral circulation which regulates vascular resistance and perfusion through myogenic, autonomic, and metabolic mechanisms).[48] A growing body of evidence links LAS with age-related cognitive dysfunction and dementia,[49−51] as well as imaging phenotypes of regional brain atrophy, cerebral small vessel disease, including white matter hyperintensities, lacunar infarcts, cerebral microbleeds, and enlarged perivascular spaces.[52,53] The relationship between LAS, pulsatile arterial hemodynamics, and cognitive dysfunction and dementia is discussed in detail in Chapter 41.

In addition, emerging data suggest that arterial stiffness also increases the risk for subclinical brain infarction and incident stroke.[5] This may be due to common risk factors between atherosclerosis and aortic stiffening and/or to an increased risk of plaque rupture induced by excessive pressure and flow pulsatility. For a detailed discussion regarding the relationship between arterial stiffness and atherosclerosis, the reader is referred to Chapter 38.

Arterial stiffness and the placental circulation

Given the fetal metabolic needs, the placenta also operates at very high-flow/low vascular resistance, particularly as pregnancy progresses toward late stages. LAS has been implicated in placentofetal pathology, particularly preeclampsia (a late pregnancy complication characterized by hypertension and proteinuria) and intrauterine growth restriction (a condition in which the fetus is smaller than expected for gestational age) (Fig. 10.4).

Preeclampsia is associated with increased LAS.[54] More importantly, differences in LAS and pulsatile hemodynamics appear to precede the development of late pregnancy complications. A high PP early in pregnancy is predictive of subsequent preeclampsia, but not of uncomplicated gestational hypertension.[55] A meta-analysis[56] demonstrated that CF-PWV is increased in women who subsequently develop preeclampsia or intrauterine growth restriction. Whether LAS and/or adverse pulsatile hemodynamics causally contribute to these pregnancy complications, whether LAS measurements have clinical value to predict these complications to facilitate early interventions, and whether pulsatile hemodynamics can be a target for preventive therapeutic interventions in this setting remains to be determines. Similarly, it is unknown whether women who develop preeclampsia exhibit long-term alterations in LAS and whether an increased LAS may lead to an increased cardiovascular risk in this population. Chapter 42 discusses the role of arterial stiffness and pulsatile hemodynamics in pregnancy-related complications.

Aortic stiffness, metabolic dysfunction, and diabetes mellitus

It has long been known that diabetes mellitus (DM) and obesity are important risk factors for accelerated large artery stiffening. However, recent data indicate that increased LAS precedes the development of overt DM, suggesting a bidirectional relationship.[57−61]

As discussed in detail in Chapter 30, there are several potential mechanisms that could explain the relationship between LAS and new-onset diabetes. LAS may contribute to the pathogenesis of insulin resistance and DM through its hemodynamic effects. The endocrine pancreas, which comprises only $\sim 1\%-2\%$ of the pancreatic mass, receives $\sim 10\%-20\%$ of its blood supply. Therefore, in contrast to the exocrine pancreatic circulation, pancreatic islet blood flow is among the highest in the body when normalized for tissue mass (Fig. 10.3).[7,62] Like in other high-flow, low-resistance vascular beds, increased LAS has the potential to impact microvascular health in pancreatic islets, leading to dysfunctional or dysregulated endocrine function. Pancreatic islets exhibit a dense glomerular capillary network, which mediates chemical signaling between various endocrine cell types. Vascular integrity may be essential to maintain an order of sequential perfusion of β, δ, and α cells, which appears to allow for an adequate inhibition of glucagon secretion by insulin.[63] Moreover, hyperglycemia and the associated beta cell activation result in islet arteriolar dilation, capillary dilation, and increased

islet capillary pressure, suggesting that local hemodynamics participate in endocrine responses[64] Therefore, pancreatic islet microvascular dysfunction may contribute to the pathogenesis of type 2 DM via impaired insulin secretion and/or an imbalance between insulin/glucagon secretion.

Additional mechanisms may mediate the relationship between LAS and new-onset DM, as discussed in Chapter 30. These include elastin degradation in the aortic wall with production of elastin-related peptides (which can block insulin signaling), neurohormonal dysregulation (increased sympathetic tone and renin-angiotensin-aldosterone system activation), liver dysfunction, and skeletal muscle dysfunction.

The liver receives ∼25% of the cardiac output and exhibits a high-flow, low-resistance arterial circulation, since the hepatic artery provides approximately one-third of the liver blood flow.[7] The hepatic arterial circulation constantly regulates arterial flow to maintain total liver blood flow constant, regardless of changes in portal vein flow (hepatic arterial buffer response), which contributes to metabolic homeostasis.[65] Multiple studies have demonstrated an association between nonalcoholic fatty liver disease (NAFLD) and LAS.[66] Furthermore, among patients with NAFLD, LAS may be associated with liver fibrosis.[67] Given the important intersection of hemodynamic arterial function and metabolic function in the liver, it is possible that LAS contributes to the progression of NAFLD and hepatic insulin resistance, but further studies are required to assess whether a causal relationship between LAS and liver fibrosis exists. Finally, abnormal pulsatile hemodynamics due to LAS may impair normal postprandial vasodilation of skeletal muscle,[68–70] further promoting insulin resistance.[71,72] In general, it remains to be seen whether LAS causally contributes to pancreatic islet, skeletal muscle, or liver microvascular dysfunction, a question that should be pursued in future studies.

Once DM ensues, LAS may favor the development of diabetic complications. Diabetic individuals exhibit much higher CF-PWV than their nondiabetic counterparts,[73] even in the setting of established CKD[37,38] or heart failure with preserved ejection fraction.[74] Among patients with existing DM, increased LAS is associated with rapid progression of microvascular complications including diabetic retinopathy, nephropathy, and neuropathy. Further research is needed to clarify the mechanisms linking LAS and accompanying pulsatile hemodynamic changes with DM. Novel strategies that target arterial stiffness may help to prevent and slow the progression of complications of DM. The bidirectional relationship between LAS and DM appears to be highly clinically relevant, may offer novel therapeutic avenues, and should be the focus of further research.

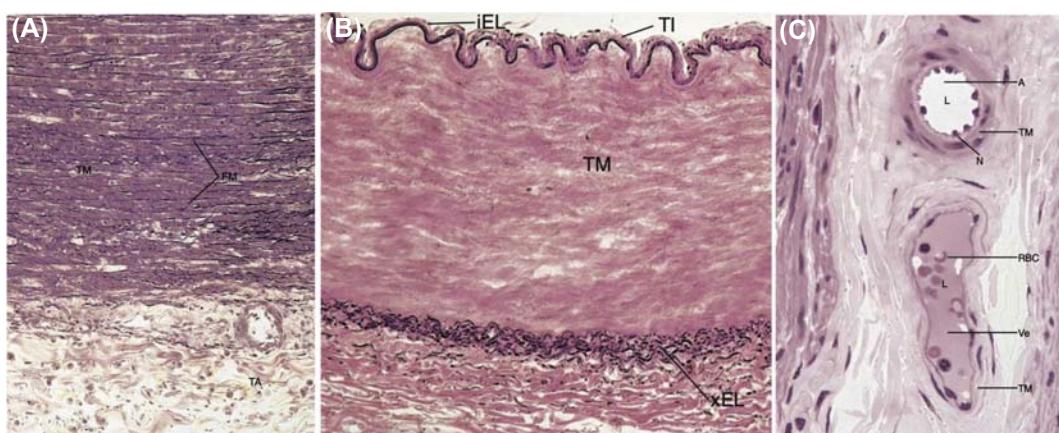
Arterial stiffness and testicular dysfunction

Several considerations also suggest a bidirectional relationship between testicular function and LAS. Androgen receptors can modulate vascular function and conversely, LAS with excess pulsatility may impact testicular microvascular function. Lower androgen levels are independently associated with greater LAS in older men.[75] The testicles exhibit Doppler features of a low-resistance vascular bed, suggesting that increased pulsatile energy in conduit vessels may damage the testicular microcirculation. An intact testicular microvascular network is required to maintain oxygen delivery and uptake by testicular tissue.[76] Abnormal vasoactive responses and structural degeneration of the testicular microvasculature occurs with aging, which is thought to play an active role in promoting aging of the testis. In animal models, a reduced capacity to regulate testicular blood flow is sufficient to impact testosterone secretion, even in the presence of intact Leydig cell function.[77] Although hemodynamic considerations and limited observational data suggest that LAS may contribute to microvascular damage in the testicles, further mechanistic research is required in this area.

Mechanisms of arterial stiffening and therapeutic approaches

The arterial wall has three main layers (intima, tunica media, and adventitia), which vary according to the artery type (Basic concept Box 10.1; Fig. 10.5 and Table 10.2).

Various processes in the aortic wall layers can affect LAS (Fig. 10.6). The medial layer is the main determinant of LAS, via its various constituents: the extracellular matrix proteins elastin and collagen, vascular smooth muscle cells (VSMCs), cell-matrix connections, and matrix constituents such as glycosaminoglycans interconnecting the extracellular matrix. In large arteries, these elements are organized in concentric elastin sheets, intertwined by smooth muscle cells and matrix material, along with collagen fibers running both in the axial and circumferential directions, providing mechanical strength to the artery. With progressive distance from the heart, arteries evolve from elastic (rich in elastin) to muscular (rich in VSMCs). The abdominal aorta, in particular, exhibits transitional ultrastructure, with a significant amount of both elastic elements and VSMCs.

Multiple pathologic processes related to elastin fragmentation/degradation, collagen deposition, collagen and elastin cross-linking by advanced glycation end-products, VSMC stiffening, medial calcification, endothelial dysfunction, and inflammation can impact LAS. These processes are briefly summarized in Fig. 10.6 and Table 10.2, but are discussed in great detail in subsequent chapters of this textbook.


BASIC CONCEPT BOX 10.1 Types of systemic arteries

Arteries are classified into three major types based on their size and morphology; these 3 types are: elastic arteries (conducting arteries), muscular arteries (distributing arteries), and arterioles. Key structural characteristics and differences between these artery types are shown in Table 10.1. Light micrographs of each type of artery are shown in Fig. 10.5.

TABLE 10.1 Main types of systemic arteries.

Artery	Tunica intima	Tunica media	Tunica adventitia	Hemodynamic role/effect
Elastic artery (conduction; e.g., aorta)	Endothelium with weibel-palade bodies, basal lamina, subendothelial layer, incomplete internal elastic lamina	40-70 fenestrated elastic membranes, smooth muscle cells interspersed between elastic membranes; thin external elastic lamina; vasa vasorum in outer half	Thin layer of fibroelastic connective tissue, vasa vasorum, lymphatic vessels, never fibers	Conduit function and compliance (major source of compliance in healthy adults)
Muscular artery (distributing; e.g., femoral artery)	Endothelium with weibel-palade bodies, basal lamina, subendothelial layer, thick internal elastic lamina	Up to 40 layers of smooth muscle cells; thick external elastic lamina	Think layer of fibroelastic connective tissue; vasa vasorum not very prominent; lymphatic vessels, nerve fibers	Distributive conduit function, some compliance, modulation of wave reflections
Arteriole	Endothelium with weibel-palade bodies, basal lamina, subendothelial layer not very prominent, some elastic fibers instead of an internal elastic lamina	One to three layers of smooth muscle cells	Loose connective tissue, nerve fibers	Provide resistance and regulate blood flow distribution through modulation of local tone

Saunders Elsevier; 2007.*

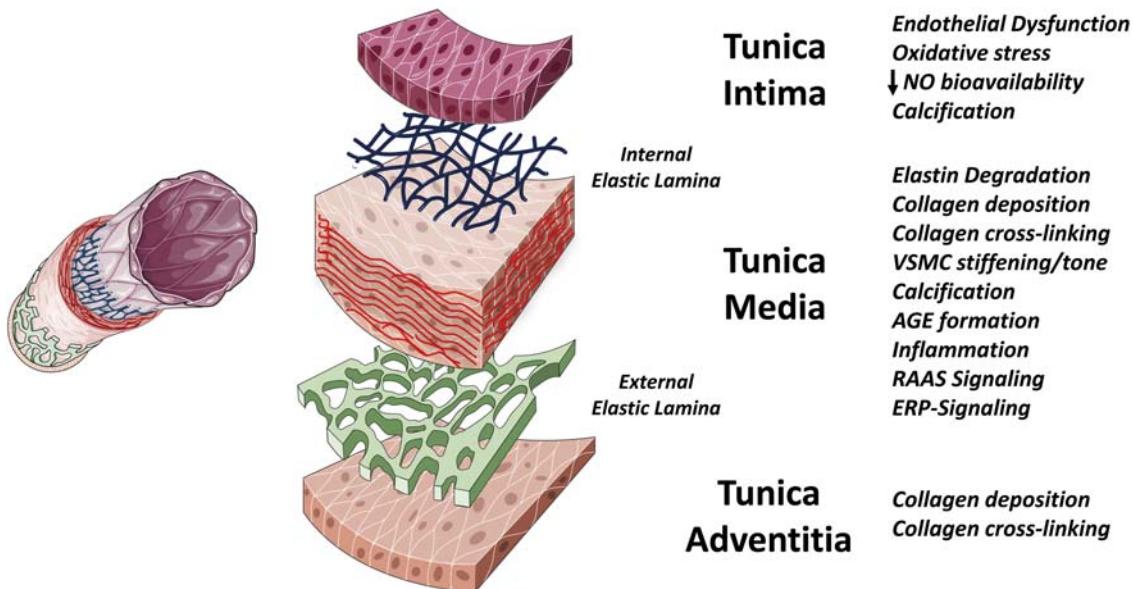
In *elastic arteries*, the tunica intima is composed of endothelial cells supported by a narrow layer of underlying connective tissue containing a few fibroblasts, smooth muscle cells, and collagen fibers. Thin laminae of elastic fibers, the internal elastic laminae, are also present. Endothelial cells are oriented parallel to the longitudinal axis of the vessel and like those in other types of arteries, exhibit Weibel-Palade bodies (small vesicles that contain von Willebrand factor and various other proteins involved in hemostasis, inflammation, angiogenesis, and tissue repair). The tunica media of the elastic arteries consists of many fenestrated lamellae of elastin, known as fenestrated membranes, alternating with circularly oriented layers of smooth muscle cells, which are less abundant in elastic arteries than in muscular arteries. An external elastic lamina is also present in the tunica media. The tunica adventitia of elastic arteries is relatively thin and is composed of loose fibroelastic connective tissue housing some fibroblasts. Vasa vasorum also are abundant throughout the adventitia and extend to the tissues of the tunica media, where they supply the connective tissue and smooth muscle cells. The aorta is the main source of compliance in the normal arterial tree.

Muscular arteries are characterized by a relatively thick tunica media composed mostly of smooth muscle cells arranged in 3−40 layers (depending on the size of the artery). The tunica intima in the muscular arteries is thinner than that in the elastic arteries. In contrast, the internal elastic lamina is more prominent than in elastic arteries and displays an undulating surface. Most smooth muscle cells in the tunica media are oriented circularly, with few bundles arranged longitudinally close to the in the tunica adventitia. Small muscular arteries have three or four layers of smooth muscle cells, whereas larger muscular arteries may have as many as 40 layers of circularly arranged smooth muscle cells. Interspersed within the layers of smooth muscle cells are elastic fibers, type III collagen fibers, and chondroitin sulfate. The tunica adventitia of muscular arteries consists of elastic and collagen fibers, and proteoglycans, with vasa vasorum and unmyelinated nerve endings in its outer region. From a hemodynamic standpoint, the tone of muscular arteries modulates arterial wave reflections.

Arterioles are arteries with a diameter <0.1 mm. The cross-sectional width of the wall of an arteriole is approximately equal to the diameter of its lumen. The tunica media of arterioles consists of 1-3 layers of smooth muscle cells. Arterioles do not have an external elastic lamina, whereas the tunica adventitia is scant and composed by fibroelastic connective tissue housing a few fibroblasts. The terminal arterioles that supply blood to capillary beds are called metarterioles. The smooth muscle layer of meta-arterioles is not continuous; rather, individual muscle cells are spaced apart, and each encircles the endothelium of a capillary arising from the meta-arteriole, allowing them to act as a sphincter upon contraction, controlling blood flow into the capillary bed.

It is important to note that changes in morphological characteristics as arteries transition from one type to another are gradual, such that some vessels have characteristics of two categories (for example, the most distal part of the abdominal aorta has a relatively high content of smooth muscle cells, whereas the carotid arteries exhibit mixed characteristics of muscular and elastic arteries as they morph from proximal to distal segments).

The role of elastin and elastin-derived peptides is discussed in detail in Chapter 19. Chapter 20 deals with the role of inflammation on arterial stiffening. Chapter 21 provides a detailed discussion of mechanisms of aortic wall calcification. The role of vascular smooth muscle dysfunction on arterial stiffening is discussed in Chapter 22, whereas chapter 23 deals with endothelial cell dysfunction and senescence. Finally, Chapter 24 discussed autonomic and neuroendocrine modulation of arterial stiffness, and Chapter 25 deals with cellular aging.

Whereas the various processes leading or contributing to aortic stiffening are discussed separately for didactic purposes, it should be noted that these processes do not occur in isolation, but rather interact to promote LAS. For example, elastin fragmentation is often followed by collagen accumulation, and the generation of elastin degradation products (elastin-related peptides) may activate signaling pathways that promote VSMC osteogenic differentiation and vascular calcification.[78] Similarly, inflammatory pathways can lead to endothelial cell dysfunction and activation, and to the release of bone morphogenetic protein-2 by endothelial cells, which in turn promotes VSMC osteogenic differentiation and vascular calcification. Given the complex interrelationships in various processes listed in Fig. 10.6 and Table 10.2, it is not surprising that pleiotropic mediators, such as various micro-RNAs[79] and *Klotho*[80] appear to exert a coordinated regulation of various processes involved in LAS, providing opportunities for therapeutic interventions.


Understanding mechanisms of arterial stiffening can inform therapeutic approaches. Although a detailed description of potential therapeutic approaches to LAS is outside of the scope of this chapter, these will be discussed in detail in subsequent chapters. Chapter 50 deals with various pharmacologic approaches to reduce arterial stiffness. Chapter 51 discusses the role of organic nitrates, dietary (i.e., inorganic) nitrates and nitric oxide donor therapy to modulate pulsatile arterial hemodynamics. Chapters 52 and 53 discuss the role of lifestyle factors interventions (exercise training and weight loss, and salt restriction, respectively) to reduce LAS. Finally, antihypertensive medications that largely act through reductions in vascular resistance or cardiac output do not necessarily change the intrinsic material properties of the arterial wall, but may lead

TABLE 10.2 General mechanisms of large artery stiffening.

Mechanism	General Description	Key Molecular Mediators
Elastin fragmentation	Elastin deposition in the arterial is limited to the fetal development period and infancy and is subsequently turned off; therefore, in adulthood, elastin fiber damage is essentially irreparable. Progressive elastin fragmentation/loss occurs due to: (a) Mechanical fatigue over the lifetime (cyclic stress); (b) elastase-mediated proteolysis.	• MMP-1, MMP-2, MMP-9, MMP-12, MMP-14, cathepsins, neutrophil elastase, other elastases. • Elastin glycation, carbamylation and peroxidation may increase its mechanical fragility and/or susceptibility to proteolysis. • Elastin degradation products (elastin-related peptides) may promote arterial damage, calcification and systemic metabolic dysregulation.
Collagen deposition	Collagen deposits occur at the arterial wall (predominantly the media), including sites of elastin breakdown	• VSMC angiotensin-II type 1 receptor activation • VSMC mineralocorticoid receptor activation
AGE-mediated collagen and elastin cross-linking	Glucose cross-links develop and AGEs form between proteins with a long half-life (such as collagen). Cross-linked collagen is more resistant to enzymatic proteolysis. Glycated elastin is more susceptible to degradation. Hyperglycemia leads to AGE formation, whereas renal dysfunction leads to reduced AGE elimination	• Glucose, uremic toxins • AGEs can activate the receptor of AGEs (RAGEs), inducing inflammation, oxidative stress and calcification pathways (via sodium phosphate co-transporter PiT-1 expression). The functional significance of AGE-RAGE interactions in vivo is unclear.
VSMC stiffening/tone	Alterations in the VSMC cytoskeleton and integrin interactions with the extracellular matrix. Likely to be more important in distal aortic segments, which are richer in VSMCs.	• Increased α-smooth muscle actin and β1-integrin expression • Increased adhesiveness to fibronectin (primate models)
Calcification	Medial calcification is predominantly mediated by the osteochondrogenic differentiation of VSMCs. This process is different from the intimal calcification associated with atherosclerosis, which is predominantly mediated by chondrocyte-like cells of bone marrow origin. Adventitial calcification may also occur, which involves myofibroblasts and/or microvascular pericytes.	• Imbalance between calcification inhibitors (MGP, fetuin A, pyrophosphate, osteopontin, osteoprotegerin, klotho) and activators (FGF-23, inflammatory cytokines, vitamin D). • BMP-2 signaling • ALP activation (degrades pyrophosphate, a calcification inhibitor) • Osteogenic transcription factors (Msx2-Wnt signaling)
Endothelial dysfunction	Reduced NO production by the endothelium may play a role in regulating VSMC stiffness/tone in distal aortic segments like the abdominal aorta. Increased stiffness of the endothelial cell cytoskeleton that is in close to the membrane (cortical cytoskeleton) may also play a role in modulating stiffness	• Oxidative stress • Nitric oxide deficiency • proinflammatory pathways
Inflammation	There are interconnections between inflammatory pathways and various mechanisms of large artery stiffening (elastin degradation, medial calcification, calcification, endothelial dysfunction)	• TNF-alpha (can activate calcification pathways via Msx2-Wnt signaling and release of BMP-2 within endothelial microparticles) • Various elastases are produced by inflammatory cells • Inflammatory cascades lead to endothelial dysfunction

to a reduction in operating stiffness, given the nonlinear arterial compliance curve, as discussed is Chapter 1.

Conclusions

LAS has profound consequences for cardiovascular health and is likely responsible for a large proportion of the global chronic cardiovascular disease burden. This burden will likely increase as the lifespan of the general population increases, even in the absence of atherosclerotic cardiovascular disease. Given the important consequences of aortic stiffening and excess pulsatility on target organs, a better understanding of molecular mechanisms that contribute to LAS should be aggressively pursued, in order to design effective pharmacologic interventions. Mechanical approaches to reduce pulsatility in the presence of irreversible aortic stiffening should also be pursued. Aortic stiffening represents an unmet, high-priority therapeutic target to ameliorate the global burden of cardiovascular disease.

Wave reflection in the arterial tree

Jonathan P. Mynard[1,2,3] and Avinash Kondiboyina[1,2]

Introduction

The pulsatility of arterial blood pressure and flow is a fundamental feature of the cardiovascular system. Although clearly arising from the ventricle's design as a pulsatile pump, the evolution of pressure and flow over time (i.e., pulse waveform during systole and diastole) and space (i.e., from central to peripheral arteries) depends not only on the properties of this pump, but also to a large extent on the properties of the vascular network. Ever since Thomas Young studied "the laws of the propagation of an impulse through the fluid contained in an elastic tube" and concluded that "application of this theory to the motion of the blood in the arteries is very obvious,"[1] it has been recognized that the initial ventricular impulse produces a wave that propagates at finite speed from proximal to distal arteries. That this "forward-running" wave is not perfectly absorbed by the arterial network, but undergoes some degree of reflection, became the subject of many pioneering studies in the 20th century that form the basis of work that continues to this day.[2–11] As with electromagnetic waves or acoustic waves, wave reflection in arteries occurs when a wave encounters an impedance mismatch, that is, a change in the wave propagation properties of the medium.

Because the impedance of the arterial network as a whole (input impedance) is greater than the local impedance of the proximal aorta (characteristic impedance), where the incident wave originates, reflected waves returning to the heart tend to augment blood pressure. Importantly, the time delay between incident and reflected waves at a given location (e.g., the heart) is determined by the distance to the reflection site(s) and the propagation speed ["pulse wave velocity (PWV)"]. Pressure-increasing reflected waves that return during diastole make an advantageous contribution to coronary perfusion pressure (as discussed in detail in Chapter 18), whereas waves that return during systole present an additional afterload to the

ventricle, which reduces pump energy efficiency.[12,13] A transition from the former to the latter situation is thought to occur with aging because the progressive loss of aortic compliance leads to a two- to threefold increase in aortic PWV,[14,15] leading to characteristic changes in the shape of pulse waveforms.[16] As will be described throughout this chapter, although various aspects of this "standard" view have been debated over multiple decades, many of the controversies relate to limitations in the way arterial wave reflection has been modeled (i.e., conceived of) and measured (i.e., quantified).

This chapter starts by introducing basic concepts around the propagation and reflection of pressure and flow waves in elastic tubes. After covering the fundamental (patho) physiological sources of impedance mismatching, we critically review the various models that have been used to "make sense" of wave reflection in the arterial system. We then explore some key complexities of the real system (re-reflections and the "horizon effect," ventricular wave reflection, and the interplay between wave dynamics and windkessel function) that render many simplistic notions of arterial wave reflection ineffective at best and misleading at worst. With these principles in mind, we then introduce and critically assess the methods that are commonly used to quantify the magnitude and timing of reflected waves.

Pressure and flow in the absence of wave reflection

To understand the impact of wave reflection, it is useful to first consider what the relationship between blood pressure and blood flow would be in a theoretically reflectionless scenario—an infinitely long distensible vessel with uniform mechanical properties. If a pulse of fluid is injected into the vessel, a change in flow (ΔQ_f) and pressure (ΔP_f) is produced that travels as a wave in the forward direction

("*f*" subscript). The mathematical description of wave travel in a distensible vessel was originally formulated by Euler in 1775, although published later.[17] Von Kries identified that ΔQ_f and ΔP_f in an elastic tube are intrinsically linked via a simple equation, now known as the "water hammer" equation[18,19] (Fig. 11.1A):

$$\Delta P_f = Z_c \Delta Q_f \qquad (11.1)$$

where Z_c is called characteristic impedance, a term that is borrowed from electrical transmission line theory,[20] noting that voltage and current are the electrical equivalents of pressure and flow, respectively. Assuming no leakage of blood through the vessel wall, characteristic impedance is determined by the inertance of the fluid (L), compliance of the vessel (C), and viscous resistance to flow (R) per unit length,[21]

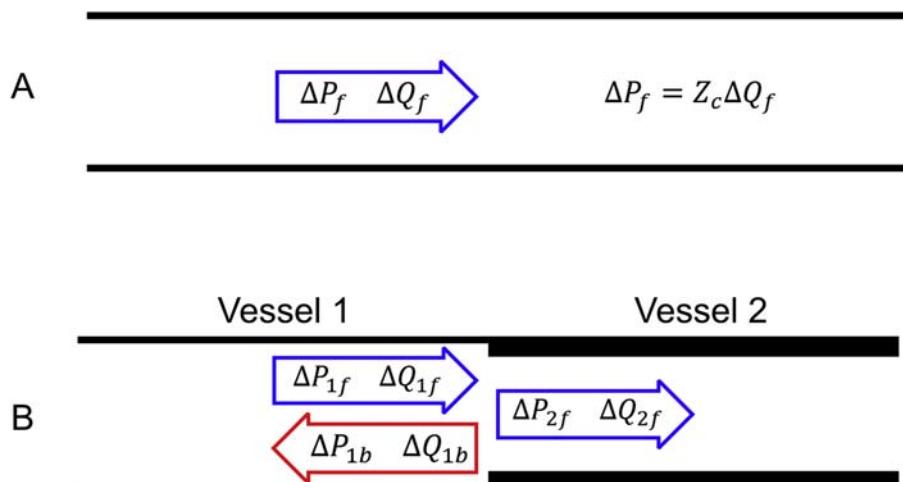
$$Z_c(\omega) = \sqrt{\frac{R + j\omega L}{j\omega C}} \qquad (11.2)$$

where $j = \sqrt{-1}$ and ω is the angular frequency of the wave, with higher frequencies corresponding to faster changes in pressure and flow. The parameters L, C, and R can be related to measurable quantities as follows:

$$L = \frac{\rho}{A} \qquad (11.3)$$

$$C = \frac{A}{\rho c^2} \qquad (11.4)$$

$$R = \frac{8\pi\eta}{A^2} \qquad (11.5)$$

where ρ is blood density, η is blood viscosity, A is lumen cross-sectional area, and c is wave speed (which increases with vessel stiffness, see Chapter 1). Importantly, resistance is negligible in large vessels but becomes significant in smaller vessels because it is inversely proportional to the square of A, and hence the fourth power of radius (Eq. 11.5). By ignoring resistance in large vessels, Eq. (11.2) reduces to $Z_c = \sqrt{L/C}$, which is frequency-independent and, via Eqs. (11.3) and (11.4), becomes:


$$Z_c = \frac{\rho c}{A} \qquad (11.6)$$

This equation implies that a higher c (e.g., due to increased vessel stiffness) will be associated with a higher Z_c, causing a larger pressure rise for a given flow (Eq. 11.1). Indeed, this principle is thought to be the major factor underlying the hypertensive effect of aortic stiffening with advancing age,[22,23] although the approximately 100% increase in Z_c starting in middle age[22,24] is tempered by an increasing aortic area.[25]

To summarize the key points in this section, in the absence of wave reflection (1) pressure and flow waveforms will have the same shape; (2) the ratio of pressure and flow is called characteristic impedance (Z_c); and (3) Z_c is essentially independent of wave frequency in large vessels and depends on vessel size and stiffness (via A and c).

The basis of wave reflection: impedance mismatching

Given the intrinsic link between pressure and flow in a reflectionless tube, *any differences* in the shape of measured pressure and flow waveforms must arise due to wave reflection. Consider two connected vessels of finite length with differing characteristic impedances (Z_1 and Z_2, Fig. 11.1B); an "impedance mismatch" therefore exists at the interface between them. If a pulse of fluid is injected

FIGURE 11.1 (A) In a uniform tube with infinite length, a forward-traveling pressure change (ΔP_f) is intrinsically linked to an accompanying forward-traveling flow change (ΔQ_f) via characteristic impedance (Z_c). (B) At the interface between two vessels that have differing Z_c, a site of impedance mismatch exists. The incident forward wave produces pressure and flow changes in vessel 1 (ΔP_{1f} and ΔQ_{1f}) and the transmitted wave produces respective changes in vessel 2 (ΔP_{2f} and ΔQ_{2f}). A reflected wave produced at the site of impedance mismatch produces further changes in pressure (ΔP_{1b}) and flow (ΔQ_{1b}) in vessel 1.

BOX 11.1 Origin of wave reflection

Wave reflection must arise at sites of impedance mismatch to satisfy the fundamental laws of conservation of energy and mass. To understand this requirement, imagine a theoretical scenario where wave reflection does not occur at the interface between vessel 1 and 2 (Fig. 11.1B). If this were so, the only pressure and flow changes would be ΔP_{1f} and ΔQ_{1f} in vessel 1 and ΔP_{2f} and ΔQ_{2f} in vessel 2, respectively. Assuming no viscous dissipation, conservation of energy requires "continuity of pressure," which means that the total pressure change in both vessels must be the same ($\Delta P_{1f} = \Delta P_{2f}$). Rewriting both sides with the water hammer equation (Eq. 11.1) would then imply that $Z_1 \Delta Q_{1f} = Z_2 \Delta Q_{2f}$. If the two vessels had the same characteristic impedance ($Z_1 = Z_2$), i.e., no impedance mismatch, then we see that $\Delta Q_{1f} = \Delta Q_{2f}$, which satisfies conservation of mass. However, if there is an impedance mismatch ($Z_1 \neq Z_2$), then the water hammer equation requires that $\Delta Q_{1f} \neq \Delta Q_{2f}$, which would violate conservation of mass. Therefore, where an impedance mismatch is present, the only way for mass and energy to be conserved, while upholding the water hammer equation in both vessels, is for a reflected wave to arise in vessel 1; this leads to Eqs. (11.7) and (11.8).

---

into the first vessel, a forward-traveling wave ("*f*" subscript) is produced that causes a change in pressure and flow in vessel 1 (ΔP_{1f} and ΔQ_{1f}, respectively). A portion of the wave energy is transmitted into vessel 2 (ΔP_{2f} and ΔQ_{2f}, respectively), but a reflected wave is also produced because of the impedance mismatch. This is akin to light or sound waves being partially reflected when they travel from one medium to another with different refractive indices or densities. The reflected wave travels in the backward direction ("*b*" subscript) and also produces a change in pressure (ΔP_{1b}) and flow (ΔQ_{1b}) in vessel 1 (Fig. 11.1B). Hence, the overall pressure change in vessel 1 is $\Delta P_{1f} + \Delta P_{1b}$ and overall change in flow is $\Delta Q_{1f} + \Delta Q_{1b}$ (Fig. 11.1). As discussed in Box 11.1, wave reflection must arise at sites of impedance mismatch to ensure that the laws of conservation of mass and (assuming no viscous dissipation) conservation of energy are fulfilled. These require that the changes in pressure and flow in both vessels be equal, hence:

$$\Delta P_{1f} + \Delta P_{1b} = \Delta P_{2f} \tag{11.7}$$

$$\Delta Q_{1f} + \Delta Q_{1b} = \Delta Q_{2f} \tag{11.8}$$

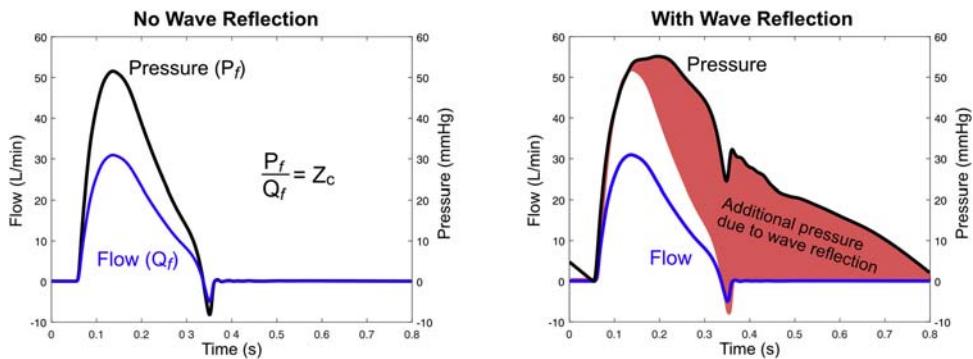
Impact of wave reflection on arterial pressure and flow

To understand how reflected waves affect pressure and flow, a critical principle is that the water hammer equation for backward-traveling waves includes a negative sign (in contrast to Eq. (11.1) for forward-traveling waves):

$$\Delta P_b = -Z_c \Delta Q_b \tag{11.9}$$

Where both forward and backward waves are present at a particular measurement site, the observed pressure (ΔP) and flow (ΔQ) changes are equal to the sum of the respective forward and backward waves ($\Delta P = \Delta P_f + \Delta P_b$ and $\Delta Q = \Delta Q_f + \Delta Q_b$), if the generally small influence of nonlinearities is neglected.[26,27] These water hammer

equations (Eqs. 11.1 and 11.9) have two very important implications for interpreting arterial hemodynamics. First, forward waves cause pressure and flow to change in the same direction (a pressure-increasing forward wave will accompany a flow increase). However, backward waves cause pressure and flow to change in opposite directions (a pressure-increasing backward wave will accompany a flow decrease). Consequently, it is backward waves that cause measured pressure and flow waveforms in arteries to differ (Fig. 11.2). With the exception of coronary arteries, where some backward waves are actively generated in the intramyocardial circulation,[28,29] wave reflection is therefore ultimately responsible for the well-known differences in the shape of arterial pressure and flow waveforms. These differences are virtually abolished by reducing wave reflection via infusion of vasodilators, whereas the differences are accentuated when wave reflection is increased via the infusion of vasoconstrictors.[9,30–33]

Reflection and transmission coefficients


The degree to which a pressure wave is reflected at the boundary between vessel 1 and vessel 2 in Fig. 11.1B can be quantified as the ratio of the reflected pressure wave (ΔP_{1b}) to the incident pressure wave (ΔP_{1f}). This is called the local reflection coefficient (Γ_P) and can be expressed in terms of the mismatch in characteristic impedance using Eqs. (11.7)–(11.9):[20,34]

$$\Gamma_P = \frac{\Delta P_{1b}}{\Delta P_{1f}} = \frac{Z_2 - Z_1}{Z_2 + Z_1} \tag{11.10}$$

Similarly, the pressure transmission coefficient (T_P) is defined as

$$T_P = \frac{\Delta P_{2f}}{\Delta P_{1f}} = \frac{2Z_2}{Z_2 + Z_1} \tag{11.11}$$

By combining Eqs. (11.8) and (11.9), it can also be shown that T_P and Γ_P are related via $T_P = 1 + \Gamma_P$. At first this may seem counterintuitive because one might

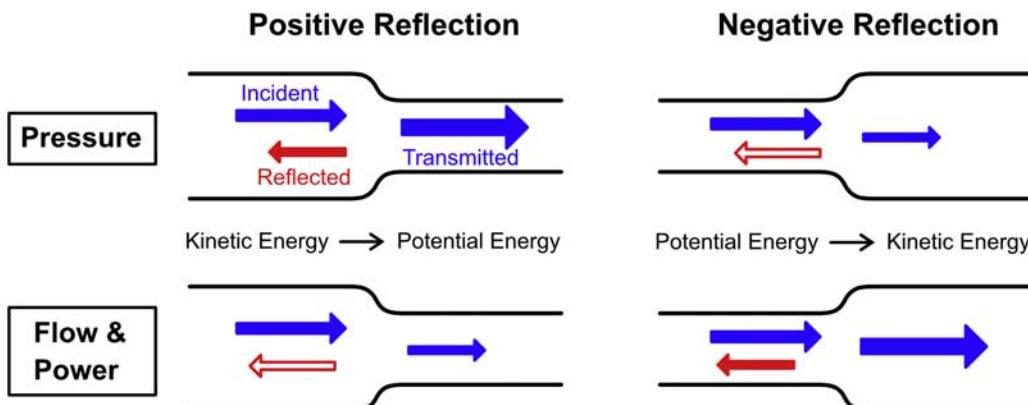
FIGURE 11.2   In the absence of wave reflection (left), flow and pressure waveforms have the same shape, scaled by the characteristic impedance (1.67 mmHg min/L in this case). In the presence of wave reflection (right), the pressure waveform diverges from the flow waveform. The red shading indicates the total pressure contributed by wave reflection above what would exist in the theoretical absence of wave reflection. Note: the diastolic pressure in both cases is assumed to be zero for simplicity of representation.

expect that a 40% reflection would be accompanied by 60% transmission. However, this intuition only applies to conserved quantities like flow and energy, whereas pressure is not a conserved quantity. On the other hand, pressure is essentially *continuous* at arterial junctions, which means that pressure does not exhibit large changes over very short distances; it can be shown that the relation $T_P = 1 + \Gamma_P$ is required to ensure such continuity of pressure.[34]

Reflection and transmission coefficients for flow (Γ_Q and T_Q) can also be defined and expressed in terms of Γ_P (Table 11.1). In addition, the coefficients of composite measures that combine pressure and flow (hydraulic power and wave intensity) can also be found by combining the respective coefficients in the same manner (Table 11.1).

To understand reflection and transmission coefficients, it is instructive to highlight three limiting scenarios:

1. *Well-matched junctions*. When there is no impedance mismatch ($Z_2 = Z_1$), no reflected wave arises ($\Gamma_P = 0$ and $\Gamma_Q = 0$) and a pressure/flow wave is transmitted forward unaltered ($T_P = 1$ and $T_Q = 1$).

2. *Closed-ended or "positive" reflection* (i.e., $\Gamma_P > 0$) occurs when a wave encounters an impedance increase ($Z_1 < Z_2$ in Fig. 11.3). If vessel 2 were progressively occluded (area approaches zero, i.e., $A_2 \rightarrow 0$), Z_2 would progressively increase. As $Z_2 \rightarrow \infty$ (i.e., complete occlusion), $\Gamma_P \rightarrow 1$ and $T_P \rightarrow 2$, which means that an incident pressure-increasing ("compression") wave will be reflected as a compression wave that further increases pressure. On the other hand, $\Gamma_Q \rightarrow -1$ and $T_Q \rightarrow 0$, which means that (as expected) transmission of flow approaches zero and therefore the reflected flow wave must totally cancel out the incident flow wave (i.e., $\Gamma_Q = -1$). *One may therefore consider positive reflection as a conversion from kinetic energy (flow) to potential energy (pressure).*


3. *Open-end or "negative" reflection* (i.e., $\Gamma_P < 0$) occurs when a wave encounters an impedance decrease ($Z_1 > Z_2$ in Fig. 11.3). If vessel 2 were progressively enlarged ($A_2 \rightarrow \infty$), $Z_2 \rightarrow 0$, $\Gamma_P \rightarrow -1$ and transmission of pressure falls toward zero ($T_P \rightarrow 0$). Hence, the reflected pressure wave entirely cancels the incident pressure wave, so that pressure at the interface does not change (just as flow does not change for a complete occlusion). The concept of negative reflection may be understood when considering the analogy of a wave propagating along a river (vessel 1) that meets the sea (vessel 2). A wave that increases water level in the river (analogous to an increase in pressure) cannot also raise sea level because the sea is effectively an infinite reservoir compared with the river. Hence to ensure continuity of pressure at the interface, the reflected pressure wave must cancel the pressure effect of the incident wave. *Negative reflection therefore involves a conversion from potential energy (pressure) to kinetic energy (flow)*, since as $Z_2 \rightarrow 0$, we see that $\Gamma_Q \rightarrow 1$ and $T_Q \rightarrow 2$; hence, the reflected wave augments flow in the same direction as the incident wave.

Although we have considered a single reflection site between two vessels, the same principles apply when considering wave reflection that is distributed through an arterial network. Positive reflection ($\Gamma_P > 0$) is well-recognized to occur in systemic arteries, causing systolic pressure augmentation and a less dome-like, and more triangular-shaped flow waveform observed with advancing age. However, as discussed in a later section, negative wave reflection ($\Gamma_P < 0$), although less widely recognized, also occurs throughout the arterial network, mainly in relation to re-reflection of backward-running waves at arterial junctions; however, negative reflection of forward traveling waves does occur in specific pathologies, such as aortic aneurysms.[35,36]

TABLE 11.1 Reflection and transmission coefficients.

	Coefficient	Expressions	Positive reflection example	Negative reflection example
Pressure reflection	Γ_P	$\frac{\Delta P_{1b}}{\Delta P_{1f}} = \frac{Y_1 - (Y_2 + Y_3)}{Y_1 + Y_2 + Y_3}$	$\Gamma_P = 0.2$ $\Delta P_{1f} = 10$ $\Delta P_{1b} = 2$	$\Gamma_P = -0.2$ $\Delta P_{1f} = 10$ $\Delta P_{1b} = -2$
Pressure transmission	T_P	$\frac{\Delta P_{2f}}{\Delta P_{1f}} = \frac{\Delta P_{3f}}{\Delta P_{1f}} = \frac{2Y_1}{Y_1 + Y_2 + Y_3} = 1 + \Gamma_P$	$T_P = 1.2$ $\Delta P_{2f} = \Delta P_{3f} = 12$	$T_P = 0.8$ $\Delta P_{2f} = \Delta P_{3f} = 8$
Flow reflection	Γ_Q	$\frac{\Delta Q_{1b}}{\Delta Q_{1f}} = \frac{Y_2 + Y_3 - Y_1}{Y_1 + Y_2 + Y_3} = -\Gamma_P$	$\Gamma_Q = -0.2$ $\Delta Q_{1f} = 10$ $\Delta Q_{1b} = -2$	$\Gamma_Q = 0.2$ $\Delta Q_{1f} = 10$ $\Delta Q_{1b} = 2$
Flow transmission	T_Q	$T_{Q2} = \frac{\Delta Q_{2f}}{\Delta Q_{1f}} = \frac{2Y_2}{Y_1 + Y_2 + Y_3}$ $T_{Q3} = \frac{\Delta Q_{3f}}{\Delta Q_{1f}} = \frac{2Y_3}{Y_1 + Y_2 + Y_3}$	$T_{Q2} = 0.72$ $\Delta Q_{2f} = 7.2$ $T_{Q3} = 0.08$ $\Delta Q_{3f} = 0.8$	$T_{Q2} = 0.8$ $\Delta Q_{2f} = 8$ $T_{Q3} = 0.4$ $\Delta Q_{3f} = 4$
Power reflection	Γ_Π	$\frac{\Delta \Pi_{1b}}{\Delta \Pi_{1f}} = \Gamma_P \Gamma_Q$	$\Gamma_\Pi = -0.04$ $\Delta \Pi_{1f} = \Delta P_{1f} \Delta Q_{1f} = 100$ $\Delta \Pi_{1b} = 4$	$\Gamma_\Pi = -0.04$ $\Delta \Pi_{1f} = \Delta P_{1f} \Delta Q_{1f} = 100$ $\Delta \Pi_{1b} = 4$
Power transmission	T_Π	$T_{\Pi2} = \frac{\Delta \Pi_{2f}}{\Delta \Pi_{1f}} = T_P T_{Q2}$ $T_{\Pi3} = \frac{\Delta \Pi_{3f}}{\Delta \Pi_{1f}} = T_P T_{Q3}$	$\Delta \Pi_{2f} = 86.4$ $\Delta \Pi_{3f} = 9.6$	$\Delta \Pi_{2f} = 64$ $\Delta \Pi_{3f} = 32$

The positive reflection example involves a bifurcation with three branches having admittances $Y_1 = 3$, $Y_2 = 1.8$, and $Y_3 = 0.2$. The negative reflection example involves a bifurcation with three branches having admittances $Y_1 = 3$, $Y_2 = 3$, and $Y_3 = 1.5$. Assumes an incident wave in vessel 1 with a nominal pressure effect $\Delta P_{1f} = 10$ and nominal flow effect $\Delta Q_{1f} = 10$ (units neglected).

FIGURE 11.3 Positive reflection occurs when an incident wave encounters an impedance increase ($Z_1 < Z_2$). The reflected wave changes pressure in the same direction as the incident wave (*filled arrows*), but changes flow in the opposite direction as the incident wave (*unfilled arrows*). The reverse is true for negative reflection.

We now consider the specific features of the arterial system that are thought to give rise to impedance mismatching and hence wave reflection, namely junctions, tapering, resistance vessels, stenoses, aneurysms, and stents.

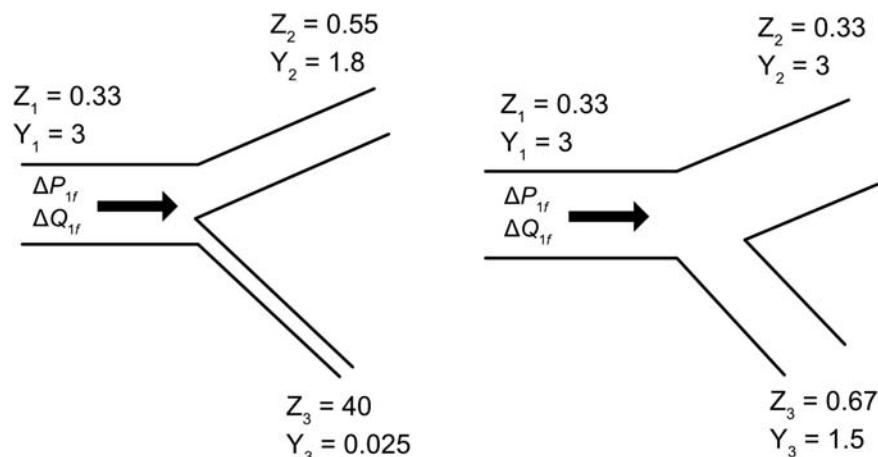
Arterial junctions

Wave reflection at junctions can be analyzed by extending Eq. (11.10) to include two daughter vessels. For simplicity,

we now write the equation in terms of characteristic admittance, which is the inverse of characteristic impedance (i.e., $Y = 1/Z_c = A/\rho c$ in large vessels).

$$\Gamma_P = \frac{Y_1 - (Y_2 + Y_3)}{Y_1 + (Y_2 + Y_3)} \qquad (11.12)$$

where the subscripts 1, 2, and 3 refer to the parent and two daughters, respectively. Additional daughter branches could be included as additional terms in the brackets (Y_4, Y_5, etc.), but we here only consider a bifurcation. As in

the previous section, the pressure transmission coefficient is $T_P = 1 + \Gamma_P$, and the same pressure change is transmitted into both daughter vessels, regardless of the degree of asymmetry in daughter radii (assuming that pressure losses that depend on branch angle are negligible).


Expressions for calculating reflection and transmission coefficients for flow and hydraulic power (i.e., $\Pi = PQ$) are provided in Table 11.1; this table includes worked examples of reflected and transmitted pressure, flow, and power waves for the bifurcations shown in Fig. 11.4 ($\Gamma_P = 0.2$ and -0.2 for the incident wave in vessel 1). It is instructive to note that, unlike pressure, flow and power are transmitted unequally between branches for an asymmetric bifurcation, with less flow and power transmitted to higher impedance/smaller branches (in vivo, this means, for example, that less flow and power from the ascending aorta are transmitted into the smaller supra-aortic branches vs. the larger descending aorta). Interestingly, both examples in Fig. 11.4 involve the same degree of power reflection ($\Delta\Pi_{1b}$) and total power transmission ($\Delta\Pi_{2f} + \Delta\Pi_{3f}$), highlighting that any degree of wave reflection (whether positive or negative) reduces power transmission, compared with a well-matched junction.

Having covered the basic theory, we now consider how much wave reflection generally occurs at arterial junctions. Assuming symmetrical daughter vessels ($A_2 = A_3$) and that $c \propto 1/A^4$ (as per the Moens-Korteweg equation), it can be shown that a bifurcation will be well-matched ($\Gamma_P = 0$) when the daughter-to-parent ratio ($\alpha = (A_2 + A_3)/A_1$) is approximately 1.15.[19,37] For asymmetric bifurcations, the optimal area ratio is slightly lower.[19] Interestingly, extensive measurements of area ratios of the arterial tree in humans found that (with the notable exception of the aortoiliac bifurcation),[38,39] in general $\alpha = 1.14 \pm 0.03$, suggesting that the arterial tree is indeed very well-matched,

facilitating the efficient transmission of forward waves from the heart to organs and tissues, with minimal reflection.[40] This principle has been a key design feature of computational models of arterial haemodynamics, where it has been found that well-matched junctions are required to produce realistic pressure/flow waveforms.[41–43] Some earlier studies suggested that bifurcations provided sites of wave reflection.[44] However, it was later found that wave reflections can be almost entirely abolished by vasodilators, which directly increase the diameter of high resistance arterioles but have little to no effect on branching patterns.[30] Hence, although wave reflection can occur at junctions if not well-matched, it is unlikely that this is the major source of wave reflection in the healthy arterial system.

Tapering

Arterial tapering refers to the gradual decrease in area (geometric tapering) or change in wall properties (elastic tapering) along the length of the vessel. Both kinds of tapering lead to a continuous change in Z_c and consequently, wave reflection also occurs in a continuous manner along the entire length of the vessel instead of at a discrete point.[45] Interestingly, Segers et al. found that such continuous reflections had similar effects on measured pressure and flow signals as discrete reflections, thus making them indiscernible with measurements at a single site.[46] Arterial tapering (which involves decreasing area and increasing stiffness) has been hypothesized to play a role in pulse amplification because the continuously increasing Z_c produces reflected waves that increasingly add to the pressure waveform as waves travel from the heart to the periphery, as per the consequences of wave reflection on pressure transmission discussed earlier in this chapter.[47–49] Tapering may also attenuate the power transmission of

FIGURE 11.4 Bifurcations with a positive reflection coefficient ($\Gamma_P = 0.2$, left) and negative reflection coefficient ($\Gamma_P = -0.2$, right) for the incident pressure wave (ΔP_f). Calculation of reflection and transmission coefficients for pressure, flow, and power, for the given nominal characteristic impedance (Z) and characteristic admittance ($Y = 1/Z$) values of vessels 1, 2, and 3, are provided in Table 11.1.

reflected waves traveling back toward the heart, since such waves see a continuous impedance decrease. The actual contribution of tapering to arterial wave reflection is uncertain, however, as tapering may be predominantly an impedance-preserving feature due to the presence of side branches.[50]

Resistance vessels

Viscous resistance is negligible in large arteries but becomes significant in smaller vessels such as arterioles. In these smaller vessels, resistance makes an appreciable or even dominant contribution to Z_c (Eq. 11.2). This abrupt increase in resistance occurs over a very short length.[51] Several lines of evidence support the view that high resistance arterioles serve as the major sites of wave reflection.[52,53] First, as mentioned above, arterial bifurcations tend to be well-matched and tapering of large conduit arteries is likely impedance-preserving,[50] both of which appear to be good design features of the arterial network. Second, vascular beds have been shown to have a relatively high reflection coefficient, with a value of 0.8 estimated for the canine femoral vascular bed[30]; there is also evidence of a relatively large backward compression wave (BCW) in the distal radial artery in humans.[54] Third, vasodilation of resistance vessels markedly reduces or even abolishes wave reflection, whereas vasoconstriction increases wave reflection.[30,32,55-57]

These observations notwithstanding, the role of peripheral resistance in generating wave reflection is still debated, primarily because changes in wave reflection may be induced without a parallel change in systemic vascular resistance.[58] For example, administration of inorganic nitrate results in a clear reduction in wave reflection, even when peripheral resistance is unchanged.[55] However, Yaginuma et al.[59] suggested that a similar phenomenon observed in several studies after administration of glyceryl trinitrate[59,60] could be explained by negative reflection arising at the interface between larger parent arteries and the dilated muscular arteries, which would offset the unchanged positive reflection occurring at the arteriolar level.

Stenosis

Stenosis is the focal narrowing of an artery, typically caused by congenital defects or atherosclerosis. While the severity of a stenosis nonlinearly determines its effective resistance to flow,[61] the associated local increase in impedance also produces positive wave reflection.[62,63] The impedance mismatch occurring at a stenosis is influenced by (1) the characteristic impedance of the parent vessel, (2) the stenotic cross-sectional area, (3) the stiffness of the stenosis vessel wall, and (4) the viscous resistance arising from complex or turbulent flow downstream to the vena contracta. Importantly, based on computational and in vitro studies, Stergiopulos et al.[64] concluded that the reflection coefficient of a stenosis rises more steeply than its resistance, suggesting that even hemodynamically insignificant stenoses (i.e., those that cause a clinically insignificant increase in resistance) may produce substantial wave reflection.

Aneurysms

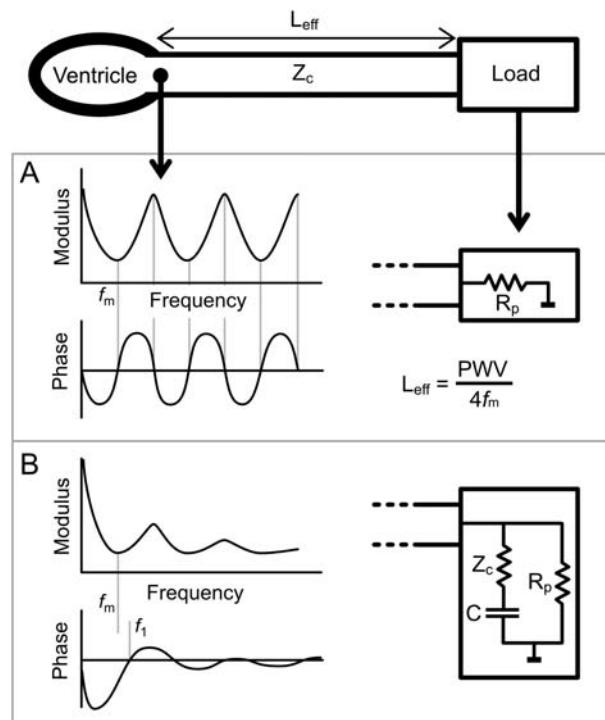
Aneurysm is the localized enlargement of an artery caused by weakening of the arterial wall. In vitro and computational studies have demonstrated that negative reflection occurs at fusiform aneurysms due to the local increase in area and resultant decrease in characteristic impedance (Eq. 11.6).[35,65] Negative reflection of the initial forward compression wave (FCW) produces a backward decompression wave (BDW) that has a pressure-decreasing and flow-increasing effect. A small BDW was detected in one patient in a pilot study before (and not after) repair of an abdominal aortic aneurysm. All three patients studied exhibited an increased (i.e., more positive) reflection coefficient after repair, suggesting that local negative reflection at the aneurysm may not always be detectable if it is overwhelmed by positive reflection from other sites.[35]

Stents

Stents are mesh-like structures made of stainless steel that eventually integrate with the vessel wall. Since the stent is stiffer than the vessel wall, two sites of impedance mismatch are created, one at the proximal end (impedance increase) and one at the distal end (impedance decrease), associated with positive and negative Γ_P, respectively. For a short stent, one might expect the reflected compression and decompression waves arising from these two sites to be almost in phase and thus cancel each other out. Indeed, a theoretical analysis by Crespo et al.[66] suggested that wave reflection from a stent is directly proportional to its length and inversely proportional to the wave speed of the parent artery (assuming very high wave speed in the rigid stent itself). A shorter stent may therefore cause less hemodynamic perturbation and contribute to a lower risk of restenosis.[67] Although not confirmed in vivo, computational studies by Papathanasiou et al.[68] predicted that the structure of a stent mesh affects wave reflection in a frequency-dependent manner, and that placement of two stents may lead to high levels of wave reflection.

Models of arterial wave reflection

When attempting to understand wave reflection in the arterial system as a whole, conceptual models are unavoidable. Mathematical models provide the blessing of

analytical precision and conceptual robustness, but also the curse of assumptions. Since the concepts and indices used to describe and quantify arterial wave reflection are based on one or another model, awareness of model limitations is crucial to avoid misinterpretation and thinking "inside the box" (e.g., only conceiving of physiological processes in terms of one specific limited model).


Broadly speaking, models of waves in arteries are generally founded on three pillars. The first is the Navier—Stokes equations that express the basic laws of fluid dynamics. Although these are derived from the unassailable laws of conservation of mass and momentum, when addressing the phenomenon of waves, these equations are usually reduced to a one-dimensional (1D) form with the aid of several simplifying assumptions—for example, long cylindrical geometry.[69,70] The second is a constitutive relation that describes the distensibility of the arterial wall (i.e., how transmural pressure relates to cross-sectional area). Due to the complex composition and mechanical properties of the arterial wall, all constitutive relations are empirical and approximate. When neglecting nonlinearities in the combined system of equations, the telegraph (or transmission line) equations are obtained. These form the basis for concepts such as characteristic impedance and impedance mismatching.

In addition to these basic model constructs regarding waves in elastic tubes, a third (and pivotal) aspect of wave reflection models is how the systemic arterial network is represented. Historically, a frequently pursued goal has been to reduce the very complex wave reflection properties of the arterial network to a model form that is as simple as possible, in the hope that a model with few parameters may provide both conceptual clarity and clinical utility. We here briefly review the most prominent wave reflection models.

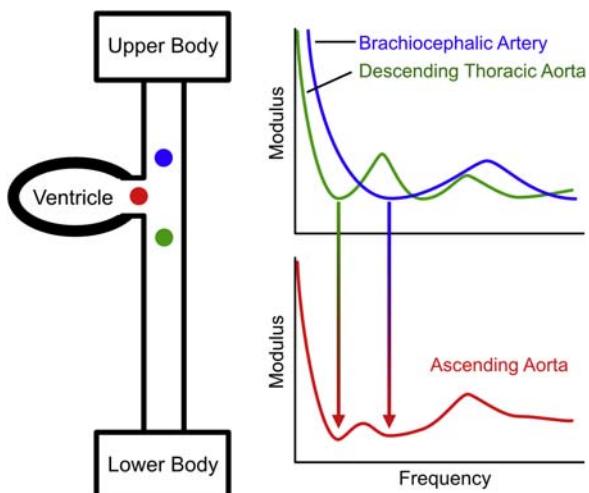
Single tube model

The simplest model of arterial wave reflection is a uniform tube, with characteristic impedance Z_c, terminated in a load that creates a single reflection site (Fig. 11.5). According to Campbell et al.,[71] the origins of this model appear to extend back to Otto Frank, who proposed that one "effective" reflection site might be used to represent the lumped effect of the many actual reflection sites distributed around the body. An "effective length" (L_{eff}) refers to the distance from a measurement site to the apparent "location" of this reflection site, while "effective reflection time" (T_{eff}) refers to the time taken for a wave to travel to this effective reflection site and back. Although long-recognized to be a simplification of reality, estimation of T_{eff} and L_{eff} has been a frequent topic of investigation over the past 80 years.[2,72—78]

An overview of the various methods used to estimate T_{eff} is provided in a later section. L_{eff} can then be calculated as PWV/T_{eff}, where PWV is pulse wave velocity. When applying these methods, it is important to keep in mind that

FIGURE 11.5 Input impedance of the single tube model with (A) resistive load, and (B) complex load (in this example, a modified windkessel).

all of them are (either explicitly or implicitly) based on the single tube model. For example, pulse wave analysis and wave separation analysis involve analysis of waveform features and are not explicitly tied to a single tube model, but when singular L_{eff} or T_{eff} are calculated, a single effective reflection site is implied. Other techniques are explicitly linked to a specific mathematical form of the single tube model. The earliest of these involved a perfectly elastic tube and purely resistive load,[75] with L_{eff} calculated via the "quarter wavelength formula" (see Fig. 11.5). However, this model exhibits unphysiological oscillations in the impedance spectrum (see Box 11.2), and so subsequent investigators variably employed tubes with pulse attenuation (i.e., viscous friction) and/or a complex load (standard or modified 3-element windkessel).[72—74] L_{eff} was estimated from the first local minimum in impedance modulus or first zero crossing of the phase, or through fitting a computational model to measured waveforms.

Importantly, given the same input data, different models and techniques lead to different values of L_{eff}, e.g., with resistive loads producing larger values than complex loads.[72,73,79] Moreover, it has been shown that the "location" of the effective reflection site (i.e., the end position of the tube) depends on where measurements are taken.[53,80,81] For example, when impedance is measured at the thoracic aorta, an apparently discrete reflection site is found at the aortic bifurcation, whereas when measured from the abdominal aorta, the discrete reflection site appears more


BOX 11.2 Impedance analysis of the single tube and asymmetric T-tube models

The input impedance defines the relationship between pressure and flow (see also Chapters 1 and 3). The impedance spectrum at the inlet of the single tube model depends on the assumptions adopted, primarily on: (1) whether the tube has uniform properties along its length, or incorporates geometric and/or elastic tapering; (2) whether the model includes lossless wave propagation, or attenuation due to viscoelasticity in the vessel wall and/or viscous friction of flowing blood, and; (3) whether the load is represented as a pure resistance, a three-element windkessel, or a modified windkessel.

Fig. 11.5A shows the input impedance of a lossless tube with a resistive load. The impedance spectrum exhibits minima and maxima that are equally spaced at frequencies kf_m, where f_m is the frequency of the first minima and $k = 1,2,3$ .... The impedance phase also crosses zero at these frequencies. The length of the tube determines f_m via the quarter wavelength formula: $f_m = c/4L_{eff}$, where c is the phase velocity (frequency-dependent wave speed). By rearranging this formula, and approximating c via a measured PWV, L_{eff} can be estimated after obtaining f_m from a measured input impedance spectrum.

This model has been criticized because the oscillations in measured impedance spectra are damped at higher frequencies. A more realistic representation of impedance is obtained by including a complex load, such as the modified windkessel shown in Fig. 11.5B (similar damping at high frequencies is obtained by including tapering or viscous attenuation in the tube, but these are not considered further here). At low frequencies, the impedance of the load approaches peripheral resistance (R_p), whereas at high frequencies, impedance approaches characteristic impedance (Z_c). Unlike the resistive load, the wave reflection properties of this load (which appear as oscillations in the input impedance) are frequency-dependent and are modulated by the load compliance (C).[85] In addition, f_m no longer necessarily aligns with the frequency of the first zero crossing of phase (f_1),[72] which means that L_{eff} is no longer uniquely defined (as it could be calculated via either f_m or f_1 using the quarter wavelength formula). To avoid this issue, L_{eff} is often equated with the length of a transmission line (i.e., single tube) that is obtained after a parameter optimization process that fits computed to measured pressure waveforms for a given measured flow waveform.[84,86] Note, however, that the L_{eff} value obtained is less than that obtained via f_m and the quarter wavelength formula, because the complex load introduces a frequency-dependent phase lag at the distal end; in other words, confusingly, the load itself has its own "effective length" that is frequency-dependent.[87] These issues have led some to conclude that attempting to define a singular effective length for the arterial system is ultimately a futile exercise.[87]

The principles underlying calculation of two effective reflection sites from the asymmetric T-tube model are the same as those for the single tube model, except that we now consider the combined effect of those two reflection sites (roughly corresponding to upper and lower bodies), when viewed from the ascending aorta (Fig. 11.6). Thus, one can estimate the distance to the two effective reflection sites via the quarter wavelength formula using the frequency of each impedance minimum and PWV at the root of each branch.[88] Since this approach implies resistive loads, an alternative is to fit a computational model (consisting of two transmission lines terminated in complex loads) to measured pressure and flow data.[89]

FIGURE 11.6 (Left) Asymmetric T-tube model consisting of one short tube approximately representing arteries feeding the upper body, and one long tube representing arteries feeding the lower body. (Right) Impedance patterns seen at the entrance of the short and long tubes combine to produce two distinct impedance minima in the ascending aorta. (Note: illustration only).

distally in the upper thigh, an effect that has been likened to chasing the end of a rainbow.[82] Thus, any statements about the main reflection site occurring at a specific anatomical location, such as the aortic bifurcation[83] or renal arteries,[80,84] should be interpreted notionally.

Other limitations of the single tube model are widely recognized. First, the large conduit arteries form a complex branching network with varying diameters and mechanical properties; therefore, the intrinsic premise that waves propagate to and from a reflection site along a uniform tube is fundamentally unrealistic. Second, wave reflection does not occur at a single location, but many. Third, L_{eff} is usually calculated from a single PWV value; since PWV is not the same in all vessels (tending to be higher in smaller vessels), the length is generally underestimated compared with a value that would be obtained if accounting for the true propagation speed. Finally, a key prediction of the single tube model is that the reflected wave will arrive earlier in more distal locations; however, this is not found to be the case in vivo, as will be discussed later in this chapter.

Asymmetric T-tube model

Seminal modeling work by Taylor[90] showed that an arterial network with an asymmetric branching pattern produces two adjacent local minima in the impedance spectrum, implying the presence of not one but two effective reflection sites. Evidence of two effective reflection sites was reported from data in the ascending aorta of dogs,[11,91] humans,[88] and other species.[53] An impedance minimum seen in the brachiocephalic trunk occurred at a higher frequency than that seen in the descending thoracic aorta, implying shorter and longer distances to effective reflection sites, respectively. These impedance patterns appeared to combine from the viewpoint of the ascending aorta, with two minima implying two reflection sites. This led to the concept that the input impedance seen at the ascending aorta resembles that expected from the asymmetric T-tube shown in Fig. 11.6.

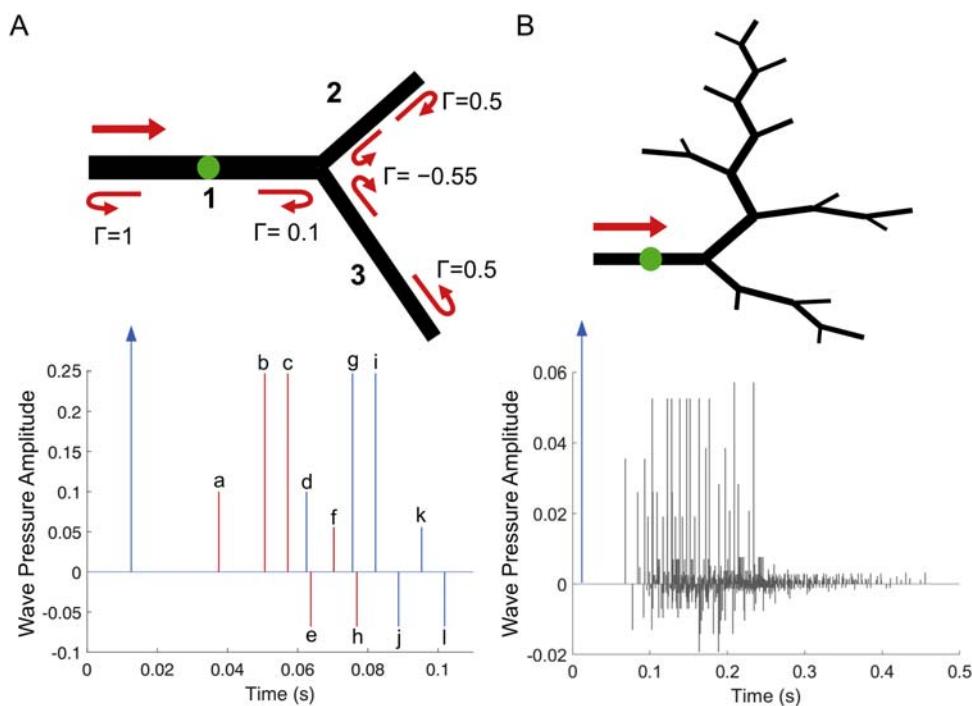
An important concept related to the T-tube model is that the input impedances of upper and lower bodies interact in such a way that fluctuations in ascending aortic impedance are lower than in any other artery. In other words, the arterial tree is designed in such a way as to minimize the return of reflected waves to the left ventricle, thus optimizing afterload.[82] This optimization appears to decrease with aging, however, because aortic stiffening primarily lowers arrival time of lower body reflections, causing a rightward shift in the first impedance minimum and a merging of the two reflection sites.[24,82,92]

Although potentially useful as a means of describing system-level impedance patterns, it has long been recognized that the asymmetric T-tube model represents a marked oversimplification of the arterial system.[11] It shares many of the same limitations as the single tube model in that any calculation of effective lengths should be treated notionally, and not corresponding to some actual discrete reflection

site. The T-tube model better represents the input impedance of the ascending aorta compared with the single tube model,[89,93] but this is not surprising given its greater complexity. The better fit does not "validate" the model in terms of its physical implications (i.e., the actual existence of two reflecting sites), despite these making intuitive sense. From a mathematical point of view, whether the parameters in a T-tube model can be uniquely determined based on input impedance has been questioned.[74] Finally, Murgo et al.[83] argued that the T-tube model implies that one should see two inflection points in the aortic pressure waveform, whereas in most cases only one is visible; similarly, it may be difficult to reliably identify distinct impedance minima and maxima due to limitations in signal fidelity.

Tapered tube models

Whereas the models considered so far involve uniform tubes, some have argued that wave reflection in the real arterial system is affected by geometric and elastic taper, and this property should be accounted for in model representations. Einav et al.[94] explored the impedance properties of a transmission line composed of many small transmission line segments, with characteristic impedance increasing progressively with distance from the inlet. It was shown that even with a well-matched (reflectionless) distal load, the input impedance of the tapered tube exhibited oscillations suggestive of wave reflection, and these oscillations were damped at high frequencies as in the real system. Fogliardi et al.[95] showed that a single tube model incorporating tapering provided a better fit to descending aortic impedance than a uniform tube. However, the parameters providing the optimal fit overestimated proximal characteristic impedance and did not predict other key physical quantities; it was concluded that the introduction of tapering did not show any identifiable benefits regarding the physiological interpretation.[95] An exponentially tapered T-tube model was also explored,[96] but heavily criticized.[97]

Branching network models


The single tube and T-tube models attempt to derive salient information about the arterial network from measured pressure and flow waveforms using the minimum possible number of parameters, a process known as the "inverse problem." By contrast, branching network models address the "forward problem," where knowledge about the complex structure and mechanical properties of the arterial network is prescribed in a model and pressure and/or flow waveforms are *predicted* via solution of reduced-order forms of the Navier−Stokes equations. This approach is useful for exploring the dynamics of wave propagation and reflection in models with realistic properties and can be used as a platform for virtual experiments. We here briefly review the commonly used types of branching network models and some of the insights they have provided about arterial wave reflection.

Linear wave tracking was originally described by Taylor[90] using a frequency domain approach applied to a randomly branching network, and by Remington and O'Brien[8] using a time domain approach applied to the dog aorta and its main branches. As the name implies, any nonlinearities in the system (such as the pressure-dependence of wave speed) must be neglected to allow individual waves to be treated independently of each other. A single "parent" wave (defined as a single sine wave in the frequency domain or a pressure-flow perturbation in the time domain) is prescribed at the inlet of the model and all reflected and transmitted "daughter" waves that are generated at sites of impedance mismatch in the system are tracked. With a unit impulse function as the parent wave, one can then build up an impulse response function.[43,98] Fig. 11.7 provides examples of the impulse response for a simple bifurcation model and a more complex branching network; convolution of the impulse response with a realistic input wave can then be used to predict hemodynamic waveforms.[43]

Using linear wave tracking, it has been shown that (1) asymmetry of a fractal network and inclusion of pulse attenuation leads to a more realistic input impedance (and thus wave reflection properties) than a symmetric, lossless fractal tree[99,100]; (2) very complex wave patterns arise in the arterial network due to multiple re-reflections,[43] as is evident in Fig. 11.7; (3) wave reflection in the periphery makes a greater contribution to aortic pressure than wave reflection in the large conduit arteries[98]; and (4) wave reflection in conduit arteries promotes transmission of pulse pressure to the microvasculature, and therefore does not protect it from excessive pulse pressure.[34]

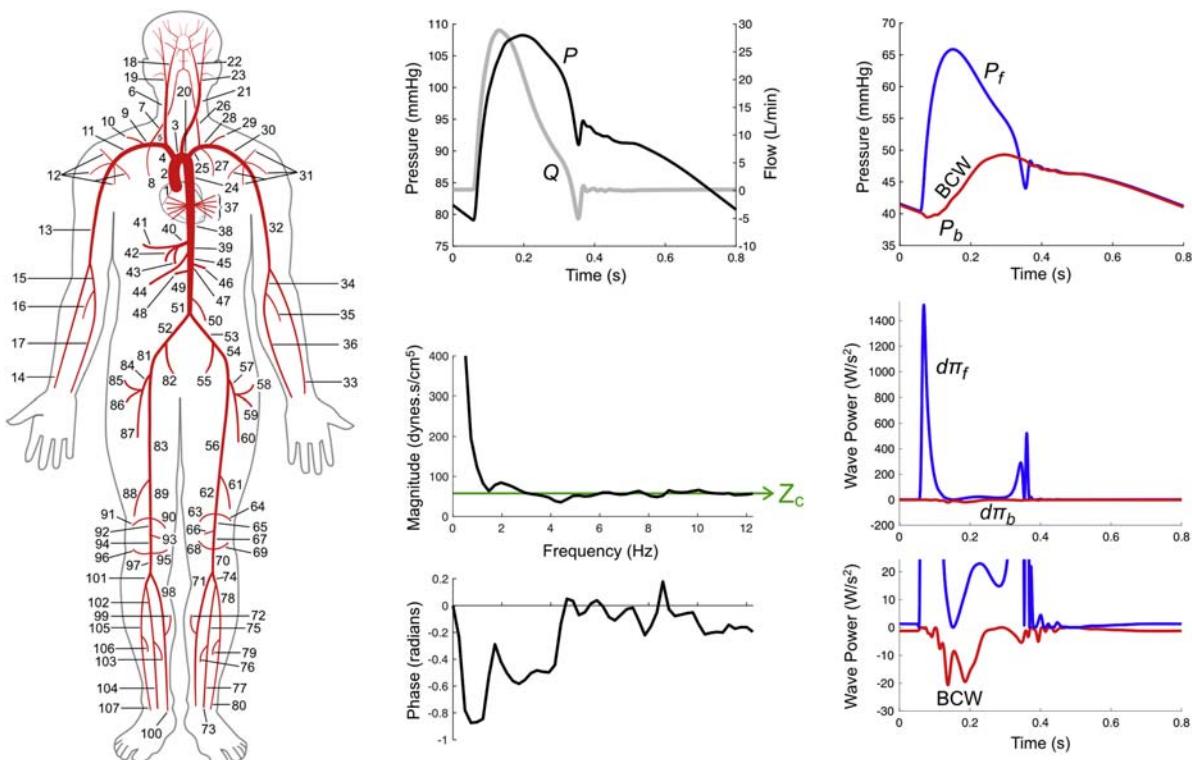
With *1D models*, the reduced-order equations governing pressure and flow for compliant tubes are solved computationally. Individual segments are connected together to form anatomically realistic networks, and boundary conditions for the heart and microvascular beds are provided at the proximal inlet and distal outlets. The first anatomical model of the major systemic arteries, constructed physically with analog electronics by Westerhof et al.,[101] was a particular type of 1D model known as a *transmission line model*. These models involve certain linearizing assumptions: cyclical diameter changes are much smaller than the diameter itself, and similarly, variations of wave speed with


FIGURE 11.7 (A) The linear wave-tracking process is illustrated in a simple bifurcation with a unit impulse sent forward from the inlet. The impulse is transmitted, reflected, and re-reflected at the bifurcation and terminal vessels. This produces multiple waves that arrive at the monitoring point (*green circle*) at different times—modulated by the length and wave speed of each vessel, and at different amplitudes—modulated by the proximal and distal reflection coefficients (Γ) at the inlet and outlet of each vessel. The pressure amplitude of individual waves is depicted by the impulse response, with forward waves in blue and backward waves in red. The input forward wave has an amplitude of 1 (represented by an *arrow*) and arrives at the monitoring site at 0.01 s. It is then reflected at the junction, producing wave "a," having traversed vessel 1 in the forward then backward directions (hence the "wave history" is 1-1). Wave "b" arises from reflection at the outlet of vessel 2, hence its wave history is 1-2-2-1. Wave "c" arises from reflection at the outlet of vessel 3 (1-3-3-1). Wave "d" is from total re-reflection of "a" at the inlet (i.e., 1-1-1). The other waves arise from multiple re-reflections as follows: e, 1-2-2-2-2-1; f, 1-3-3-2-2-1 (also 1-2-2-3-3-1); g, 1-2-2-1-1; h, 1-3-3-3-3-1; i, 1-3-3-1-1; j, 1-2-2-2-2-1-1; k, 1-3-3-2-2-1-1 (also 1-2-2-3-3-1-1); l, 1-3-3-3-3-1-1. (B) Wave tracking in a relatively small branching network produces a multitude of reflected and re-reflected waves (in this case, forward/backward waves are not differentiated with color).

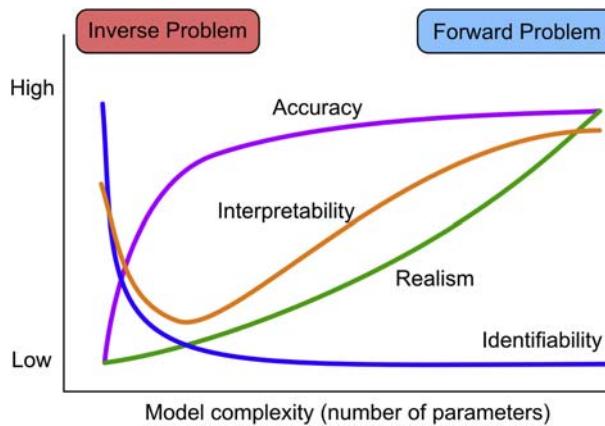
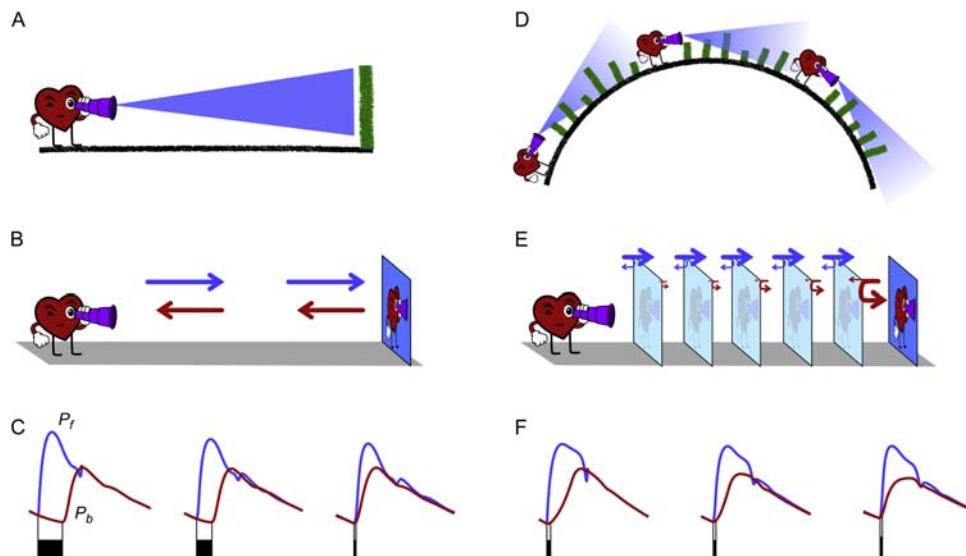
changes in blood pressure are negligible. The resulting equations are mathematically equivalent to those that govern electrical transmission lines. Four elements describe a basic transmission line segment (per unit length): (1) series inductance representing blood inertia (L), (2) series resistor representing energy dissipation due to blood viscosity (R_v), (3) parallel resistor representing leakage through the vessel wall (R_l, often taken to be zero), and (4) parallel capacitor representing local wall compliance (C). Equations for calculating characteristic impedance and reflection coefficients discussed elsewhere in this chapter are based on this model.


Nonlinear 1D models provide the greatest level of realism (for a reduced-order model) in terms of describing arterial hemodynamics, as they account for the nonlinear behavior of the arterial wall and many other physiological phenomena that will not be reviewed here. These models have undergone extensive refinement and validation over the past 40 years and are now widely used as an in silico research platform in the arterial hemodynamics field.[41,70,102–107] These models provide pressure and flow waveforms, an input impedance spectrum, and wave patterns that closely resemble those seen in vivo (Fig. 11.8).

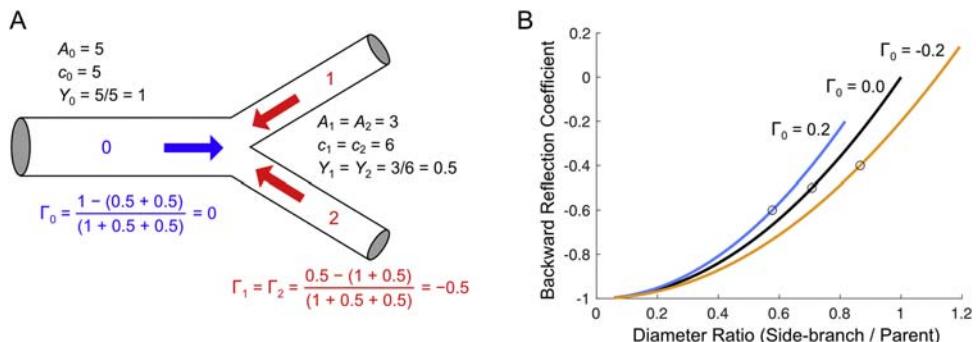
Synthesis

Fig. 11.9 displays the tradeoffs that exist when modeling arterial wave reflection in terms of *accuracy* (can the model predict measured hemodynamics?), *identifiability* (is there a unique set of optimal model parameters?), *interpretability* (can we correlate model parameters with physical properties of the system?), and *realism* (does the model representation and its interpretation correspond with reality?). We suggest that any model may be useful for certain purposes, but every model has limits in scope and utility. Simple models, such as the single tube or asymmetric T-tube (and windkessel models that do not account for wave travel), are suited to estimating bulk or effective properties of the arterial system (inverse problem), but these lack realism and can therefore lead to false conclusions if interpreted literally rather than notionally.[58,108] With increasing model complexity, there is a steep incline in the ability of even simple models to accurately predict pressure-flow patterns at a specific arterial location, but this is not matched by high levels of realism. Complex models, such as anatomically realistic 1D models, are suited to studying the mechanisms underlying arterial wave

FIGURE 11.8   Schematic of a nonlinear one-dimensional model of the systemic arteries and the predicted pressure (P) and flow (Q) waveforms, input impedance (magnitude and phase), and forward (green) and backward (red) components of pressure (P_f and P_b, respectively) and wave power ($d\pi_f$ and $d\pi_b$, respectively) in the ascending aorta. Wave reflection produces a backward compression wave (BCW) seen with wave separation and wave power analysis, and, in the input impedance, a departure from characteristic impedance (Z_c, blue line) at nonzero frequencies. This model is an updated and adapted version of that reported by Reference 41; segment numbers for cerebral arteries are not shown.

FIGURE 11.9 Relationship between the complexity of the models of wave reflection and their accuracy, realism, interpretability, and identifiability. Low complexity models, such as the single tube model, are typically used for the inverse problem (estimating system properties from haemodynamics), but these have limited accuracy and realism. High complexity models, such as one-dimensional network models, are used for the forward problem (predicting haemodynamics from system properties) but have poor identifiability.


dynamics (forward problem) and attain high levels of accuracy, realism and interpretability. However, due to the large number of parameters involved, identifying a unique set of parameters describing an individual is extremely challenging. Very simple models (for the inverse problem) and very realistic models (for the forward problem) can be

readily interpreted; however, although adding a few additional parameters to a simple model improves accuracy, the physiological meaning of those extra parameters (interpretability) is often unclear. Our understanding of arterial wave reflection is entrenched in model descriptions; these models are most useful when their properties, strengths, and limitations are kept clearly in sight.


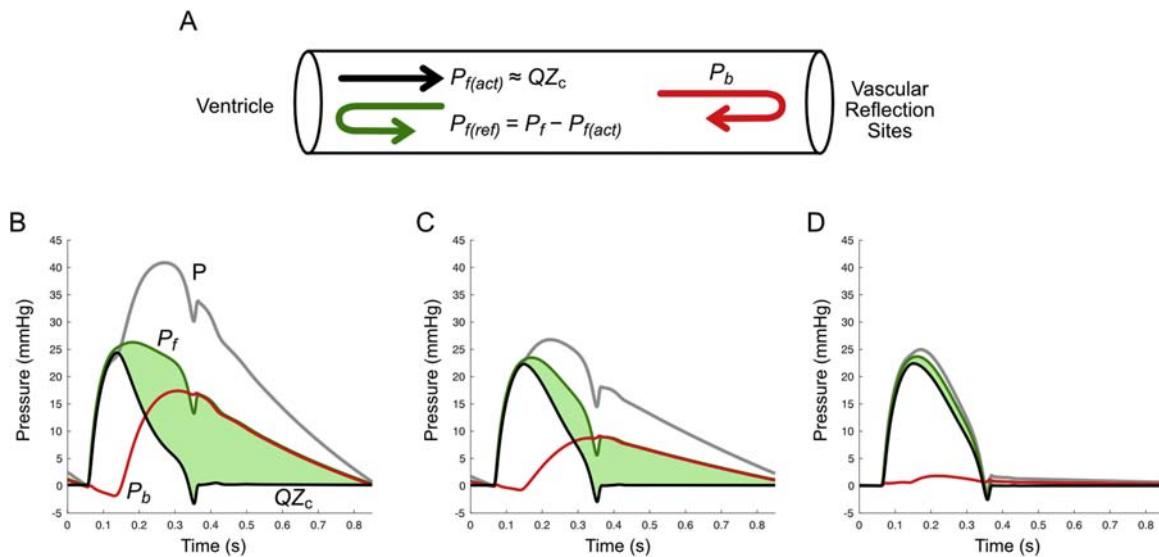
Re-reflections and the horizon effect

It is often incorrectly assumed that the delay between backward (reflected) and forward (incident) waves should decrease with greater distance from the heart, which would occur if the arterial system were a tube terminated with a single reflection site. Fig. 11.10 shows two analogies of this situation, an observer viewing a single object (panel A) or light waves propagating unhindered to a single mirror and back again (panel B). In these scenarios, the delay between forward and backward waves will decrease as the observer approaches the reflection site, as in Fig. 11.10C, which shows forward and backward components of pressure from a 1D model of a single uniform tube.

In reality, however, calculated L_{eff} has been found to be approximately constant relative to the measurement point, when assessed at different points along the aorta.[53,80,81] This may be explained on the basis of two key properties of the arterial system. First, wave reflection is distributed throughout the network; although some uncertainty exists

FIGURE 11.10 Viewing the arterial network as uniform tube with a single major reflection site may be likened to (A) observing a single landmark (green bar) from a distance, or (B) seeing one's reflection in a single mirror. (C) The delay between forward and backward waves (here shown as blood pressure components P_f and P_b) decreases progressively as the observer moves toward the reflection site (*black boxes*); however, this phenomenon is not observed in vivo. Better analogies of arterial wave reflection involve (D) many reflections sites distributed through space and a "horizon" effect, or (E) a series of "one-way" mirrors that efficiently transmit forward waves and produce only minor reflection (*blue arrows*), but that strongly reflect backward waves (*red arrows*); (F) the delay between P_f and P_b onset is then relatively constant regardless of observer location because the reflected waves that are seen mainly arise from the reflection sites nearest to the observer.

FIGURE 11.11 (A) Reflection coefficient (Γ) for a forward-traveling wave (*blue arrow*) or backward traveling waves (*red arrows*) approaching a symmetrical bifurcation, calculated from characteristic admittance ($Y = A/(\rho c)$, where A is area, c is wave speed, and blood density $\rho = 1$ for simplicity). The junction is well-matched in the forward direction ($\Gamma_0 = 0$), but there is strong negative reflection ($\Gamma_1 = \Gamma_2 = -0.5$) in the backward direction. (B) Reflection coefficient in the backward direction in a daughter branch of a bifurcation for a range of daughter/parent diameter ratios, given specified parent vessel reflection coefficients in the forward direction ($\Gamma_0 = 0.2$, 0, and -0.2). *Circles* indicate the case of a symmetric bifurcation.

as to the relative contribution of bifurcations, tapering, and resistance vessels to reflection, all of these sources are spatially distributed throughout the body. Second, the main conduit arteries are well-matched in the forward direction, but not the backward direction.[109,110] For a symmetrical bifurcation that has a reflection coefficient of 0 for forward waves, backward waves in the daughter branches face a reflection coefficient of -0.5 at the junction (Fig. 11.11A). This can be shown by swapping Y_2 or Y_3 with Y_1 in Eq. (11.12), for waves in vessel 1 and 2, respectively. Given fixed forward reflection coefficients, Fig. 11.11A plots the backward reflection coefficients for different daughter-to-parent diameter ratios. These coefficients approach -1 for very small branches, which means that the backward wave is totally re-reflected and has a minimal effect on pressure in the parent branch.


Hardung[10] first described the consequences of this strong negative reflection in the backward direction as follows (translated from German): "The side branch represents a kind of trap for the incoming wave, from which it can only emerge very weakly." For a network with multiple generations of branching, the situation is therefore something like that depicted in Fig. 11.10E. Here junctions are represented as one-way mirrors (mostly transparent in the forward direction and mostly reflective in the backward direction). Forward waves (blue arrows) are efficiently transmitted, with only minor reflection at each junction. By contrast, backward waves (red arrows) returning from the peripheral reflection sites (last mirror) are strongly reflected at each junction, such that very little wave energy returns to the observer. The importance of this phenomenon in the arterial system was evidenced by the finding that distal aortic occlusion in dogs (which introduced a large reflected wave at that site) had an almost imperceptible effect on hemodynamics in the ascending aorta (Westerhof et al.[150]; Van den Bos et al.[151]).

The process of "wave-trapping" in a branching network leads to the so-called wave horizon effect, in which the return time of reflected waves is about the same regardless of where measurements are performed.[81] As depicted in Fig. 11.11D, only waves reflected from relatively nearby sites are observable, because waves originating more distally are progressively attenuated by re-reflection at junctions. Furthermore, the view seen by the observer is similar regardless of the viewpoint. Fig. 11.11F shows results from a tapered tube simulation; because reflection occurs at each point along the vessel, and backward waves are partially trapped by negative re-reflection, the delay between the onset of forward and backward pressure waves is almost the same at different monitoring points.

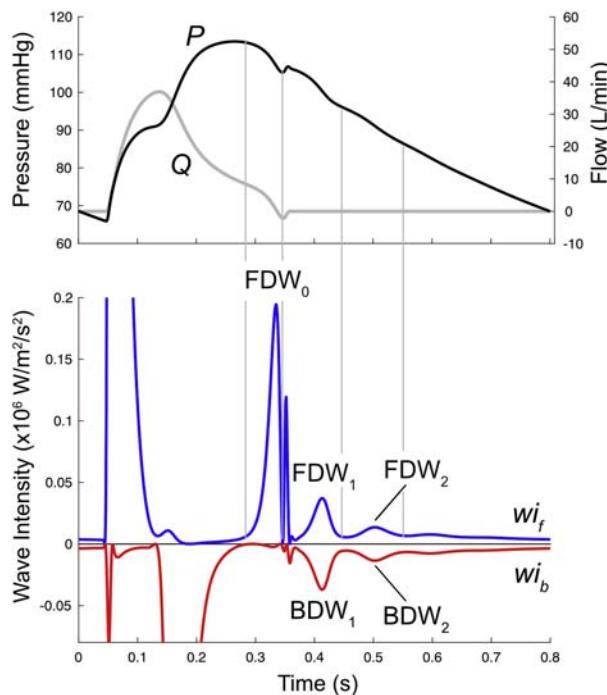
An interesting avenue for future research may be to investigate the circumstances under which wave-trapping is reduced and transmission of backward waves increased, for example, the effect of changes in aortic tapering or stiffness with age. One example of a situation where reflected waves from apparently diffuse/peripheral sites appear to be strongly transmitted back to the ventricle is in the fetal lamb, where a very large BCW is observed in the proximal pulmonary arteries.[111,112] The resulting abrupt flow decrease during mid-systole is also seen in adult humans with pulmonary arterial hypertension,[113] where the reflected wave can also cause partial closure of the pulmonary valve well before the onset of ventricular relaxation.[114,115] In these cases, strong reflection occurs throughout the peripheral vascular bed, rather than in one branch, so although the backward transmission of individual waves may be small, the combined effect of many waves in concert appears to be large.

Ventricular wave re-reflection

The ventricle is often described as the active source of forward waves and the vasculature as the passive locale of

FIGURE 11.12 (A) The ventricle actively produces forward-running pressures waves ($P_{f(act)}$), which are approximately equal to flow (Q) times characteristic impedance (Z_c). Backward-running waves are also re-reflected at the ventricle ($P_{f(ref)}$), contributing to the overall forward component of pressure (P_f), which undergoes reflection in the vasculature (P_b). (B–D) Pressure waveforms from simulations of a ventricle-tube-load model, as in panel A, with different load impedances causing (B) high, (C) medium, and (D) low levels of vascular wave reflection, similar to that presented by Phan et al.[116] The shaded green area represents $P_{f(ref)}$. For clarity, end-diastolic pressure is offset to zero for each waveform.

wave reflection. However, the ventricle is also a major source of wave reflection. Consider what reflected waves approaching the ventricle encounter—a relatively stiff, closed chamber during systole and a closed aortic valve during diastole. The ventricle is therefore essentially a "dead-end" from the perspective of backward-running waves, with a reflection coefficient close to one.[74] The caveats to this are that (1) a small amount of wave energy is likely transmitted into the coronary arteries and (2) the ventricle constitutes a time-varying complex impedance, so the ventricular reflection coefficient (Γ_v) will be lower for high-frequency waves.[74]

There are several important implications of ventricular wave reflection. First, the forward component of pressure (P_f) is formed by the combination of two quite separate mechanisms, (1) active ventricular contraction ($P_{f(act)}$) and (2) re-reflection of backward waves that arise from vascular wave reflection ($P_{f(ref)}$, Fig. 11.12). Second, the backward wave (P_b) does not represent the total effect of vascular wave reflection on pulse pressure; rather, its effect is better represented by $P_b + P_{f(ref)}$, which is equivalent to $P - Q \times Z_c$ (i.e., the difference between measured pulsatile pressure and the product of flow and Z_c). Third, the forward wave should not be considered independent of the reflected wave, nor equated with "ventricular function" per se (in contradistinction to vascular wave reflection), as elegantly demonstrated by Phan et al.[116] Findings that the forward wave contributes to central pressure augmentation[22,117] are not inconsistent with the principle that this augmentation ultimately arises from vascular wave reflection, and that


vascular wave reflection is responsible for differences in arterial pressure and flow waveforms.

Wave reflection, windkessel function, and diastolic pressure decay

The principle that wave reflection underlies all differences in pressure and flow waveforms holds when considering what is perhaps the most obvious difference: during diastole, pressure decays in an approximately exponential fashion while flow remains zero due to the closed aortic valve. This phenomenon is usually interpreted as the decline in pressure of the compliant arterial "chamber" that is discharging its volume through a peripheral resistance. This windkessel model assumes infinite wave speed, which is problematic during systole when wave phenomena dominate but is a reasonable assumption during diastole when waves are highly dispersed (i.e., the wavelengths of waves remaining in the system are long compared with the physical length of the body, so pressure gradients within the large arteries are small and the spatial dimension can be ignored). While the windkessel and wave theories have sometimes been considered "opposing" models, the windkessel model can in fact be derived from (and can be seen as a mathematical reduction of) the wave model.[118] It is therefore instructive to consider how diastolic hemodynamics can be explained in terms of the more general wave theory.

Early work in this area includes that of Singer,[119] who showed that "the major contribution of the reflected wave is

the maintenance of the diastolic pressure" and Sipkema et al.[91] who noted that "the exponential decay is due to diffuse reflection." More recently, Mynard and Smolich[118] showed that the diastolic pressure decay arises specifically from repeated and diffuse reflection of the late-systolic forward decompression wave (FDW). The FDW drives the late-systolic flow deceleration and pressure fall preceding the dicrotic notch. While most discussion around wave reflection revolves around reflection of the early systolic FCW as a BCW, it stands to reason that the FDW is also reflected in the vasculature. Positive reflection of the FDW gives rise to a BDW that further reduces pressure (Fig. 11.13). This wave is further re-reflected at the closed aortic valve giving rise to another FDW, which undergoes further reflection in the vasculature, and so on (Fig. 11.13). Although a series of discrete FDWs and BDWs can sometime be observed in vivo with wave intensity analysis,[45,118] the diffuse nature of wave reflection generally leads to low (albeit nonzero) wave intensity and a lack of distinct wave peaks during this time.

FIGURE 11.13 The diastolic pressure decay arises from repeated reflections of the late-systolic forward decompression wave (FDW$_0$). This wave undergoes positive reflection in the vasculature, returning as a backward decompression wave (BDW$_1$), which is then totally re-reflected at the closed aortic valve, producing an FDW$_1$ of equal magnitude. This forward wave is further reflected in the vasculature (BDW$_2$) and re-reflected at the valve (FDW$_2$) and so on. Data taken from a one-dimensional model of a single tube terminated with a single reflection site (a three-element windkessel). With in vivo data, discrete decompression wave peaks (such as FDW$_1$ and FDW$_2$) are often not visible due to the distributed/diffuse nature of wave reflection.

Methods for assessing the magnitude and timing of arterial wave reflection

This section describes the various methods that are available for quantifying the magnitude and timing of reflected waves, both of which hold important clinical significance. The focus here is on "global" reflection, that is, the combined effect of all wave reflections throughout the arterial network, in contrast to "local" reflection that relates to a single site of impedance mismatch as discussed earlier in this chapter (e.g., single bifurcation). A summary of these techniques is provided in Tables 11.2 and 11.3.

Pulse wave analysis

Aortic pressure waveforms typically display an initial rise that accompanies early systolic flow acceleration, followed by a secondary pressure "augmentation," as shown in Fig. 11.14.[83] Two fiduciary points used to separate these two pressure rises are the "shoulder" point and the "inflection" point, detected via derivatives of the pressure waveform (Fig. 11.14). Kelly et al.[16] found that the shoulder point generally coincided with the time of peak flow, implying that the following augmented pressure, which occurs when flow is decreasing, must be due to reflected waves. However, the inflection point is thought to better correspond with the arrival time of reflected waves and is now more widely used[51]; it should be noted that, confusingly, some papers refer to the "inflection" point as the "shoulder" point.

Augmentation pressure (AP) is defined as AP $= P_{pk} - P_i$, where P_{pk} is peak systolic pressure and P_i is the pressure at the inflection point.[83] Augmentation index (AIx) is then defined as:

$$\text{AI}x = \frac{\text{AP}}{\text{PP}} \tag{11.13}$$

where PP is pulse pressure. AIx increases with age but tends to plateau or even decrease after middle age.[16,77,120,121] Although caused by wave reflection, the limitations of AIx as a measure of reflection magnitude are widely recognized. Negative values of AIx occur in young adults but these do not imply negative wave reflection. AIx is strongly influenced by factors that are not related to reflection magnitude per se, such as heart rate,[122] ventricular function,[123–125] and the arrival time of reflected waves.[126,127]

Arrival time is calculated as the delay between the onset of the initial pressure rise and the inflection point (T_i in Fig. 11.14). T_i was proposed to be a surrogate marker of arterial stiffness, under the principle that the reflected wave will return earlier as PWV increases. A meta-analysis by Baksi et al.[120] showed that T_i decreased only modestly with age and the inflection point always

TABLE 11.2 Summary of techniques for quantifying global wave reflection magnitude.

Method	Definition	Advantages	Disadvantages
Augmentation index	$AIx = AP/PP$	Requires a pressure waveform only	Modulated by various factors other than wave reflection (e.g., heart rate, forward waves, reflection arrival time) Negative values do not indicate negative reflection
Reflection magnitude (time domain)	$RM = \Delta P_b / \Delta P_f$	Intuitive interpretation, scalar index of global reflection	Requires pressure and flow/velocity waveforms; re-reflection contributes to ΔP_f
Global reflection coefficient	$\Gamma_P(\omega) = \frac{Z_{in}(\omega) - Z_c}{Z_{in}(\omega) + Z_c}$	Comprehensive representation of arterial reflection properties for all wave frequencies	Complex quantity (not single number), frequency domain analysis less intuitive than time domain analysis
Terminal reflection coefficient	$\Gamma_0 = \frac{R_p - Z_c}{R_p + Z_c}$	Quantifies contribution of resistance vessels	Neglects pulsatile haemodynamics, physical meaning of reflection at zero frequency is unclear
Reflection coefficient (real part of first harmonic)	$Re(\Gamma_1) = \left\|\frac{Z_{in}(\omega_1) - Z_c}{Z_{in}(\omega_1) + Z_c}\right\|$	Scalar summary of reflection coefficient for the largest harmonic	Neglects contribution of other harmonics, requires frequency domain analysis
Reflection coefficient (real part of multiple harmonics)	$Re(\Gamma_i) = \left\|\frac{Z_{in}(\omega_i) - Z_c}{Z_{in}(\omega_i) + Z_c}\right\|$ where $i = 1,2,3 \ldots$	Provides information about reflection for different frequencies	Provides multiple metrics of reflection; interpretation is not intuitive
Normalized reflection coefficient	$\Gamma_{norm} = \sum_{i=1}^{N} w_i \Gamma_i$, where $w_i = H_i / \sum_{j=1}^{N} H_j$	Scalar summary of global reflection coefficient, accounts for all (nonzero) harmonics	Complex calculation requiring frequency domain analysis
Wave reflection index (frequency domain)	$WRI = \Gamma_P(\omega)_{max} - \Gamma_P(\omega)_{min}$ for harmonics >2 Hz	Scalar summary of global reflection	Based on the single tube model, conceptually difficult
Wave reflection index (wave intensity)	$WRI_{peak} = BCW_{peak}/FCW_{peak}$ $WRI_{area} = BCW_{area}/FCW_{area}$ $WRI_{centroid} = BCW_{centroid}/FCW_{centroid}$	Intuitive time domain approach	Emphasizes high-frequency reflection. Prone to error due to nonlinear amplification effects

AP, augmentation pressure; *BCW*, backward compression wave; *FCW*, forward compression wave; H_i, modulus of the i–th harmonic of the pressure spectrum; *PP*, pulse pressure; Z_{in}, input impedance; Z_c, characteristic impedance; ΔP_f, amplitude of forward component of pressure ("f"); ΔP_b, backward component of pressure ("b"); Γ_i, modulus of the i–th harmonic of the reflection coefficient spectrum; ω_i, angular frequency of the i-th harmonic.

occurred in the first two thirds of systole. It was suggested that these data conflicted with the concept that reflected waves arrive mainly during diastole in youth, and that a progressive shift to earlier reflection time is a key factor underlying isolated systolic hypertension.[128] Moreover, calculated effective reflection distance computed using T_i ($L_{eff} = PWV \times T_i/2$) increases with age, implying a distal shift in reflection sites.[77] However, it has been shown that neither the shoulder nor inflection points align with reflected wave arrival time determined by wave separation analysis, and that L_{eff} calculated with the latter does not change with age.[76,129] The use of T_i to estimate L_{eff} assumes that the arterial system behaves as a single tube and that a single reflected site produces a reflected

wave that has the same morphology over the life course. Simulation studies in a realistic network model showed that T_i is relatively insensitive to arterial stiffness changes and, conversely, is sensitive to proximal reflections produced by aortic tapering, suggesting that it may not provide a satisfactory representation of "global" reflection time.[126]

In summary, despite the widespread use of AIx and T_i to estimate the magnitude and timing of reflected waves, these should be used with caution as their limitations are well-recognized.[76,125,129–131] Many of these limitations have been revealed by comparison to wave separation analysis, which is considered the "gold standard" for assessing reflected waves.

TABLE 11.3 Summary of techniques for quantifying effective return time of reflected waves.

Method	Definition	Advantages	Disadvantages
Pulse wave analysis			
Time to shoulder point	T_s (Fig. 11.14)	Requires only a pressure waveform	Represents time of peak ejection, not arrival time of reflected waves
Time to inflection point	T_i (Fig. 11.14)	Requires only a pressure waveform	Not always detectable, sensitive to noise (depends on second derivative), does not agree with wave separation
Wave separation			
Foot-to-foot time	T_r (Fig. 11.15B and C)	Uses forward/backward components of pressure	Foot time may not be clearly defined, especially for backward wave
Zero-crossing method	T_r (Fig. 11.15D)	Uses forward/backward components of pressure	Wave separation performed in frequency domain
Frequency domain analysis			
First minimum in impedance modulus	$T_m = \frac{1}{2f_m}$ (Fig. 11.5)	–	Based on uniform tube model with resistive load. Complex analysis, not intuitive.
First zero crossing in impedance phase	$T_1 = \frac{1}{2f_m}$ (Fig. 11.5)	–	Based on uniform tube model with resistive load. Not intuitive. Does not align with T_m in real system.
Model-based analysis			
Fit waveforms to single tube model	$2L/PWV$	Simple representative model	Value obtained depends on modeling assumptions and boundary conditions
Wave intensity analysis			
Foot-to-foot (FCW-BCW)	T_{foot} (Fig. 11.17)	Intuitive time-domain method	Foot of the BCW often not well-defined.
Peak-to-peak (FCW-BCW)	T_{peak} (Fig. 11.17)	Intuitive time-domain method	BCW may not have single well-defined peak.
Centroid-to-centroid (FCW-BCW)	$T_{centroid}$ (Fig. 11.17)	Accounts for the whole morphology of each wave	WI emphasizes high-frequency reflection.

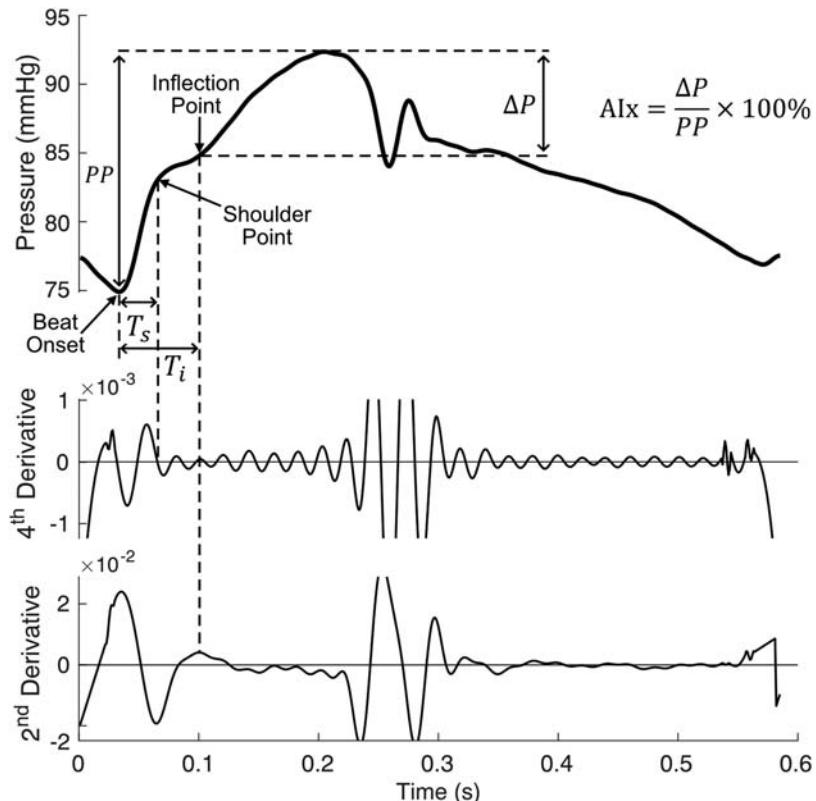
BCW, backward compression wave; *FCW*, forward compression wave; f_m, frequency of the first minimum in the impedance modulus; f_1, frequency of the first zero-crossing of impedance phase; *L*, length of the single tube model; *PWV*, pulse wave velocity.

Wave separation

Considerable insights into the wave reflection properties of the arterial tree can be gathered by "separating" the measured pressure and flow waveforms into their forward and backward components, noting that, as mentioned earlier, the forward component also includes re-reflections from the ventricle (Fig. 11.12). Both frequency-domain and time-domain methods of wave separation have been developed, with both giving comparable results.[9,132−134] Wave separation requires pressure and flow waveforms at a particular site, with forward (*f*) and backward (*b*) components obtained in the time-domain as:

$$P_f = \frac{1}{2}(P - P_{ud} + Z_c Q) \qquad (11.14)$$

$$P_b = \frac{1}{2}(P - P_{ud} - Z_c Q) \qquad (11.15)$$

$$Q_f = \frac{1}{2}(Q + (P - P_{ud})/Z_c) \qquad (11.16)$$


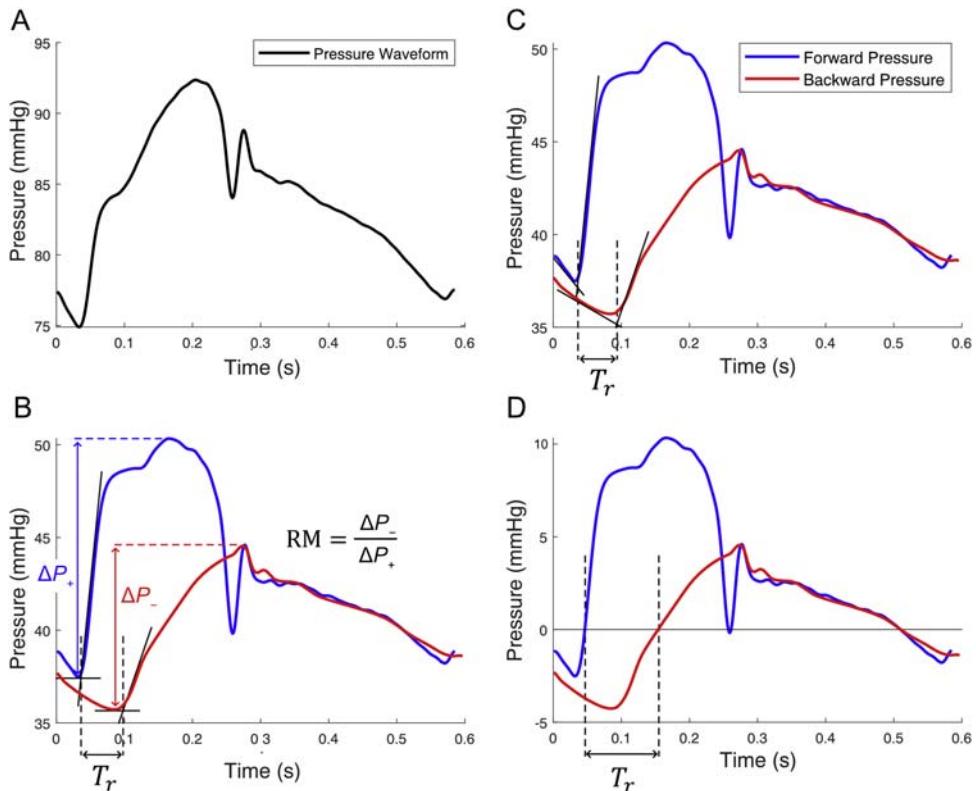
$$Q_b = \frac{1}{2}(Q - (P - P_{ud})/Z_c) \qquad (11.17)$$

where Z_c is characteristic impedance. Undisturbed pressure (P_{ud}) enables assessment of wave potential (absolute values of P_f, P_b, Q_f, and Q_b),[118,135] but can be neglected if only investigating pulsatile aspects of the waveforms (e.g., wave reflection).

Reflection magnitude is calculated from the pressure or flow components as:

$$RM = \frac{\Delta P_b}{\Delta P_f} = -\frac{\Delta Q_b}{\Delta Q_f} \qquad (11.18)$$

where Δ here refers to the overall amplitude of the respective waveform (Fig. 11.15B). Advantages of this approach

FIGURE 11.14   The shoulder point is identified by the second zero-crossing of the fourth derivative of the pressure waveform in the direction from above to below zero. The inflection point is identified by the second peak of the second derivative of the pressure waveform. The shoulder point or the inflection point can be used to estimate reflection time (T_s and T_i, respectively) by their time difference to beat onset time. ΔP is the pressure difference between the systolic pressure and the inflection point. Dividing ΔP by the pulse pressure (PP) gives the augmentation index (AIx), an index of reflection magnitude.


(in contrast to AIx) are that (1) it can correctly attribute pressure changes to backward and forward waves even if they occur simultaneously, and (2) it can capture wave reflection effects that span both systole and diastole.

Compared with RM, there is less consensus regarding the best method for estimating reflection time using wave separation. The most common method takes the difference between the onset (foot) of the backward and forward pressure waveforms as reflection time (T_r). While the foot can be found by visual inspection, Chiu et al.[136] developed the "intersecting tangents" method, in which a tangent is drawn at the point of maximum gradient on the upstroke of the pressure waveform and a horizontal tangent is drawn through the point of minimum pressure at the foot; the point of intersection of the tangents is taken as the foot (Fig. 11.15B). One variant of this approach is to replace the horizontal line with a line of best fit between the minimum and a few preceding points (Fig. 11.15C).[126,137] However, Segers et al.[129] noted that the "foot" is often not clearly defined by a single point, especially for backward waveforms, and instead proposed the zero-crossing method. Here, mean pressure is subtracted from the pressure waveform before wave

separation (essentially, setting $P_{ud} = \text{mean}(P)$ in Eq 11.14). This results in P_f and P_b waveforms that cross the time axis; the difference between the first zero crossing of these waveform is then taken as T_r (Fig. 11.15D). Another study took the difference between the time of peak backward and forward pressure[138]; however, this is likely to be confounded by re-reflections from the ventricle.

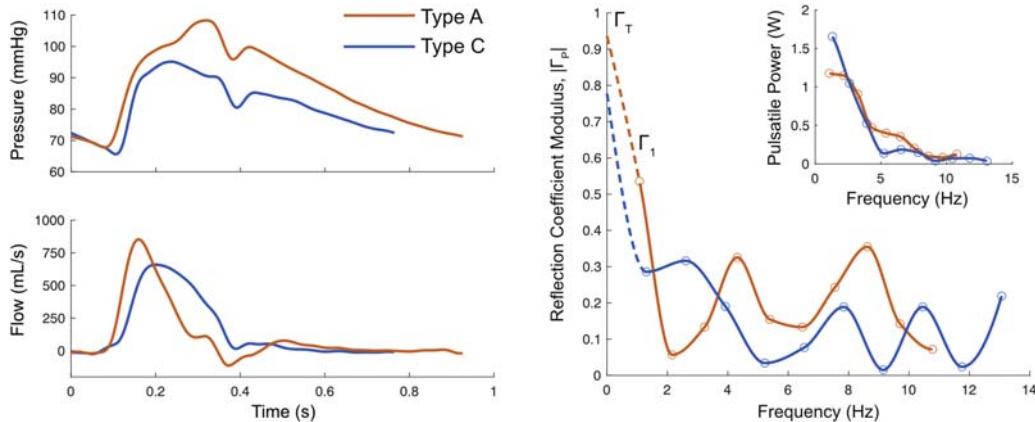
Frequency domain analysis

A number of frequency domain or impedance-based techniques have been used to evaluate the magnitude and timing of wave reflection. These provide insight into the frequency-dependence of wave reflection, although they are not commonly used in clinical studies as they can be difficult to grasp for the nonmathematician. Frequency domain analysis is covered in Chapter 3; in brief, pressure and flow are expressed as a series of sinusoidal harmonics, $P(\omega)$ and $Q(\omega)$ (where $\omega = 2\pi f$ and f is frequency) and can be used to calculate an input impedance spectrum $Z_{in}(\omega) = P(\omega)/Q(\omega)$. The following indexes of reflection have been proposed:

FIGURE 11.15   Using wave separation, a pressure waveform (A) can be separated into the forward and backward wave components (B). From this, the reflection magnitude (RM) is calculated as the ratio of the backward pressure amplitude (ΔP_b) to the forward pressure amplitude (ΔP_f). Reflection time (T_r) is calculated as the time between the foot of the backward and forward pressure components, found using the intersection of a tangent line through the pressure upstroke at the point of maximum gradient, and (B) a horizontal line from the minimum pressure, or (C) a line of best fit between minimum pressure and a few preceding points. T_r can also be calculated by subtracting the mean pressure before wave separation and taking the time difference between the first zero crossing of the backward and forward pressures (D).

The *reflection coefficient spectrum*, or "global reflection coefficient,"[9] expresses Eq. (11.10) in the frequency domain and considers the impedance mismatch between characteristic impedance (Z_c) at the measurement site and the lumped frequency-dependent input impedance of the downstream circulation (Z_{in}).

$$\Gamma_P(\omega) = \frac{Z_{in}(\omega) - Z_c}{Z_{in}(\omega) + Z_c} \qquad (11.19)$$

When plotted versus frequency, the modulus of $\Gamma_P(\omega)$ exhibits a peak at the fundamental frequency and falls at higher frequencies (Fig. 11.16). At low frequencies, $\Gamma_P(\omega)$ approaches the zero-order or "terminal reflection coefficient" (Γ_T), or the impedance mismatch between Z_c and peripheral resistance[56]; however, the physical meaning of this coefficient is unclear since mean pressure and flow are not considered waves that could be reflected. A more common metric of reflection magnitude is Γ_1, or reflection coefficient for the fundamental frequency (i.e., heart rate), noting that this harmonic holds the most pulsatile energy (Fig. 11.16 inset).[24,139] Although $\Gamma_P(\omega)$ is frequency-dependent, and hence not a single number, Xiao et al.[140]


proposed a scalar (i.e., single number) normalized reflection coefficient (Γ_{norm}) equal to the sum of $\Gamma_P(\omega)$ moduli weighted to the normalized pressure moduli, which was considered analogous to reflection magnitude obtained via wave separation analysis.

Another approach for assessing wave reflection in the frequency domain involves directly analyzing the impedance spectrum. Noting that wave reflection causes oscillations in the impedance spectrum around Z_c (Fig. 11.5), the "wave reflection index (WRI)" is defined as the difference between maxima and minima of impedance spectra in the mid-to-high frequency range, which Nichols et al.[141] defined as >2 Hz.

Frequency domain methods for assessing reflection time (and hence, L_{eff}) are covered in Box 11.2 and summarized in Table 11.3.

Wave intensity

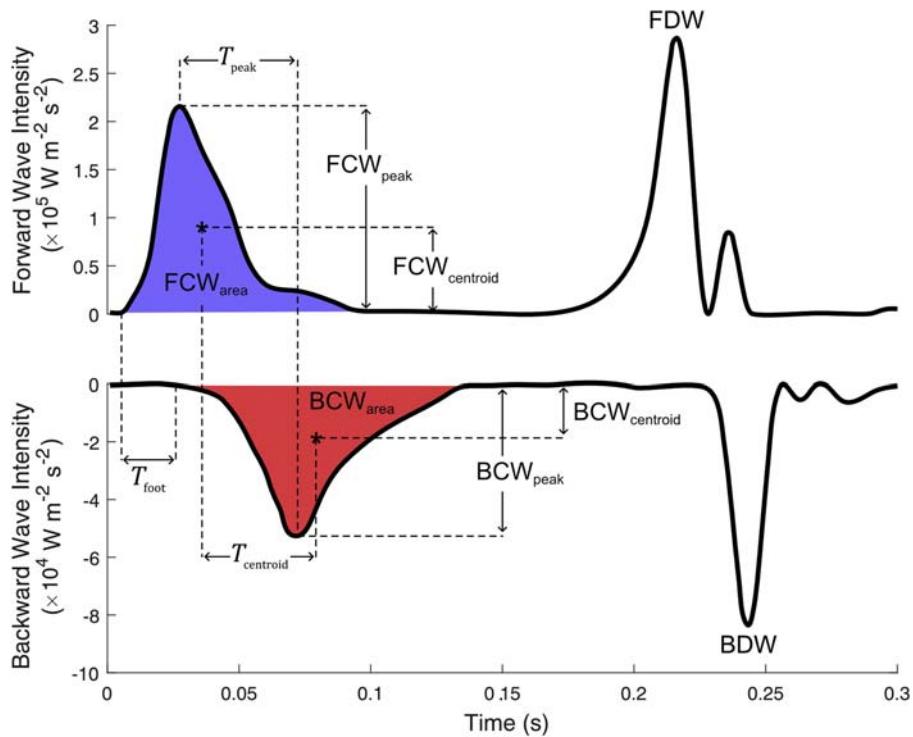
Parker and Jones[142] introduced wave intensity analysis as an intuitive time-domain method of analyzing forward and backward waves. While covered in more detail in

FIGURE 11.16 Frequency-dependent reflection coefficient modulus $|\Gamma_P(\omega)|$ for Type A and Type C aortic waveforms taken from Murgo et al.[83] (with thanks to Prof. Patrick Segers). Open circles indicate reflection coefficient for the first 10 harmonics. The dashed lines indicate that reflection coefficient approaches the "terminal reflection coefficient" (Γ_T, i.e., the nominal mismatch between Z_c and peripheral resistance) at very low frequencies. Γ_1 refers to reflection coefficient at the fundamental frequency (i.e., first harmonic), which contains the most pulsatile power (see inset) but is dependent on heart rate. Less pulsatile power resides in high-frequency harmonics, which also undergo generally minor reflection.

Chapter 3, briefly, time-corrected wave intensity (wi) is defined as:

$$wi = \frac{dP}{dt}\frac{dU}{dt} \tag{11.20}$$

where dP/dt and dU/dt are the derivatives of pressure and velocity. As for pressure and flow, wave intensity can be separated into forward and backward components as follows:

$$
\begin{aligned}
wi_f &= +\frac{1}{4\rho c}\left(\frac{dP}{dt} + \rho c\frac{dU}{dt}\right)^2 \\
wi_b &= -\frac{1}{4\rho c}\left(\frac{dP}{dt} - \rho c\frac{dU}{dt}\right)^2
\end{aligned}
\tag{11.21}
$$


which has the convenient property that forward waves have positive wi and backward waves have negative wi. Wave power, proposed by Mynard and Smolich,[143] uses flow in place of velocity and has the benefit that it is conserved at junctions, allowing the proportion of reflected and transmitted wave power (in Watts) to be quantified. However, when measured at a single site, the two techniques are essentially equivalent. Fig. 11.17 shows a typical wave intensity profile in the aorta and identifies four different types of waves, a FCW reflected as a BCW and a FDWs reflected as a BDW.

In studies of wave intensity, reflection magnitude is estimated as the ratio of the BCW to FCW amplitude, termed the WRI (Fig. 11.17). While peak intensity may seem the logical choice for quantifying wave amplitude, in some instances, the BCW is relatively diffuse and may not contain a single distinct peak; moreover, although peak

intensity relates to the maximum rate of change of pressure and velocity, it does not represent the overall effect of the wave on these signals (which relates to the height *and* width of the wave). WRI is therefore more often calculated as the ratio of the area under the BCW and FCW[29,144] or, less commonly, as the ratio of their centroids (Fig. 11.17).[145]

Mynard et al.[146] showed that the dependence of wave speed on pressure causes both the peak and area of the FCW and BCW to amplify as these waves propagate. This can cause errors in estimating reflection magnitude, even leading to a WRI that exceeds the theoretical limit of 1.[111,147] Importantly, Mynard et al.[146] found that the reflection magnitude obtained by wave separation of the pressure waveform (Eq. 11.18) was not susceptible to this issue and accurately quantified reflection.

It is also important to note that WRI is generally much smaller than RM. This is partly because WRI is theoretically equivalent to the power reflection coefficient (Γ_Π in Table 11.1), which is equal to the square of the pressure or flow coefficients (Γ_P and Γ_Q).[146] In addition, the multiplication of pressure and velocity derivatives acts as a high pass filter, suppressing low frequency reflection and emphasizing high-frequency reflection. However, as discussed above, due to the relatively efficient transmission of forward waves, and distributed nature of arterial wave reflection, the high-frequency components of pressure and flow are minimally reflected, while the majority of reflection occurs in the low frequency range. Indeed, the aortic BCW is often observed to be very small,[148,149] which can lead to the false impression that very little wave reflection occurs in the arterial system.

FIGURE 11.17 From the wave intensity profile, a wave reflection index can be obtained by taking the ratio of backward compression wave (BCW) to forward compression wave (FCW) peak intensity (BCW$_{peak}$/FCW$_{peak}$), intensity at wave centroid (BCW$_{centroid}$/FCW$_{centroid}$), or area under the wave (BCW$_{area}$/FCW$_{area}$). Reflection time can be obtained using the difference of the foot (T_{foot}), peak (T_{peak}), or centroid ($T_{centroid}$) of the BCW and FCW. The forward decompression wave (FDW) and backward decompression wave (BDW) are also shown, but generally not used to quantify reflection. Note the different Y-scales for forward and backward wave intensity plots.

Alastruey et al.[145] investigated several methods for calculating reflection time using wave intensity, namely, defining BCW and FCW time via the (1) peak, (2) foot, and (3) centroid (Fig. 11.17). Using a single tube computational model with a discrete reflection site, they found that the foot method produced the closest estimate of theoretical reflection time. However, the accuracy of these methods in a more realistic network model was less clear owing to the diffuse nature of reflections. Although not specifically investigated, the aforementioned emphasis of high-frequency reflection in wave intensity analysis may mean that the timing of global wave reflection is not adequately captured.

Summary

Wave reflection arises due to impedance mismatching in the arterial network. Although the exact locations of reflection are uncertain, the well-matched design of the conduit arterial network appears to facilitate efficient transmission of forward waves to vascular beds. However, wave reflection necessarily occurs because of the high impedance of smaller vascular beds compared with the low impedance of conduit arteries. Wave reflection occurs at a myriad of spatially distributed sites, and methods that quantify a reflection distance or reflected wave arrival time relate to the lumped or "effective" reflection properties of the network, which should be applied and interpreted with extreme caution. Simplified models of wave reflection capture these lumped properties but provide limited insight into the complex nature of arterial wave dynamics. At arterial junctions, forward waves undergo minimal reflection, whereas backward waves undergo strong negative reflection, limiting the transmission of reflected wave power to the heart. The resulting horizon effect leads to an approximately constant delay between forward and backward waves, regardless of the measurement site. Backward-running waves are also re-reflected by the ventricle during systole and closed aortic valve during diastole, with the resulting forward-running waves contributing to the forward component of pressure. Forward pressure is therefore not generated solely by active ventricular contraction, and the total impact of arterial wave reflection on blood pressure is greater than the commonly used indices of reflection magnitude imply.

Chapter 12

Linking arterial stiffness to microvascular remodeling

Arinola O. Lampejo[1], Nien-Wen Hu[1], Ariana Suarez-Martinez[1], Prasad V.G. Katakam[2], Jerome W. Breslin[3], Shayn M. Peirce[4] and Walter L. Murfee[1]

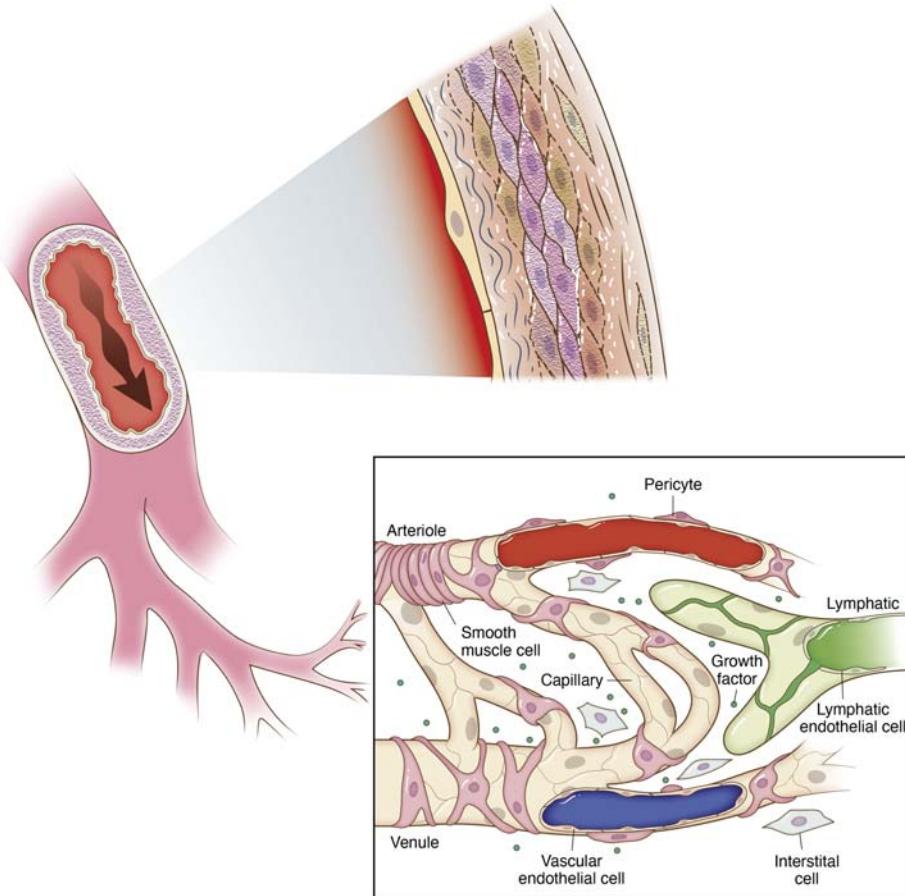
Motivation


Large artery stiffening (LAS) and more generally arterial stiffening are associated with aging and numerous age-related pathologies including diabetes, atherosclerosis, chronic kidney disease, hypertension, and cerebrovascular disease. Vessel wall remodeling across pathologies involves a concert of cellular and molecular mechanisms, which have been comprehensively reviewed[1−8] and are further detailed in the accompanying book chapters. Consideration of these mechanisms emphasizes that arterial wall stiffening may have implications beyond just a decrease in wall compliance related to changes in the local extracellular matrix. The fact that microvascular dysfunction occurs in the same disease states and is caused by similar, if not overlapping mechanisms, suggests there are more direct linkages between LAS and microvascular remodeling that may be important to consider in the progression of disease.[9,10] Signals that may transmit pathology between macro- and microvessels fall into two categories: circulating factors and hemodynamics. Whether and to what extent arterial stiffening and specifically LAS directly influences downstream functional adaptations of microvascular networks remains unclear because the presence and effects of these signals at the microvascular level are largely undetermined. However, a review of the literature reveals putative mechanisms of communication between arteries and the microcirculation that may contribute to both LAS and downstream abnormalities in microvascular structure and function, creating feedback loops that may further exacerbate disease.

The objective of this chapter is to explore the links between LAS and microvascular remodeling. The chapter first offers a view of arterial wall stiffening from a microvascular remodeling perspective, focused on overlapping cell types. As microvascular remodeling encompasses the growth of new capillaries, capillary acquisition of perivascular wrapping cells, and patterning alterations, the major roles of overlapping cell types involved in arterial stiffening will then be described for the multiple subprocesses that coordinate microvascular remodeling. Next, known microvascular remodeling alterations associated with hypertension and aging will be used to highlight how gaps in our current understanding make links to the macrocirculation less clear. The chapter will culminate with a discussion of how circulating factors may be coupled with hemodynamic changes in LAS. In light of our incomplete understanding, the challenge of linking blood vessel remodeling across the macro- and microvascular systems serves to identify important knowledge gaps for future research.

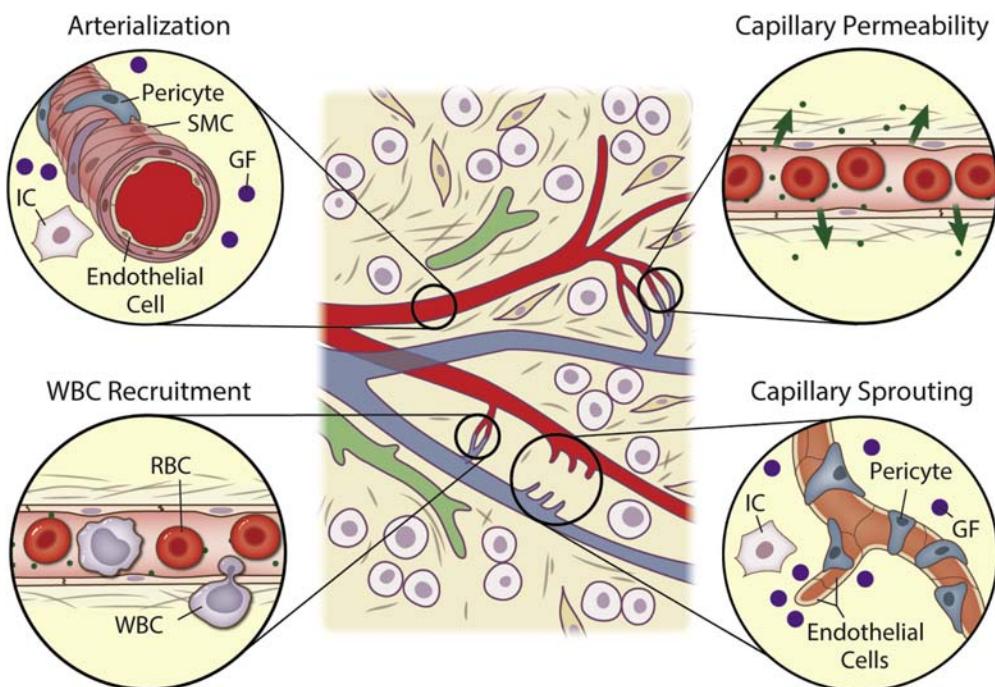
A microvascular remodeling view of large arterial stiffening

LAS is related to aging, insulin resistance, preeclampsia, cognitive impairment, myocardial dysfunction, kidney disease, and stroke.[1−6,11] From a remodeling perspective, the causes and consequences of LAS can be associated with age or age-related changes in altered cell behavior. Moreover, the same cellular players involved in LAS and more generally arterial stiffening are implicated at the microvascular level (Fig. 12.1). Dynamics associated with the interplay between smooth muscle cells (SMCs), pericytes, endothelial cells, fibroblasts,

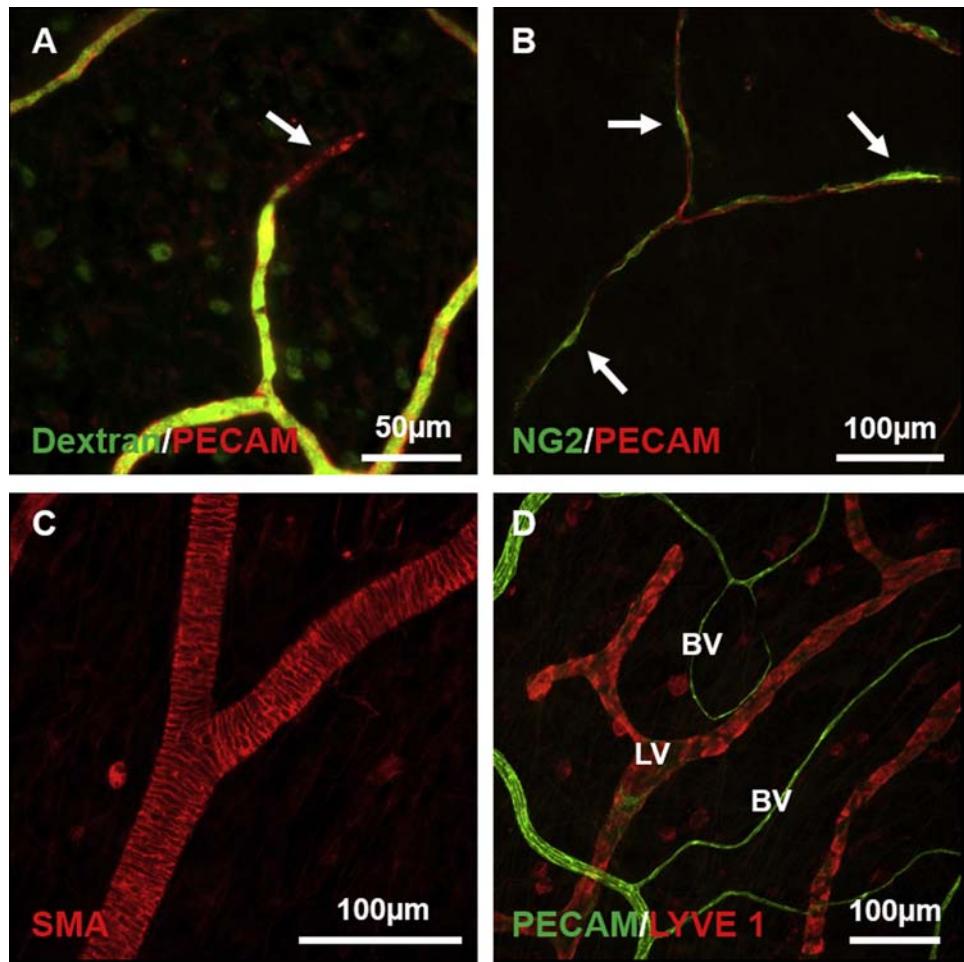
FIGURE 12.1 Basic structure of microvessels. All microvessels are lined with endothelial cells and are wrapped by perivascular cells, including smooth muscle cells and pericytes. The spectrum of cell morphologies and phenotypes present along the different vessel types emphasizes the importance of cell−cell interaction and coordination for maintaining microvascular function. The overlap of these cell dynamics with those involved in large artery stiffening (LAS) highlight the need to interrogate common mechanisms of dysfunction. *Printed with permission from Anita Impagliazzo.*

and macrophages are critical to microvascular function and adaptation. Despite the prognostic importance of cell responses in both large and small vessel remodeling, little is known regarding how and why these mechanisms are triggered to manifest integrated pathology in one patient versus another. Patient-specific phenotypic signatures undoubtedly depend on phenotypic variabilities in the local microenvironment and motivate the need to better understand cell dynamics from a systems level view.

While common cellular and molecular alterations have been identified across the macro- and microvessel levels, there still remains a question about whether the common signals represent mechanistic links. Are the effects also common? Does LAS trigger microvascular dysfunction and remodeling? Do imbalances generated by improper microvascular function contribute to LAS? A difficulty in answering these questions is that stiffening is associated with disease states, and it is difficult to delineate cause and effect relationships. Hence, microvascular remodeling

might be a cause of the disease state rather than a direct consequence of increased arterial stiffness. What is apparent is that the hallmark characteristics of LAS (elastin breakdown and degeneration, increases in fibrinogen and collagen content), tell just part of the story.[11−13] Increases in circulating factors like transforming growth factor beta (TGF-β), tumor necrosis factor alpha (TNF-α), and interleukin-6 (IL-6) highlight a proinflammatory shift, which is also known to have direct effects on the microvasculature.[14−16] The milieu of circulating inflammatory factors can be attributed to endothelial cell dysfunction characterized by oxidative stress, decreased nitric oxide (NO) bioavailability, increased proinflammatory factors, and mitochondrial oxidative stress.[1] In larger vessels, inflammation is linked to elastin breakdown and matrix remodeling which are key to wall stiffening. The inflammatory environment can trigger vascular SMCs to adopt a more synthetic phenotype, exhibit shape changes, proliferate, migrate, and increase integrin expression levels.[12,13] Whether microvascular SMCs and


pericytes experience phenotypic changes that are similar to SMCs in larger arteries remains under-investigated; however, proinflammatory cytokines are known to invoke these behaviors in the perivascular cells of the microcirculation in diseases such as diabetes.[17]

A general thought is that increased pulse waves due to LAS are transmitted to the level of the microcirculation, especially in tissues with low-resistance vascular beds such as the kidney, brain, and placenta.[1,6] The increase in elastic modulus of stiffened arteries results in increased pulsatility, which can translate into increased pressure and altered flow velocity profiles in the microcirculation. These altered hemodynamics are often assumed to include increased shear stress, a regulator of endothelial cell function. However, as we consider later in this chapter, the actual velocity profiles, and thus, shear stress levels, are currently not known. Moreover, shear stress ranges depend on the specific microvascular network patterning and specific vessel geometries. Evidence suggesting that microvascular network patterns are specific to the type of tissue, and that blood flow regulation can be controlled at the capillary level, complicate our intuition and motivate the need for more careful thinking (and perhaps quantitative modeling[18]) about how hemodynamics and circulating factors are transmitted across the hierarchy of the vasculature.[19]


Cell dynamics involved in microvascular growth and remodeling

In order to appreciate the links between large vessel wall remodeling and remodeling of the microcirculation, it is helpful to identify common cell players. This section provides an overview of cell types involved in microvascular growth and remodeling, which also play a role in LAS. Thus, linking LAS with the microvasculature should involve the recognition that remodeling at the microvascular level is an amalgamation of subprocesses involving the same cell types involved in arterial stiffening: endothelial cells, pericytes, SMCs, and macrophages (Figs. 12.2 and 12.3).[20–24] It should be noted for the sake of clarity that the direct role of endothelial cells and pericytes in large vessel wall remodeling can be debated depending on the remodeling scenario. In particular, pericytes are included in the list because they can phenotypically resemble dedifferentiated SMCs or adventitial fibroblasts and both of these cell populations can be associated with atherosclerosis and aspects of large vessel wall remodeling.

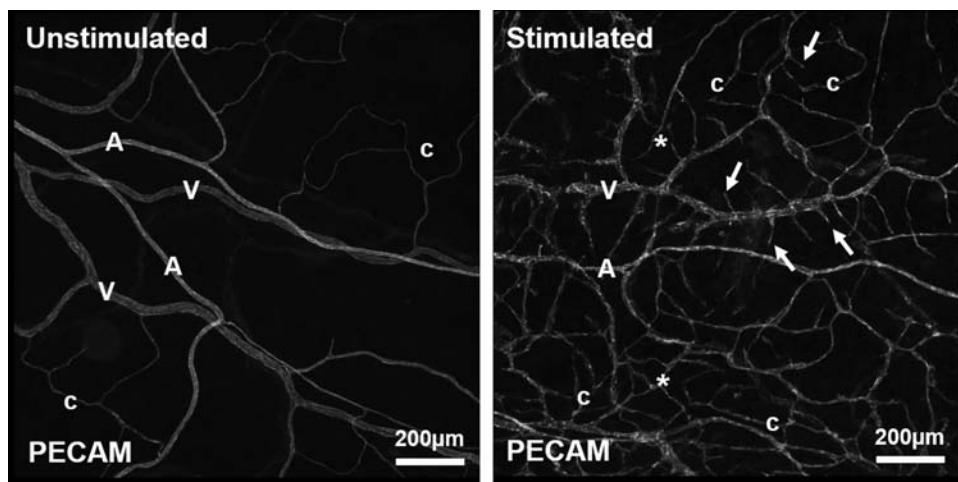
Microvascular remodeling is traditionally characterized by three subprocesses: vasculogenesis, angiogenesis, and arteriogenesis (Table 12.1). It has been suggested that vasculogenesis, or the formation of blood vessels from endothelial progenitors, is driven by endothelial cell and pericyte

FIGURE 12.2 Microvascular network function and remodeling. Microvascular remodeling can be thought of as a continuum of subprocesses interrelated across space and time. For example, angiogenesis involves the sprouting of new capillaries from existing ones and is achieved via the interactions of endothelial cells, pericytes, and interstitial cell populations that secrete and respond to local growth factors. The differentiation of pericytes into smooth muscle cells and associated vessel maturation is termed "arterialization," which leads to functional vasoreactivity. Other cell dynamics related to these microvascular processes include permeability and white blood cell trafficking, or recruitment. *Printed with permission from Anita Impagliazzo.*

FIGURE 12.3   Cell types associated with the microvascular networks. (A) Endothelial cells: Platelet endothelial cell adhesion molecule-1 (PECAM)-positive labeling (red) identifies endothelial cells along capillaries and a capillary sprout. Intraluminal labeling with a fixable dextran (green) identifies vessels and the stalk of the capillary sprout, but does not label the extending tip cell (arrow). (B) Pericytes: Example of neuron-glial antigen 2−positive pericytes (green, arrows) wrapping along PECAM-positive endothelial cells at the capillary level (red). (C) Smooth muscle cells: Smooth muscle α-actin labeling (red) identifies tightly wrapped cells oriented circumferentially around an arteriole. (D) Lymphatic endothelial cells: LYVE1 labeling (red) identifies lymphatics near PECAM-positive blood vessels (green). "BV" identifies blood vessels and "LV" identifies lymphatic vessels. Images were obtained by immunolabelling adult rat mesenteric tissues.

recruitment of precursor cells.[25] Angiogenesis is defined as the growth of new endothelial cell-lined vessels from existing ones, and arteriogenesis refers to the process of enlarging existing collateral arterioles to form functional arteries and involves, in part, the recruitment of perivascular cells and their subsequent differentiation into SMCs.[20,24,26] These processes cause the structural adaptations of microvascular networks that are characterized by new vessels and altered network patterning (Fig. 12.4), which can profoundly impact key microvascular functions including, vascular permeability, vasoreactivity, and leukocyte adhesion.

Endothelial cells

In addition to preventing thrombosis and being a physical barrier between blood and tissue compartments, endothelial cells have specific roles that aid in maintaining normal vascular function. These additional roles include regulating vascular tone for dilation and constriction, regulating passage of all molecules and proteins across the vascular wall, appropriately responding to shear stress, being integral participants in inflammation, and lastly, being one of the most critical cell types involved in angiogenesis.[27,28] Numerous biomarkers, including vascular endothelial growth factor (VEGF), TGF-β, and TNF-α, are involved in the regulation of endothelial cell dynamics.[29]


Capillary sprouting seen during angiogenesis is characterized by the proliferation and migration of endothelial cells. Capillary sprouting begins with the degradation of the basement membrane and weakening of nearby endothelial cell adhesions.[23] From this destabilized location in the

TABLE 12.1 Traditional microvascular remodeling processes.

	Angiogenesis	Vasculogenesis	Arteriogenesis
Definition	Angiogenesis is defined as the growth of new blood vessels from existing vessels.	Vasculogenesis is defined as the formation of new vessels from progenitor cells.	Arteriogenesis involves the remodeling of preexisting vessels and can be classified into two categories: (1) enlargement of collateral arterioles and (2) capillary acquisition of smooth muscle cell coverage (i.e., arterialization).
Key cell types	Endothelial cells, pericytes, and macrophages	Endothelial progenitor cells	Endothelial cells, pericytes, smooth muscle cells, and macrophages
Key characteristics	Angiogenesis is characterized by endothelial cell or capillary sprouting.	Vasculogenesis is most commonly associated with development. Vasculogenesis in the adult is less common and potentially involves the integration of vascular progenitor cells into new vessels remodeled by angiogenesis or arteriogenesis.	Collateral vessel enlargement triggered by increased flow and involves wall remodeling. Arterialization involves with pericyte recruitment is interrelated with angiogenesis.

The full understanding of how new vessels form in the adult remains incomplete. For example, intussusception and vascular island incorporation represent nontraditional processes (either understudied or underappreciated) that can contribute to microvascular growth. For descriptions of the information in this Basic Science Box, see References. 23,24.

FIGURE 12.4 Comparison of an unstimulated and stimulated angiogenic microvascular network from adult rat mesenteric tissue. Immunolabeling against Platelet endothelial cell adhesion molecule-1 (PECAM) identifies endothelial cells throughout the hierarchy of microvascular networks. (A) Unstimulated adult rat mesenteric microvascular network. (B) Angiogenic networks are characterized by increased vessel density (*) and increased capillary sprouting (*arrows*) off existing venules and capillaries. "A" identifies arterioles. "V" identifies venules. "c" identifies capillaries.

endothelial membrane, an endothelial tip cell equipped with specialized filopodia can branch out into the extracellular matrix (ECM), providing directional guidance for the continued migration of the sprout.[30] The tip cell, which does not form a lumen or proliferate, is followed by another specialized endothelial cell known as the stalk cell. The stalk cell forms a lumen and proliferates behind the tip cell, further elongating the sprout by pushing the sprout further from its vessel of origin.[31] Tip cells and stalk cells are not only different in function but in phenotype as well. Stalk cells possess high levels of Notch signaling while tip cells have low Notch activity but high platelet-derived growth factor-b (PDGF-β), vascular endothelial growth factor receptor-2, delta-like ligand 4, and unc-5 homolog b expression.[32–34] As the sprout extends, further ECM is degraded and pericytes are recruited to the sprout extension to provide support and stabilization.[35] These elongated vascular sprouts eventually anastomose with neighboring mature vessels or other capillary sprout extensions originating from neighboring vessels.

Recent evidence implicates cellular energetics in new blood vessel formation independent of angiogenic signaling.[36] Specifically, endothelial cell glycolysis has been shown to drive vessels sprouting in multiple vascular beds except brain, as endothelial cells are considered to be glycolysis addicted even though they are exposed to the highest oxygen levels in the blood.[37−39]

Factors such as alterations in wall shear stress levels can have a significant impact on various endothelial dynamics. Shear stress has been shown to regulate microvascular permeability, growth factor secretion, growth factor receptor expression, and endothelial dynamics during capillary sprouting.[40−42] Increases in vascular wall shear stress can also affect the function and phenotype of perivascular cells, which in turn can affect how they interact with and are recruited to vessels. The study of these dynamics at the microvascular level can provide a new way to investigate relevant pathologies and discover new connections between cellular behaviors and the dynamics of larger vessels.

In order to link endothelial cell function at the microvascular level to LAS, consider the microenvironment of a single endothelial cell. As endothelial cells line the inner interface of blood vessels, they are involved in several key cellular and physiological functions including vessel permeability, cell trafficking, and hemostasis. This is the case regardless of the vessel level. Along arterioles at the entrance of the microcirculation, endothelial cells play a role in regulating blood flow through controlling vessel diameter. Then in capillaries and postcapillary venules, endothelial function is more associated with basal permeability, which can be generally characterized as continuous flux of plasma components from the blood into the interstitial space. Permeability can become elevated when agonists such as VEGF, bradykinin, histamine, or serotonin activate their respective membrane receptors on endothelial cells. Elevated permeability is common in inflamed tissues, and is also frequently accompanied by increased leukocyte rolling, adhesion, and diapedesis into surrounding tissues which further amplifies inflammatory signals. For example, TNF-α can contribute to elevated microvascular permeability indirectly by activating neutrophil recruitment into local tissues.[43,44] Activated neutrophils cause conformational changes in endothelial cells that allow increased paracellular diffusion of fluid and solutes.[45,46] Elevated permeability, combined with other inflammatory signals from neutrophils, alters the local tissue environment by increasing diffusion distance for oxygen to reach local parenchymal cells, thus impairing normal tissue homeostasis.[47] In turn, resident cells adapt to the new tissue environment to limit tissue and organ dysfunction. In many cases, the resulting changes include signals that promote angiogenesis, tissue remodeling, and fibrosis. The accumulation of these types of adaptive events reflects the aging process of tissues and organs, and parallels the slow, creeping development of increased arterial stiffness with age.

Pericytes

Another very important type of supporting cell involved in angiogenesis is the pericyte.[20,21] These perivascular cells wrap around and have direct cell-to-cell contact with endothelial cells comprising capillaries and express markers including PDGFR-β, smooth muscle α-actin (SMA), desmin, and neuron-glial antigen 2.[20,21] Pericytes in the microcirculation have been shown to have the following roles: control of capillary diameter via direct contact and paracrine signaling, stabilization and maturation of microvasculature, control of vessel permeability, and promotion of endothelial cell survival and proliferation.[31,48−52]

During angiogenesis, pericytes are recruited to blood vessels in response to PDGF-β, where they aid in stabilizing endothelial cell proliferation and migration.[31] After pericytes have been recruited and there is direct contact with endothelial cells, the assembly of the basement membrane matrix begins with the deposition of laminin, fibronectin, and collagen IV as the sprout elongates.[53] The basement membrane is assembled and maintained by both endothelial cells and pericytes. Importantly, pericytes can promote or inhibit angiogenesis by manipulating the local growth factor environment. For example, pericytes secrete VEGF to signal endothelial cell sprouting or activate angiopoietin 1 (Ang1)/Tie2 signaling to stabilize endothelial cells, respectively.[53]

Dynamics implicated in arterial stiffening include SMC differentiation and matrix deposition. Intriguingly, the altered smooth muscle behavior resembles in many ways pericyte recruitment, pericyte differentiation from fibroblasts or SMCs, and a similar local matrix deposition. For example, consider fibrosis and hyperplasia of the intima and media. Fibrosis and hyperplasia involves SMC to myofibroblast transitions and overlaps the process related to fibroblast and vascular pericyte interactions associated with fibrosis in the lung during chronic kidney disease. Thus, the interconnected nature of different vascular systems and the importance of both macro- and microvessel remodeling emphasizes a value in attempting to understand cell mechanisms on different levels.

Smooth muscle cells

SMCs also make up a key component of blood vasculature in both large and small vessels. SMCs regulate several key processes including vasoconstriction, vasodilation, and maintenance of vessel structure and function.[13] SMCs are commonly identified based on SMA expression, though

other markers such as smooth muscle-myosin heavy chain are also expressed and are indicative of a more contractile phenotype.[54]

While pericytes are involved in stabilizing the new sprout, SMC destabilization is critical along pre- and postcapillary vessels to allow for endothelial sprouting. Destabilization of the adhesions with endothelial cells is triggered by vasodilation, which results in an increase in local vascular permeability.[55] Hence, alterations in vaso-reactivity and endothelial cell barrier function will influence new vessel growth. Like pericytes, SMCs are regulated by Tie2 signaling, which upon stimulation with the inhibitor Angiopoietin 2, induces SMCs to detach from vessels prior to angiogenesis.[29]

Common characteristics of LAS are decreased NO bioavailability and endothelial oxidative stress,[1] both of which are interrelated and influence SMC behavior at the microvascular level. For example, reduced NO bioavailability is the hallmark of cardiovascular disease. Increased oxidative stress from excessive production of reactive oxygen species (ROS) results in the degradation of NO to form peroxynitrite. This oxidative-nitrative stress is the major instigator of vascular remodeling in pathological states.[56−59] Recent evidence also implicates altered cellular energetics in vascular smooth muscle remodeling and microvascular dysfunction.[60,61] For example, glycolytic enzyme activity in SMCs has been shown to promote vascular remodeling in pulmonary hypertension.[60] Furthermore, mitochondria-mediated mechanisms have also been implicated in the macro- and microvascular dysfunction that accompanies aging,[61] ischemic heart disease,[56] and diabetes.[62−64]

Macrophages

Often occurring in conjunction with inflammation, angiogenesis is a common response to injury, which is why macrophages are a key cell of interest in understanding microvascular remodeling. Macrophages affect their surroundings by secreting growth factors, chemokines, and modulatory enzymes as well as by undergoing phagocytosis to remove apoptotic cells. They can also be affected by their local microenvironment, raising the question of how they impact microvascular remodeling processes.[22] Macrophages can be divided into at least two distinct subpopulations based on the mechanisms underpinning their activation. M1 macrophages, or classically activated macrophages, are stimulated by interferon gamma, TNF-α, and lipopolysaccharide, while alternatively activated (M2) macrophages are stimulated by interleukin-4 and interleukin-10.[22] M1 macrophages are known to secrete cytotoxic and proinflammatory agents, while M2 macrophages more commonly secrete growth promoting factors and anti-inflammatory signals that stimulate angiogenesis.[65−67] Though the specific roles of the macrophage subtypes are still unclear, it has been suggested because of the differences in the agents they secrete that M1 macrophages may help stimulate capillary sprouting while M2 macrophages, along with pericytes, may play a role in stabilization of new vessels.[22,68]

In addition to regulating angiogenesis via paracrine mechanisms, macrophages have also been suggested to directly interact with the other key cell types involved in the pruning of vascular networks.[22] Like pericytes, macrophages can form bridges between neighboring capillary sprouts, thus enhancing anastomoses.[17,22] Macrophages interact with SMCs by mediating arteriogenesis through enlargement of collateral arteries.[68] It has also been suggested that macrophages can transdifferentiate into endothelial cells, pericytes, and SMCs, enabling them to participate directly as building blocks in microvessel networks.[22]

Given that circulating monocytes can give rise to macrophages, the suggested roles of macrophages in microvascular remodeling also highlight the importance of leukocyte trafficking, including leukocyte adhesion. The adhesion cascade first occurs in three key steps: rolling, activation, and arrest.[69] After the leukocyte is tethered to the endothelium, rolling is controlled by transiently binding to selectins, such as E-selectin and P-selectin. Rolling eventually transitions to the slow rolling phase until the leukocyte arrests through increased β_1- and β_2-integrin binding. This transition from rolling to arrest is known as activation and is mediated by chemokines including chemokine ligand 5 (CCL5), c-x-c motif chemokine 4 (CXCL4), and CXCL5. The leukocyte then undergoes adhesion strengthening, spreading, and begins crawling on the blood vessel wall to macrophage antigen-1- and intercellular adhesion molecule-1−rich emigration sites. Finally, during paracellular and transcellular transmigration, the leukocyte will penetrate the endothelial cell barrier and begin migrating through the basement membrane. Leukocyte transmigration is regulated by expression of various junctional molecules, including platelet endothelial cell adhesion molecule-1, endothelial cell-selective adhesion molecule, junctional adhesion molecule, and CD99, all of which can also affect vascular permeability through numerous molecular interactions. Thus, as we have described before, each dynamic cellular process influences another cell type or cellular process. So, when considering the impacts of transmitted signals from the macro- to microcirculation levels, it is critical to identify how each of the subprocesses is influenced by disease and ask whether the responses may be integrated.

Lymphatic endothelial cells

While not often a primary focus of study in the field of microvascular remodeling, lymphatic endothelial cells also

participate in structural remodeling of lymphatic microvessels in response to many of the chemical and mechanical stimuli mentioned above. Lymphatic microvascular networks consist of lymphatic capillaries, which are also termed initial lymphatic vessels. Initial lymphatic vessels are lined with endothelial cells, void of wrapping SMCs or pericytes, are spatially coordinated with blood microvascular networks, and can even form junctional connections with these networks.[70,71] Importantly, along with the blood microvessels, lymphatic microvessels are responsible for maintaining tissue homeostasis. Lymphangiogenesis, or the growth of new lymphatic endothelial segments that participate in lymphatic fluid uptake, is linked to inflammatory states which could also persist in settings of LAS. Thus, lymphatic endothelial cells could be affected by the same disease processes that cause LAS. Furthermore, alterations in lymphatic microvascular structure and function as a direct result of LAS should not be ruled out, although little is known about this intersection. We do know that lymphangiogenic and angiogenic signaling often overlap with one another, and that the presence of lymphatic vessels influences blood vessel growth, and vice versa.[72] Recently, lymphangiogenesis has been implicated as a characteristic of hypertension and age-related renal injury.[73,74] Given the interrelationships between lymphatic endothelial cells, blood endothelial cells, and macrophages, they represent an under-investigated aspect of the microcirculation that warrants future investigation in the context of overlapping cell dynamics with those involved in larger vessel stiffening. For example, one particular phenomenon that involves arterial endothelial cells, macrophages, and lymphatic vessels is the formation of atherosclerotic plaques. It has been long known that lymphatic vessels play a key role in reverse cholesterol transport.[71] The loss of lymphatic clearance capacity impairs local tissue homeostasis and results in the buildup of cholesterol, which is usually taken up by macrophages. This leads to the formation of atherosclerotic plaques in the arterial walls.[75] This pathology remains an ongoing clinical problem, and how other risk factors, such as hypertension or inflammatory states associated with chronic diseases impact the coordination of microvascular delivery and lymphatic clearance to maintain optimal homeostasis in the arterial wall remains an area that requires more thorough investigation.

Consideration of microvascular patterning alterations associated with hypertension and aging

The integration of cell dynamics involved in microvascular remodeling subprocesses leads to network level patterning changes that then influence network resistance and local hemodynamics. As pulsatility and altered hemodynamics are potentially transmitted from arteries to the microcirculation, consideration of the patterns in age-related pathologies is warranted.[1,6] This section will provide an overview of microvascular pattern alterations associated with hypertension and aging (two key conditions associated with macrovessel wall remodeling).

Structural rarefaction, defined as the anatomical loss of microvessels, is commonly associated with hypertension and other age-related diseases and is attributed to impaired angiogenesis.[76] Based on the logic that fewer parallel vessels result in increased microvascular resistance, structural rarefaction has also been linked to increased systemic resistance, which increases mean arterial pressure for any given cardiac output.[77] In some cases, microvessel rarefaction has been reported to precede increases in systemic blood pressure, further implicating its role as a causal contributor to hypertension.[78,79] Concurrent with rarefaction, microvascular networks in hypertension are characterized by increased oxidative stress, elevated circulating leukocytes, and endothelial cell apoptosis.[80] The connections between rarefaction and hemodynamics raise questions about relationships between altered pressures and pulsatile blood flow velocity due to LAS. The answers, of course, are unknown and not straightforward because any assumptive links are based on knowledge gaps. Recent evidence suggests that microvessel rarefaction, at least in hypertension, is more complex than vessel loss. Microvascular networks in spontaneously hypertensive rats display patterning alterations highlighted by increased arterial/venous anastomoses that serve to normalize resistance.[81] In addition, while increased microvascular tone has been reported in hypertensive networks,[82–84] the diameters of individual vessels might not necessarily be decreased.[85] Indeed, vasoconstriction is not present along all arterioles. Even the concept of impaired angiogenesis is challenged by evidence that hypertensive networks can undergo normal levels of angiogenesis.[86] Hence, emerging evidence challenges the paradigms that have shaped our understanding. Relating these newer findings to traditional paradigms has caused a reconsideration of how the microcirculation is altered during hypertension and an evolving understanding about how this impacts hemodynamics.

Aging is also associated with microvascular dysfunction characterized by impaired vasoreactivity, increased oxidative stress, and reduced blood flow.[76] Aging is characterized by impaired angiogenesis, vessel loss attributed to decreases in growth factor levels (i.e., PDGF and VEGF), decreases in NO bioavailability, increases in mitochondrial stress.[76] Further influenced by alterations in other pro- and antiangiogenic factors, the aged environment is generally thought to invoke microvascular rarefaction. Still, rarefaction might be tissue-specific, and the hemodynamic implications of microvessel rarefaction remain under investigation.[87,88] For example, as in the case of

hypertension, the evidence for decreased angiogenesis or rarefaction can be assumed to associated with increases in microvascular network resistance. Interestingly, an increase in resistance would increase the pressure drop across a network, raising questions about how this might influence vessel specific stress levels and local velocity profiles. Moreover, work by Sweat et al. suggests (at least in mesentery networks) that aging alone does not increase microvessel resistance.[87]

The need for further characterization of tissue-specific microvascular alterations in hypertension and aging is also highlighted at the cellular level. As indicated in a previous section, vascular pericytes play a critical role in regulating microvascular remodeling. However, there is a lack of information about how pericytes adapt during aging and in response to hypertension.[77] For aging, pericyte presence, structure, and function remains under investigation. While studies support a loss of pericyte coverage in the aged brain and kidney,[89,90] other evidence suggests that in specific tissues aging results in an increase in pericyte number and that aged pericytes can display increased expression of SMA.[91,92] These findings are supported by RNA sequencing data indicating increased PDGF-β receptor expression despite decreased PDGF growth factor levels.[87] In the setting of hypertension, even less is known about whether pericyte phenotype and function is altered. For example, the number of SMA-positive pericytes was reported to be increased in brain tissue harvested from SHR versus in normotensive control WKY strain rats.[93] On the other hand, in the hypertensive retina, pericyte numbers have been reported to be decreased relative to normotensive controls.[94] Considering the impact of perivascular cell presence, structure, and phenotype on vessel function, such cellular adaptations during aging, hypertension, or other pathologies ultimately modulate local and systemic hemodynamics. Thus, linking any changes in hemodynamics at the macrocirculation level down to the microcirculation necessitates identification of microvascular network patterns and altered cellular dynamics along specific vessel types within a network.

Circulating factors and hemodynamics as putative links between arterial stiffness and the microcirculation

Thinking about links between macro- and microvessels parallels the identification of links between different organs during disease states. Consider the links between cardiac dysfunction and chronic kidney disease.[11] Is one related to the other? Are there mechanistic links? The superficial answers are yes, but there is probably more than one single contributor. Just as numerous circulating factors and hemodynamic parameters may link two organ systems

together in health and disease, they may also link structure and function across the macro- and microcirculations and coordinate adaptations in both systems in response to pathology.

Indeed, serum levels of inflammatory biomarkers, such as TGF-β, high-sensitivity C-reactive protein, TNF-α, and IL-6 are associated with LAS across numerous pathological environments.[1,16,95] Each chemical cue can influence microvascular function. For example, increased levels of TNF-α can interfere with endothelial nitric oxide synthase, leading to a decrease in NO, which could prevent angiogenesis. Some inflammatory mediators that are present in hypertension,[96] such as thrombospondin-1 (which is released by endothelial cells exposed to elevated shear stress levels) are antiangiogenic[97] and could provide a direct mechanism by which hemodynamic changes in large vessels impact structural adaptations in microvessels. Other factors, such as angiopoietin 2, have been identified as causal regulators of both hypertension and stiffness.[14,15] Angiopoietin 2 in the context of stiffening can have upstream effects on monocyte chemoattractant protein-1, matrix metalloproteinases (MMPs), nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB), ROS, and NO. Angiopoietin 2−induced hypertension is also characterized by a loss of microvessels, or rarefaction, which has been linked to increased MMP levels. It is important to point out that MMP inhibition is generally associated with increased matrix deposition in large vessels, whereas MMP increases are present in the microcirculation. Furthermore, broad spectrum MMP inhibition with doxycycline is sufficient to normalize blood pressure and reverse microvascular rarefaction and growth factor receptor cleavage in spontaneously hypertensive rats.[98,99] The effects of doxycycline on large vessel remodeling remain unclear, yet the role of MMPs in the microcirculation during stiffening emphasizes the importance of evaluating potentially differential effects of these circulating factors and drugs used to impact MMP levels in both large and small vessels. It is not as simple as recognizing that the circulating cues can moderate cell macro- and microvascular cell dynamics. Elucidation of common mechanisms requires comprehensive comparison of local effects.

Consistent with the theme of this chapter, the question remains whether these biochemical links are secondary to vessel wall stiffening, implicating hemodynamic changes as the more critical link between large vessels and the microcirculation. A more direct link is the increased pulsatility attributed to changes in artery wall elasticity.[100−106] Undoubtedly, altered flow profiles at the microcirculation level can influence red blood cell passage, local hematocrit, local effects on viscosity, endothelial cell function, and leukocyte adhesion.[23,40] However, more preeminent questions should focus on the actual altered flow profile within a

microvascular network due to upstream arterial stiffening and whether local mechanotransduction mechanisms are altered. Cell mechanotransduction sensing elements include cell—cell junctional proteins, integrins, the cytoskeleton, growth factor receptors, and even ion channels. Thus, any changes to these sensing elements along the microvascular endothelium could influence shear responses.

Increased pulsatile shear stress is thought to be crucial in high flow/low-resistance tissues like the brain and kidney.[1,6,100] These tissues are susceptible to pulsatility and altered hemodynamics because of the lack of upstream vasoconstrictor vessels. However, the actual microvascular flow profiles in these tissues remain to be determined, making it difficult to appreciate the transmitted effects, especially given emerging evidence for a role of vascular pericytes in regulating capillary diameters.[20,21,107—109] Microvascular network flow regulation is more complex than arteriole vasoregulation and can involve diameter control at lower caliber vessel levels and network repatterning. With that being said, increased pulsatility and shear stress are definitive regulators of endothelial cell behavior.

Wall shear stress is due to viscous forces associated with fluid flow and is dependent on velocity gradient, viscosity, and vessel geometry. Endothelial cells along a microvascular network experience levels of shear stress of $\sim 5-150$ dyne/cm^2, with capillaries experiencing closer to the 10 dyne/cm^2 level.[40] But, as noted above, the actual shear stresses experienced by angiogenic vessels are not clear.[110] Even more so, the thresholds for influencing cell behavior remains unclear. Work by Song et al. suggested that shear stresses below 3 dyne/cm^2 inhibited endothelial sprouting.[111] In contrast, work by Galie and colleagues also using a microfluidic based assay suggested that stresses above 10 dyne/cm^2 increase sprouting.[112]

Interestingly, most of the initial evidence implicating shear stress as a regulator of angiogenesis is based on in vitro experiments.[40,113,114] The in vivo link is supported by evidence of increases in the number of capillaries after treatments that result in increased perfusion. For example, seminal work treated animals with prazosin and then quantified vessel numbers in the skeletal muscles.[41,115] Complicating the interpretation of the results, prazosin increased vessel diameter therefore causing more than just an increase in shear stress.

In addition to shear stress, wall shear stress gradients can also play a role in angiogenesis by influencing endothelial proliferation, cell matrix adhesion, migration, and soluble factor production.[116—118] Consideration of the effect of flow pulsatility on local shear stress values and stress gradients further complicates our understanding. With shear stress being dependent on the velocity derivatives, a time-dependent velocity gradient suggests a changing or pulsatile shear stress profile few studies address. The knowledge gap related to increased pulsatility and microvascular remodeling is probably best highlighted by a lack of literature search results. Searching for "pulsatile shear stress microcirculation", "pulsatile shear stress capillary", and "pulsatile shear stress angiogenesis" resulted in 30, 36, and 10 papers, respectively (search done in January 2021). In one example, pulsatile shear stress was shown to induce a significance increase in PECAM-1 phosphorylation, ICAM-1 expression, and NF-kB activation.[119] These results are consistent with evidence that increased pulsatility and potential higher shear stress can cause decreased microvascular diameters and can reduce permeability via increases in tight junction protein expression. On the other hand, pulsatile shear stress has been suggested to promote NO production, increase NO bioavailability, and even endothelial cell proliferation.[120—123] Finally, in another report, high shear stresses (40 dyne/cm^2) and pulsatility decreased junctional morphologies.[121]

Reflection on what is known regarding shear stress and the microcirculation exposes an important knowledge gap—local shear stresses along specific vessel types in a microvascular network, especially due to altered flow conditions that might be attributed to upstream macrovessel remodeling, are unknown. The lack of measurements of shear stress values in vivo has resulted in the mechanistic role of shear stress in angiogenesis remaining ambiguous.

Conclusions and future opportunities

LAS is a hallmark of aging and numerous disease states. While it is obvious that the macro- and microcirculations are coupled both mechanically and biochemically, how the presence of disease impacts the content and transmission of information flowing between these two vascular environments is not well understood. Given the similarities in cell types, cellular dynamics, ECM remodeling, and the role of hemodynamic forces across the entire circulatory tree, it stands to reason that pathological stiffening of large vessels could adversely impact the structure and function of downstream microvessels and, conversely, that alterations in the structure and function of the microcirculation could contribute to stiffening of large vessels. In addition, overarching cellular and molecular mechanisms could simultaneously affect macrovascular and microvascular function. Hence, studying the cross-talk between large and small vessels in diseases characterized by pathological wall stiffening will undoubtedly yield a more comprehensive understanding and suggest novel therapeutic targets. Advances in noninvasive in vivo measurement techniques will provide more comprehensive, accurate, and dynamic assessments of large and small vessel hemodynamics and biomarkers.[124,125] In addition, applications of computational modeling and analysis can provide a more robust platform for systematically integrating, interpreting, and therapeutically manipulating cause and effect relationships that span spatial and temporal scales.[18,126—128] Measurement and modeling of LAS and microvascular adaptations

simultaneously (within the same experimental systems and to the extent that is possible clinically) will also likely reveal new mechanisms of chemomechanical cross-talk and their local and systemic contributions to disease. Finally, numerous reports have established the role of biological sex and sex hormones in the vascular function in health and disease states. Sex differences impact all cell types associated with the vascular wall at both the macro- and microvasculature levels,[129−131] further highlighting how cellular dynamics associated with stiffening and microvascular remodeling might be heterogeneous across groups or individuals. Looking forward, our lack of understanding represents an opportunity for comprehensively linking how cellular dynamics can influence transmitted links throughout the vasculature.

Chapter 13

Myocardial function: from myofilaments to cardiac pump

The heart is an amazing organ. The heart and cardiovascular system have evolved to overcome the limitations of diffusion ensuring adequate supply of nutrients and oxygen to tissues while providing a route for homeostatic communication between major organ systems. From ontogenesis and embryogenesis, the heart's structure has progressively evolved to fully match *the organism's functional needs* as a highly resilient and enduring pump system that not only ensures its self-supply but also extensive communication with all bodily systems through the vasculature. *Self-supply* through the coronary circulation is closely matched to requirements through local metabolic regulation. In homeothermic air-breathing animals, the cardiovascular system has evolved to a system in series circulation, with the heart fully divided into left and right sides, for systemic and pulmonary pumping, respectively. The highly compliant and vast low-pressure pulmonary circulation interacts with the lungs for achieving full oxygenation and continuous renewal of oxygen carrying capacity. Cardiac output is the main driver of renal filtration and urine output, while renal feedback guarantees effective circulating volume through regulation of sodium balance. The heart provides *steady perfusion to all systems*, in particular the gastrointestinal tract from which it retrieves nutrients, the musculoskeletal and nervous systems to which it provides oxygen and nutrients and from which it effectively clears catabolites, and the kidneys which are perfused in order to promote glomerular filtration. As an efficient system that overcomes the limitations of diffusion, the cardiovascular system not only carries oxygen, nutrients, and catabolites but also brings all organs and tissues into close proximity as carrier of endocrine mediators and intercellular signaling molecules such as cytokines, growth factors, and adipokines. Unsurprisingly, the heart itself is quite active as an *endocrine organ*, and its function and structure are extensively influenced by endocrine mechanisms.[1] The heart integrates neural input through vagal and sympathetic fibers. Finally, the cardiovascular system provides an entry port and means of spread to the hematopoietic system.

The heart is an adaptive pump

The heart as a pump adapts and remodels to meet body demands throughout lifetime but eventually fails with aging and lifelong insults. All these mechanisms are finely tuned and enable *extraordinary adaptions throughout lifetime*. The fetal-to-neonatal transition courses with fast structural, metabolic, and functional changes that suddenly enable adaption to an active respiratory system while pregnancy and long-term adaptions to exercise training also involve slower but substantial structural and functional remodeling. Acute adaptions to various forms of stress are also outstanding and further highlight the role of regulatory mechanisms, such as neurohumoral adaptations.

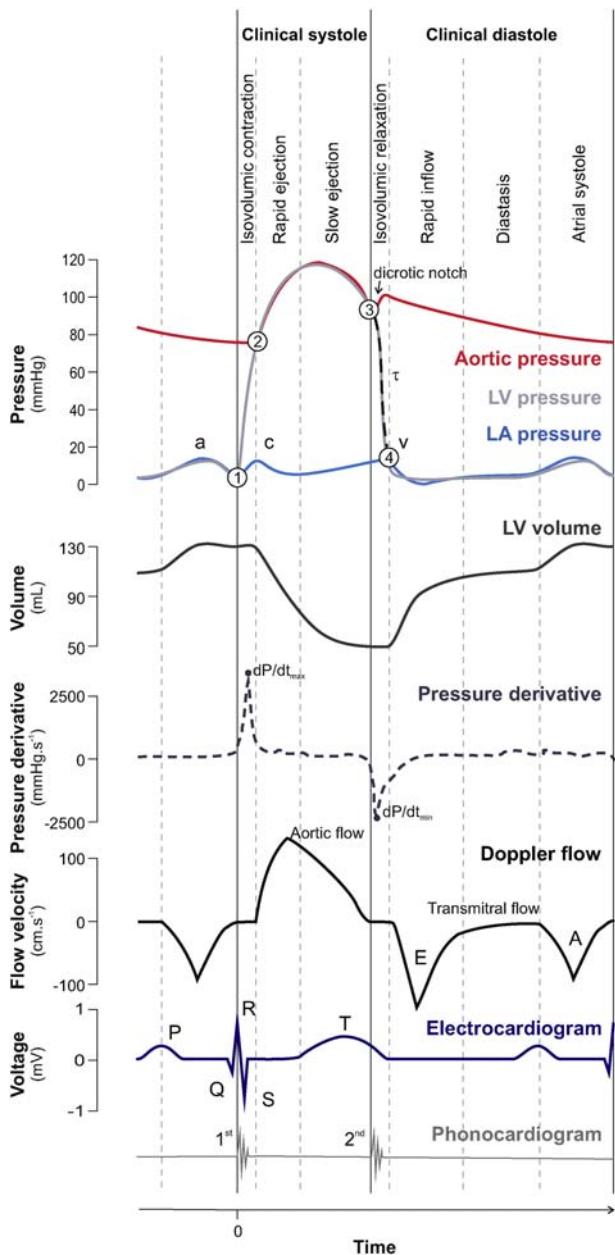
Despite their remarkable durability, the cardiac pump and the cardiovascular system eventually wear out with aging. Atherosclerosis, loss of elastic content, altered and increasing fibrosis, decreased metabolic flexibility and impaired organelle, cell and tissue repair, and turnover mechanisms ultimately have a toll on the ability to cope with demands. *Decreased cardiovascular reserve* is one of the major components of human senescence. In today's developed world societies, improved healthcare has sustainedly increased longevity while work and social habits dictated sedentary lifestyles and unhealthy diets. Predictably, the population ages and the prevalence of obesity, systemic arterial hypertension, and diabetes mellitus are

higher. These and other comorbidities drive adverse cardiovascular remodeling, further impairing cardiovascular reserve in a growing number of individuals. *Heart failure with preserved ejection fraction (HFpEF)* is an example of impaired cardiovascular reserve, combined with alterations of renal, muscular, and pulmonary function (among various other abnormalities).[2] In the aging population, the health toll of HFpEF now outweighs that of classical heart failure with reduced ejection fraction (HFrEF). Improved health care and prompt interventions for ischemic heart disease substantially reduced the number of patients that overcome extensive myocyte loss due to ischemic insults with left ventricular (LV) dilation and decreased ejection fraction.

Cardiac structure is tightly coupled to function

The heart is composed of *intertwined sheaths of myocardial tissue* interspersed with coronary vessels. Myocardial tissue is mainly composed of striated muscle cast into a thin mold of connective support tissue. Unlike skeletal myocytes, cardiomyocytes act like a *functional syncytium* both in electrical and mechanical terms; cardiomyocytes show complex branching patterns and (mainly) top-to-top mechanical and electrical connections between themselves through specialized cell membrane domains, the intercalated disks, where gap junctions concentrate. Highly organized high-order macromolecular structures arranged in tandem, with top-to-top connections at Z-lines, the sarcomeres, confer the typical striated appearance to cardiomyocytes on histological examination. Sarcomere length under physiological conditions ranges from 1.6 to 2.2 μm. Sarcomeres are composed by partly overlapping thin and thick filaments essentially formed by *actin and myosin* proteins, respectively, combined with other structural and regulator proteins. One of these proteins, *titin*, stands out because of its giant size and filamentous structure that bridges the span of half a sarcomere, connecting thick filaments to Z-lines. It constitutes an essential structural scaffold that stabilizes actin-myosin interaction as well as a key regulator of myocardial passive properties, namely compliance.[3]

Action potentials and contraction arise at an intrinsic pace, which is modulated by the autonomic nervous system and neuroendocrine influences but is fully independent from central somatic neural input. A small subset of cardiomyocytes, the *conduction system*, specializes to evoke and convey action potentials eliciting synchronized patterns of myocardial contraction that maximize cardiac chamber pump performance.

Moreover, a specialized connective tissue structure, the *fibrous skeleton*, completely separates thin-walled highly compliant chambers, the left and right atria (that receive venous return from the pulmonary and systemic circulations,


respectively), from thicker-walled LV and right ventricular (RV) chambers (that do most of the pumping into the systemic and pulmonary arteries). Atrial and ventricular contraction are coordinated so that ventricular contraction only starts upon maximal filling following atrial ejection. Indeed, atria contract upon spreading of action potentials generated at the sinus node, the natural highest-frequency pacemaker in cardiac conduction tissue, but transmission to the ventricles is delayed at the unique gateway connecting atria and ventricles through the fibrous skeleton, the atrioventricular node. The spread of the action potential within ventricles is governed by fast-conducting Purkinje cells arranged in thick bundles that ramify throughout the endocardial surface. The fast and sequential pattern of activation ensures maximal performance by first activating the interventricular septum and subendocardial papillary muscles (the myocardial extensions that connect through chordae tendineae to the atrioventricular valves), and only then producing synchronous torsional free-wall contraction of both ventricles from the apex toward the base. This provides a stable support axis and prevents valve prolapse.

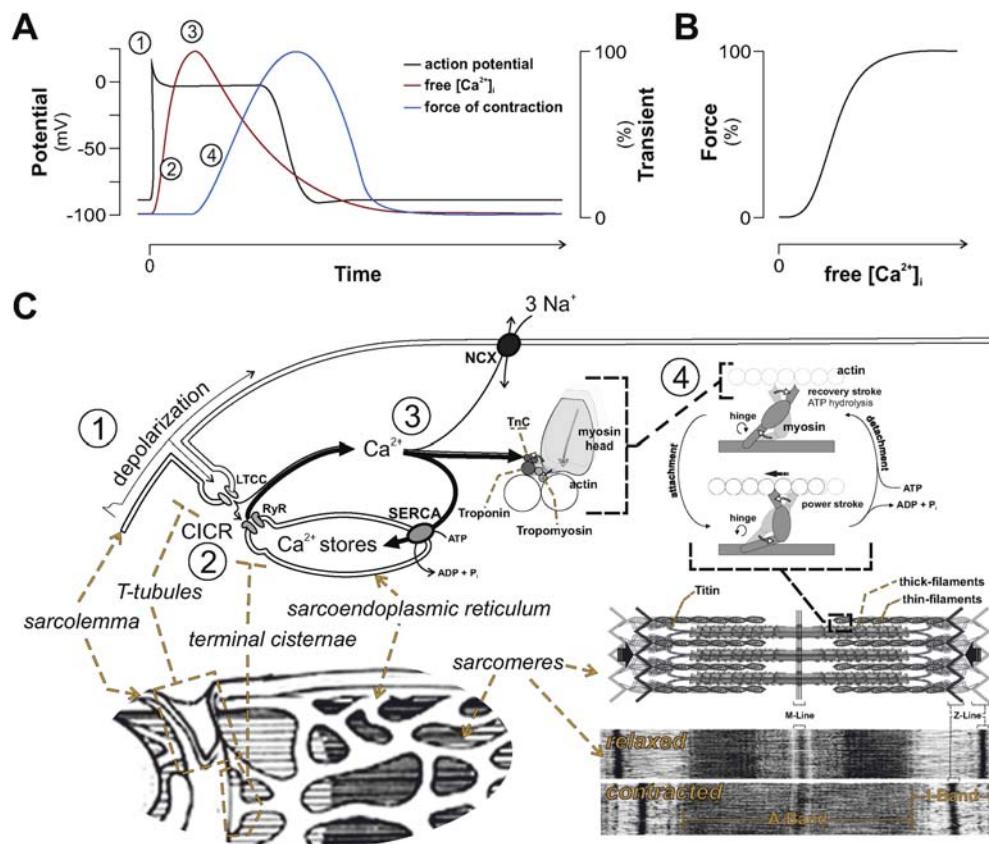
The RV is thinner and more compliant than the LV, and is well adapted to accommodate fluctuations in venous return and to pump blood into a low resistance and likewise highly compliant pulmonary circulation. RV geometry clearly distinguishes a saccular body reservoir and an outflowtract infundibulum. The saccular body contracts first through a bellows-like movement that brings the free-wall close to the interventricular septum ejecting through the outflow tract infundibulum, which contracts in a peristaltic-like movement.[4] Quite distinctly, the LV's shape is close to elliptical and its wall is thicker, holding an extra layer of obliquely oriented myocardial fibers. LV contraction proceeds from apex to base, toward the aortic valve, and is aided by a twisting movement that further helps to reduce circumference and longitudinal axis against the high-resistance systemic circulation. Upon ventricular contraction, thin semilunar aortic and pulmonary valves prevent reflow from the arteries back to the heart.

The cardiac cycle

In this chapter, we provide a general review of the cardiac cycle and mechanisms of myocardial contraction and relaxation. Chapter 14 deals with these processes, more specifically as they relate to systolic-diastolic coupling.

The cardiac cycle (Fig. 13.1) is the sequence of events in each heartbeat.[5] The normal cardiac cycle relies on repeated and sequential twitch activations of cardiac chambers' muscle cells and competent cardiac valves for directing flow and for separating low from high pressures. The LV swiftly alternates organ perfusion at high pressures with filling from pulmonary vessels at low pressures. When the sinus node fires, a wave of depolarization is spread through the atria, which is captured on the

FIGURE 13.1 The cardiac cycle according to Wiggers. Synchronous electrical, hemodynamic, and auscultatory features of a cardiac cycle illustrated for the left ventricle (LV). Timings of valve opening and closure are represented by: (1) mitral valve closure, (2) aortic valve opening, (3) aortic valve closure, and (4) mitral valve opening. Signals are color coded. Main features of each signal are represented: the dicrotic notch in aortic pressure tracing, the a (atrial contraction), c (ventricular contraction), and v (venous filling) waves in the left atrial (LA) pressure tracing, the peak rates of LV pressure rise (dP/dt_{max}) and fall (dP/dt_{min}), the E (early) and A (atrial) waves in transmitral flow, the P, QRS and T waves of the electrocardiogram and the first and second heart sounds. Transaortic and transmitral Doppler flow signals are aligned and merged. The dashed region of LV pressure fall between (3) and (4) is used to derive the time constant of LV relaxation, τ.

electrocardiogram as the P wave; this depolarization leads to *atrial contraction*, extra flow to and filling of the ventricles through the atrioventricular valves (identified as an A, or atrial, wave on transmitral or transtricuspid Doppler flow), leading to maximum end-diastolic ventricular volume. The fourth heart sound S_4 (not shown) is due to deceleration of blood flow after atrial contraction.[6] Conduction is delayed at the atrioventricular node, for allowing ventricular contraction to be delayed till completion of priming by atrial contraction.


Systole follows atrial contraction. Depolarization quickly spreads through the specialized conduction system to both ventricles in a typical pattern that yields the QRS wave complex in the electrocardiogram and elicits ventricular contraction; atrioventricular valve closure prevents reflow to the atria and ventricular pressure briskly rises (electromechanical coupling). This pressure rise marks the beginning of mechanical systole and a distinctive sound related to atrioventricular valve closure can be heard on cardiac auscultation as the first heart sound (S_1). The upstroke in ventricular pressure initially proceeds without ejection. As soon as ventricular pressure exceeds arterial pressure, fast ejection into the aortic root is initiated. Ejection work and arterial flow carry on while active crossbridges keep cycling and even beyond the start of active relaxation and crossbridge inactivation. The transition from muscular contraction to relaxation occurs early during the ejection phase (see later).[7] At mid-ejection, the pressure gradient reverses, aortic pressure exceeds LV pressure, but flow into the aortic root still continues. This continuing flow results from inertia or kinetic energy imparted to blood flow by ventricular contraction, and is known as the momentum of blood flow.[8] During systole, ventricular volumes decrease from maximal end-diastolic to minimum end-systolic volume. The volume ejected during each systole, which is stroke volume, is transferred to the arterial side of the circulation. While part of it flows to tissues, another part is accommodated by the elastic components of big arteries with pressure build-up and storage of volume. Flow velocity however decreases during the late and slow ejection phase. The build-up in arterial pressure that now surpasses decaying ventricular pressure soon offsets the kinetic energy (inertia) of ejection and eventually leads to semilunar valve closure to prevent reflow to the ventricles. This marks end-systole and the transition to clinical diastole, which is signaled by a distinctive second heart sound on cardiac auscultation (S_2). While the heart sounds S_1 and S_2 are commonly believed to be caused by closing of valves, most investigators now agree that cardiac sounds result from vibrations of cardiac structures produced by acceleration or deceleration of blood flow.[6,9]

Then comes *diastole*. Upon semilunar valve closure, which is characterized by a dicrotic notch on arterial pulse, flow to peripheral circulation continues, being driven by inertia of blood flow combined with elastic recoil of big arteries. Pressure and flow decay to diastolic blood pressure levels, until next atrial contraction and ventricular ejection. Diastole proceeds in the ventricles and active relaxation mechanisms steeply decrease pressure during isovolumic relaxation. Nevertheless, ventricular filling only starts when atrial pressure overcomes ventricular pressure thereby opening the atrioventricular valves. Active relaxation forces fuel a strong atrioventricular pressure gradient that promotes a rapid-ventricular filling phase (sometimes termed suction) which can be tracked by a distinctive dominant E (early) wave in transmitral Doppler flow measurements and is responsible for most of ventricular filling.[10] Initial rapid filling is driven by a pressure gradient from atrium to ventricle. Thereafter, fast filling keeps occurring despite a slight reversed gradient and is driven by inertia.[11] This is quite similar to what happens during ejection. The third heart sound S_3 (not shown) is caused by deceleration of blood flow at the end of rapid filling.[6] This is usually followed by a period of pressure equalization between atria and ventricle and a slow filling phase of passive filling (diastasis), until a new atrial contraction originates from pacemaker activity. These events take place in right and LV chambers but not entirely synchronously. Since the sinus node is in the right atrium, right atrial systole slightly precedes left atrial systole. In contrast, there is a minor delay in RV contraction compared with LV contraction. As afterload is much lower in the pulmonary circulation, the onset of relaxation occurs earlier in the RV.

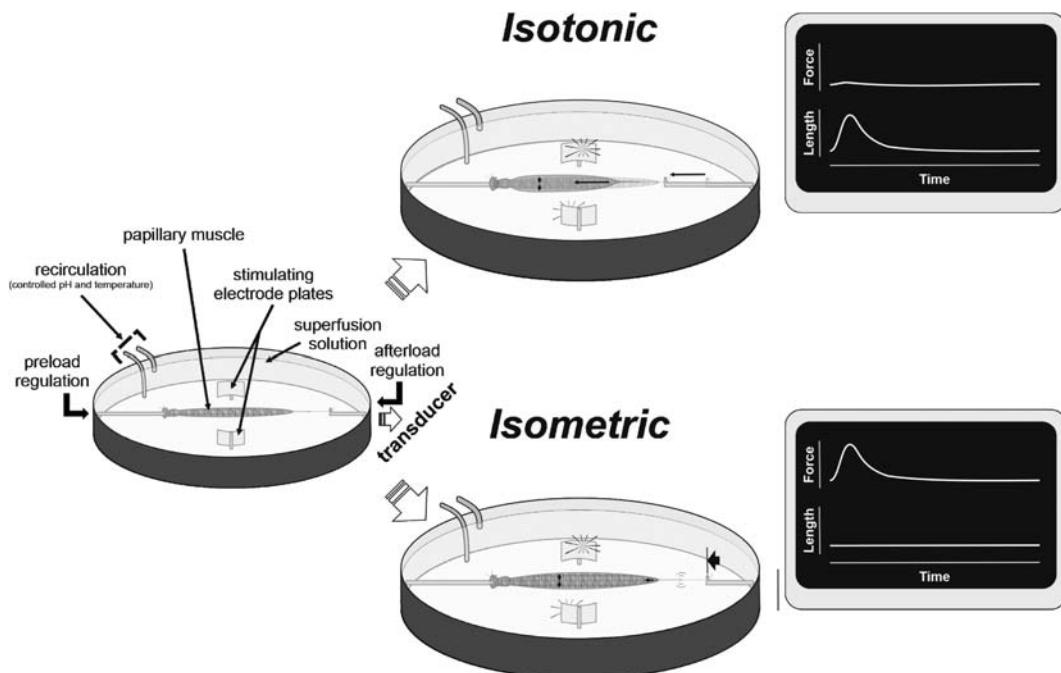
Electromechanical coupling

Within the cardiomyocyte, action potentials propagate through sarcolemmal invaginations, the T (transverse) tubules. L(long-lasting) calcium channels in the T-tubules mediate a brisk minor calcium inflow. In close vicinity with the T-tubules, type II ryanodine receptors calcium channels in terminations from the sarcoendoplasmic reticulum, the terminal cisternae, release large sarcoendoplasmic reticulum calcium stores open upon sensing calcium inflow (calcium-induced). This calcium transient activates the myofilaments, eliciting force development and cell-shortening (*electromechanical transduction*).[12] Fig. 13.2

FIGURE 13.2   Subcellular mechanisms underlying myocardial electromechanical coupling and contraction. A graphical presentation of the time sequence of cardiomyocyte action potential, calcium transient and twitch is depicted in panel (A) Events 1−4 correspond to: (1) initial depolarization, (2) calcium-induced calcium release (CICR), (3) calcium reuptake, and (4) crossbridge cycles. The close interrelationship between cytosolic calcium levels and force of contraction is highlighted in panel (B) An illustration of molecular players in relation to ultrastructure and to events 1−4 from panel A is given in panel C, for further details refer to text. *LTCC*, L(long-lasting)-type calcium channels; *NCX*, sodium-calcium exchanger; *RyR*; ryanodine receptors; *SERCA*, sarcoendoplasmic reticulum calcium ATPase; *TnC*, troponin (C)

summarizes the mechanisms of electromechanical coupling and contraction as well as the underlying structural organization of cardiomyocytes.

Mechanisms of myocardial contraction

Reversible *multilinking between actin and myosin* is the molecular mechanism underlying contraction during calcium transients. At low cytosolic calcium concentrations, the tropomyosin-troponin complex binds to actin through troponin-I, preventing interaction with myosin whereas at high concentrations, calcium reversibly binds troponin-C inducing conformational changes that expose actin to myosin and enable activation of crossbridges. Active bridges constantly cycle from attached to detached state due to myosin's ATPase activity. Energy consumption is partly converted into conformational changes that promote myofilament sliding and sarcomere shortening.


Under experimental conditions, cardiac muscle may be completely unstretched (slack length). Upon activation, when cardiac muscle is experimentally activated and unloaded, the myocardium achieves maximum shortening velocities. *In vivo*, however, cardiac chambers hold volume and thus cardiac muscle is stretched to some degree; this is usually called preload, the load that precedes contraction. Moreover, during contraction load is never null and

myofilament sliding is counteracted by load imposed on crossbridges and muscle force develops; this is called afterload, the load the muscle must bear after contraction starts. Indeed, if the muscle is not allowed to shorten at all (which occurs if for example, papillary muscles, muscle strips, or single myocytes are pinned in an experimental ex vivo setup), crossbridge cycling becomes futile and all the energy is wasted into force development; this is called an isometric contraction. Isotonic contractions are those in which shortening occurs against a constant load. The concept is illustrated in Fig. 13.3.

The major determinant of force development and myocardial shortening is the *number of actively cycling crossbridges* which in turn is dependent on the magnitude of the calcium transient, myofilament sensitivity to calcium, myosin's ATPase rate, and sarcomere length. The latter dictates both the extent of actin and myosin interaction and three-dimensional lattice spacing between them.[13]

Mechanisms of myocardial relaxation and ventricular filling

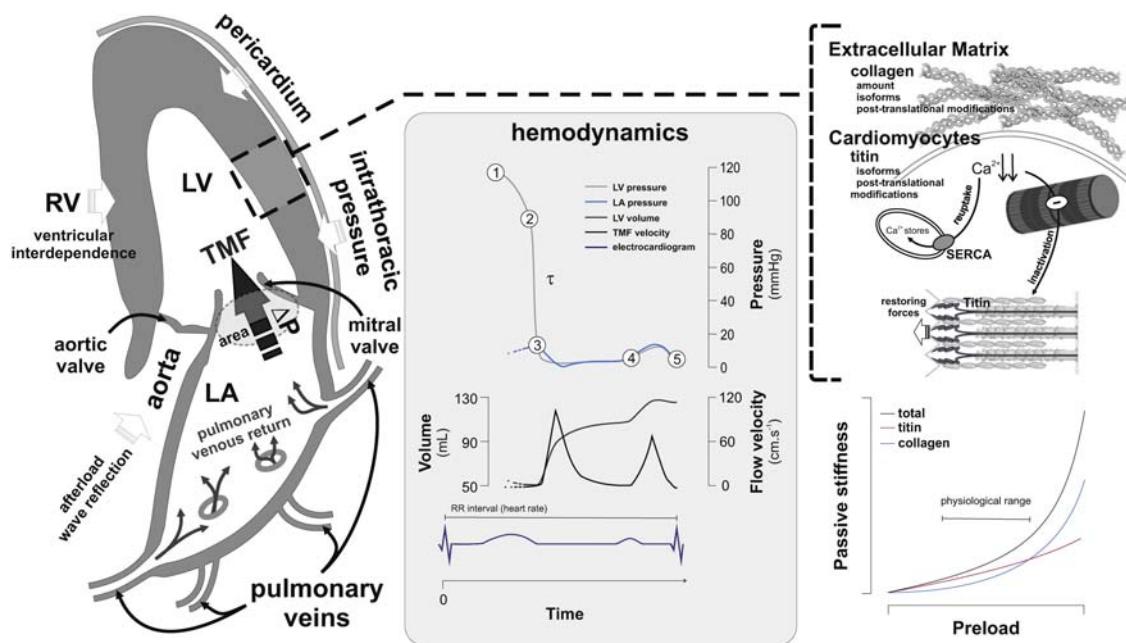
While calcium release is triggered by the action potential, repolarization by itself cannot restore cytosolic calcium levels to the relaxed state. The key determinant of calcium transient decay is sarcoendoplasmic reticulum


FIGURE 13.3 Isotonic and isometric contractions illustrated in the papillary muscle experimental setup. A papillary muscle quickly excised from a euthanized small laboratory animal can sustain mechanical activity ex vivo if it is provided an oxygenated nourishing superfusion solution with constant temperature and pH as well as electrical stimulation (usually set to a desired frequency). Upon fixation to connecting pins (in the picture by suture wires), its length (preload) can be adjusted. In each contraction, the transducers record both shortening (upward shift on the length tracing) and force development. If the setup is programmed with free pins, contraction approximates pure isotonic (no afterload) whereas with fixed pins contraction is purely isometric (maximum afterload, no shortening).

calcium ATPase which actively restores sarcoendoplasmic reticulum stores while resetting cytosolic calcium levels.[14] Calcium transient decay promotes crossbridge inactivation and myocardial relaxation. Of note, this starts well before the termination of ejection and semilunar valve closure that denote transition from clinical systole to diastole. Therefore, paradoxically, relaxation is an active process that already begins during early ejection well before end-systole. The mechanisms of relaxation, filling, and LV compliance are depicted in Fig. 13.4.

Although the main driver of calcium transient decay is the sarcoendoplasmic reticulum calcium ATPase, we must acknowledge that its activity is highly regulated by phospholamban along with many intracellular-signaling pathways. Likewise, other transporters such as the cell membrane sodium-calcium and sodium hydrogen exchangers, cell energy and acid-base status, molecular and mechanical determinants of crossbridge detachment, titin

and mechanical restoring forces after contraction all dictate the speed and extent of relaxation. *Ventricular filling* is not simply governed by relaxation; active relaxation prepares cardiac chambers to accommodate incoming blood flow, but the extent of inflow itself is dictated by *the completion of myocardial relaxation, the time available for diastolic filling and chamber compliance*. Chamber compliance is dependent on geometry and material properties (myocardial compliance). Myocardial compliance in turn is a function of the properties of extracellular matrix and of cardiomyocytes themselves, with titin assuming a predominant role. Additionally, external mechanical determinants such as intrathoracic pressure, pericardial restraint, and ventricular interdependence also determine filling in vivo. Indeed, ventricles demonstrate a high degree of interdependence because of their shared interventricular septum and the restraining influence of the surrounding pericardium, whose volume remains fairly constant throughout the cardiac

FIGURE 13.4 Mechanisms underlying diastole. The left hand illustration highlights *extrinsic determinants* of left ventricular (LV) diastole: (i) afterload and wave reflection that influence relaxation, (ii) the right ventricle (RV), pericardium and intrathoracic pressure that exert their influence mostly in late diastole (iii) venous return from the pulmonary circulation that acts as driving pressure for filling, (iv) the left atrium (LA) whose function as a reservoir and conduit but also as a pump late in diastole plays a crucial part in diastole as well, and, finally, (v) it is the varying pressure gradient (ΔP) throughout diastole and the area for transmitral flow (TMF) that dictates filling. The *hemodynamic aspects of diastole* are summarized in the central panel as an excerpt of Fig. 13.1. Key events are numbered: 1 is the beginning of myofilament inactivation after calcium reuptake and marks the start of physiological diastole, although no filling as yet occurred, 2 is aortic valve closure and signals the start of clinical diastole (according to heart sounds), 3 indicates mitral valve opening and actual start of LV filling, as can be tracked by TMF velocity tracings, 4 denotes the start of atrial contraction ("atrial kick"), a final contribution to LV filling, and, finally, 5 stands for end-diastole, when all forces must balance to settle LV compliance. It is between 2 and 3, during isovolumic relaxation that pressure decay without concomitant changes in volume is modeled by fitting to derive an index of myocardial relaxation, time constant τ. In this central panel, it becomes clear how tachycardia can shorten diastole with a detrimental impact on LV filling. Lastly, the *major determinants intrinsic to the myocardium* are underscored in the right panel. Briefly, while calcium reuptake by sarcoendoplasmic reticulum calcium ATPase (SERCA), myofilament inactivation, and restoring forces play a key role in relaxation and early filling, titin and collagen are the fundamental determinants of end-diastolic LV compliance. Within the physiological working range titin from cardiomyocytes plays the principal role whereas collagen may determine a steep rise in filling pressures in sudden overfilling. The incremental role of titin and collagen in determination of LV compliance and their interplay is graphically summarized in the lower right panel. Both changes in titin and collagen have been implicated in increased LV stiffness in HFpEF.

cycle. Interdependence occurs in parallel because the interventricular septum shifts toward the other cavity when pressure or volume builds-up during either systole or diastole. Interdependence also occurs in series because each ventricle's input is the other ventricle's output.

Cardiac metabolism

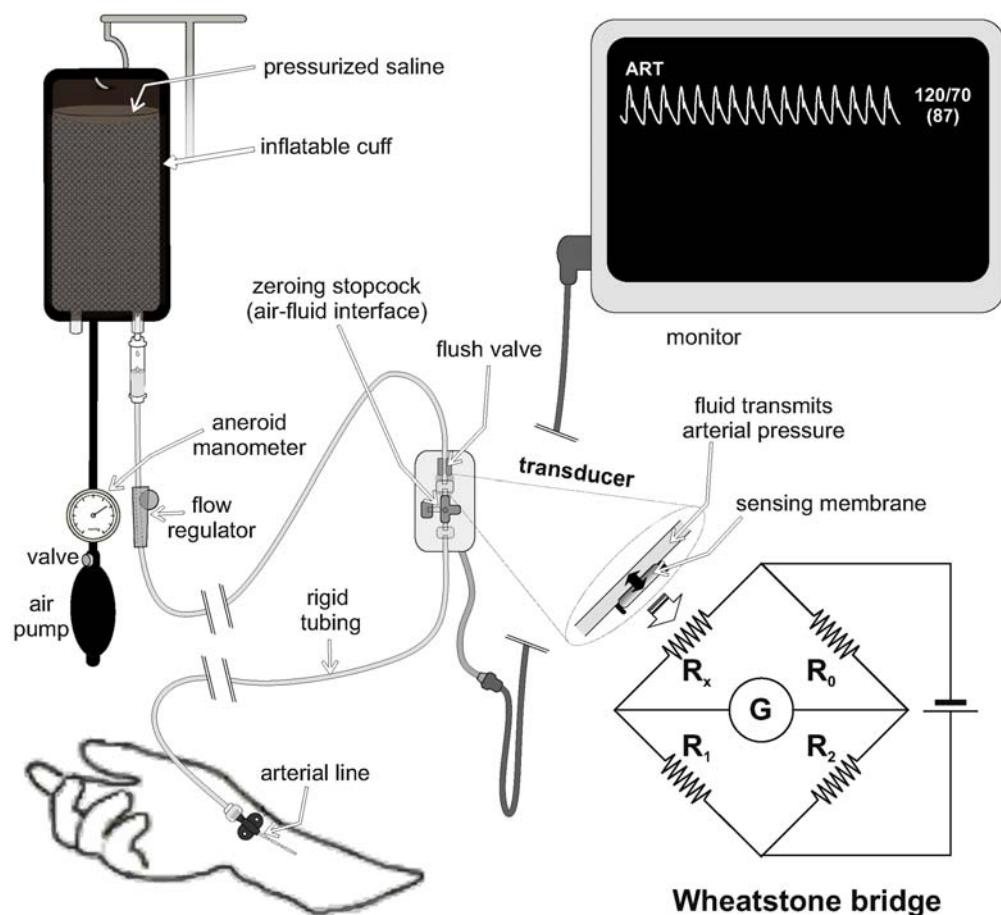
Cardiomyocytes sustain cyclic contraction throughout the lifespan without fatigue because their physiology is strictly adapted to aerobic metabolism favoring fatty-acids as stable energy substrates. Increased tissue demands raise cardiac power yield which raises energy expenditure but also enhances cardiac output and coronary flow. Coronary flow is further raised due to coronary arterial vasodilation mediated by catabolite build-up and endothelial mechanisms.

Cardiac performance is governed by heart rate and loading conditions

Independently from neurohumoral influences, increased heart rate enhances systolic performance, which is partly ascribed to incomplete calcium reuptake, expansion of calcium stores, and enhanced calcium transients. This is known as the *Bowditch effect* or force-frequency relationship.[15] A positive force-frequency relationship is typical of healthy myocardium and will hold for high stimulation rates ex vivo as long as metabolic needs are assured and experimental conditions sustain optimal calcium handling. *In vivo*, however, while at moderate heart rates increases, this enhances active relaxation and restoring forces enabling optimal filling, at heart rates higher than 150−160/min, this adaptation is offset by decrease in *time available to relax and fill*. When the sinus node fires rapidly, as an adaption to increased demands, cycle time decreases, but as calcium transient and contraction show only minor changes with heart rate, it is diastole that shortens. Slow filling may be substantially curtailed and atrial contraction, which normally makes a minor contribution to ventricular filling, then becomes more important because the time available for ventricular filling is limited. At rapid heart rates, atrial contraction is even superposed on rapid LV filling. This is a powerful coordination for maximizing filling during exercise. When heart rate further increases, cardiac performance gets impaired with lower output and with congestion.

Increased ventricular filling volume or preload enhances systolic performance through the *Frank−Starling* mechanism, which is partly explained by extra crossbridge recruitment due to increased calcium sensitivity and higher thin and thick filament overlap. Likewise, increased afterload, or resistance to ejection due to arterial impedance and vascular resistance also raises crossbridge activity and

cardiac performance, which is known as the *Anrep effect* or cooperative activity. Accordingly, lower afterload and decreased resistance to ejection will lead to *shortening inactivation* and enhanced myocardial relaxation. Myocardial stretch, however, also elicits a lagging slower secondary response, the slow force response, that is mediated by autocrine/paracrine mechanisms and leads to amplification of calcium transients.[16,17] Within moderate physiological ranges, increased preload or afterload also enhance relaxation and possibly compliance in the healthy myocardium.[17]

All the aforementioned feedback responses, which help increase cardiac output to meet demands, are modulated by many signaling pathways. While heart rate, preload, and afterload do have an impact on cardiac performance, myocardial functional and energetical status also determine the overall response to sudden hemodynamic stress.[18] Indeed, the failing myocardium may decrease contractile performance at higher load or higher stimulation frequency. Impaired Frank−Starling and negative force-frequency relationships are hallmarks of myocardial failure. Accordingly, relaxation may become impaired and end-diastolic pressures may rise under even moderate loading conditions in the failing heart.


Functional assessment of the cardiovascular system

Most experimental observations underlying our knowledge on fundamental principles of cardiac function regulation derive from experimental setups with ex vivo assessment of *single fibers, muscle strips, and papillary muscles* (such as the one illustrated in Fig. 13.3), which were translated to in vivo *animal cardiovascular function studies*. While experiments enable straightforward assessments of myocardial contractility (for instance, by assessing isometric force at constant heart rate with varying preload, or conversely assessing response to stepwise increases in heart rate at constant preload), achieving the same goal in vivo remains challenging. In *clinical practice* and *clinical research*, monitoring the electrical activity of the heart and measuring blood pressure is relatively straightforward. A surface electrocardiogram and noninvasive intermittent blood pressure readings with oscillometry are widely available at every clinical scenario. When it comes to assessing cardiac volumes, blood flow, cardiac output, and continuous intracavitary or intravascular pressure, however, the invasiveness of procedures, technical expertise, and specialized equipment required constrain the application to specific settings such as cardiology, intensive care medicine, or anesthesiology practice.

Most of the mechanical processes inherent to cardiac physiology can be understood by measuring *chamber volumes and geometry, blood pressure and flow*.

Echocardiography is the most straightforward approach to estimate cardiac volumes, but ventriculography or advanced imaging methods, such as cardiac magnetic resonance, can also be employed. Likewise, ultrasound Doppler can assess flow velocity and upon determination of cross-sectional area flow can be computed from echocardiography. This enables determination of cardiac output at various anatomic locations, e.g., the LV or RV outflow tracts. While the variability in estimation of cross-sectional area and to a minor extent the angle of alignment with Doppler flow raises some concern which led many to consider the direct Fick method or thermodilution as the gold standard, echocardiography is a reasonable means to estimate cardiac output for most purposes. Fick's method is a simple consequence of the law of preservation of mass. Cardiac output to the organism is derived by matching tissue oxygen extraction as assessed by differential oxygen content between arterial and venous blood with oxygen

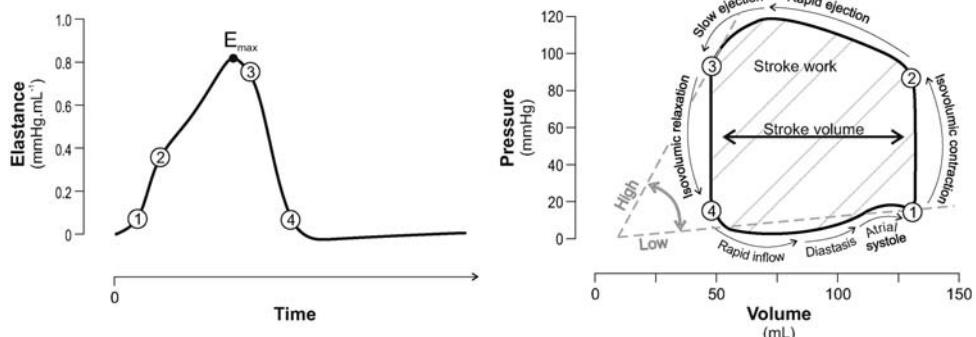
uptake by the respiratory system. If oxygen consumption cannot be measured directly, estimation by nomograms (indirect Fick method) leads to substantial error, unfortunately this is the current clinical standard in most hemodynamic laboratories. Thermodilution relies on pulmonary artery catheter (Swan-Ganz) and analysis of temperature recordings obtained when a cold marker solution is injected (intermittent readings) or the catheter warms blood in pulses (continuous recording). Finally, intravascular pressure monitoring requires placement of a catheter and intracardiac pressure readings require guidance of the catheter to the specific location, be it by echocardiography or fluoroscopy. In clinical practice, intracardiac and intravascular pressures are usually recorded with fluid-filled catheters coupled to rigid tubing and an external transducer in which a membrane is deflected by pressure oscillations varying one of the resistances in a Wheatstone bridge circuit (Fig. 13.5).

FIGURE 13.5   Continuous pressure recording with fluid-filled catheter. The diagram depicts standard preparation for invasive arterial pressure monitoring in the clinical setting. A radial artery is catheterized in the diagram, but other sites of arterial or venous cannulation follow the same scheme. A pressurized saline solution that fills a rigid tubing system of standard dimensions transmits pressure fluctuations to a transducer which consists of a sensing membrane (usually silicone based) and an electric circuit which is usually a Wheatstone bridge (or any modification of it). Briefly, the branching circuit consists of 4 resistances (R), one of which varies according to the pressure sensed at the membrane (R_x). Current flows either through R_x and R_1 or R_0 and R_2. These two arms are interconnected by a galvanometer (G). Current measured by G correlates with fluid pressure. The circuit must be zeroed by opening the system to atmosphere pressure at the level of the heart, at which point R_0 is set equal to R_x which means no current flows through G (0 mmHg). Pressure in the tubing system keeps a very low flow-rate that prevents the system from clotting.

Upon zeroing, pressures are calibrated and displayed in a monitor. Usually, the temporal resolution of clinical recordings goes up to 250 Hz and these are prone to damping, artifacts, and external wave reflection from tubing. In research settings, micromanometer tip catheters can provide high-fidelity recordings with high-temporal resolution, without damping and other artifacts. Please refer to Chapter 2 for a more extensive discussion of methods to assess intra-arterial pressure.

Assessing intrinsic cardiac performance: contractility, relaxation, and compliance

None of the abovementioned methods can accurately capture cardiac performance in terms of contraction, relaxation, and compliance, as these are intrinsic myocardial properties that can only be gauged acceptably if we minimize confounding by external determinants such as heart rate and loading conditions. To illustrate this concept, we resource to *ejection fraction*, the most commonly (mis)used contractility estimator in clinical practice. Ejection fraction is appraised by imaging methods, usually the echocardiogram, as stroke volume/end-diastolic volume. By simple inspection of the mathematical formula, it becomes clear that we statically estimate the amount of shortening (stroke volume) at a given preload (end-diastolic volume). Furthermore, we know that during ejection, the cardiac pump performs work not only in the form of shortening but also as force. In point of fact, force development (pressure throughout systole, or afterload) and shortening (stroke volume) are inversely related. Ejection fraction is therefore both preload and afterload dependent and cannot reliably be used to gauge contractility. When we consider diseased hearts, stroke volume remains well preserved until advanced stages of the disease. In these circumstances, EF predominantly reflects enlargement of the LV (low EF, HFrEF) or LV volume reduction (high EF, HFpEF), rather than contractility.[19]

Myocardial contractility (*inotropy*) relates to the ability of the myocardium to perform mechanical work (i.e., to generate force and shorten), independently of changes in preload, afterload or heart rate. Likewise, myocardial relaxation (*lusitropy*) relates to the ability to lengthen and relief force development; finally, ventricular *compliance* relates to the ability to accommodate blood at low pressures despite these same determinants and other external mechanical influences. LV relaxation and compliance are also usually estimated by echocardiography in clinical practice. Various measurements and indices obtained from transmitral flow Doppler and tissue Doppler recordings at the myocardium adjoining the mitral ring. It is good practice to take blood pressure and heart rate into account for interpreting data. A more extensive discussion of the relationship between diastolic function and mitral inflow characteristics is presented in Chapter 14.


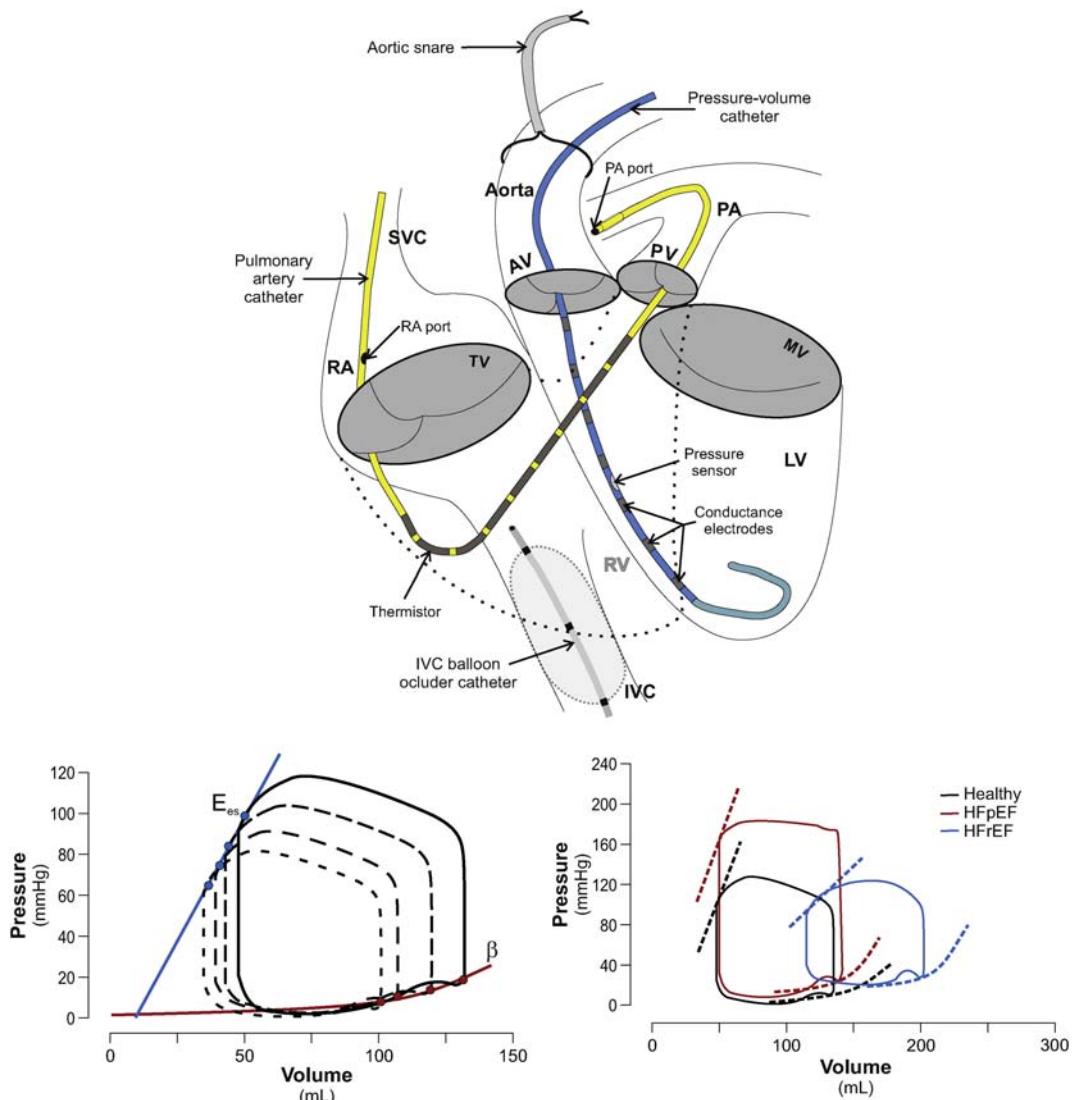
From catheter-derived pressure recordings, contractility can be estimated by measuring peak rate of pressure rise, the maximum of pressure derivative, dP/dt_{max}, which occurs during isovolumic contraction and is dependent on preload. An LV pressure derivative and corresponding dP/dt_{max} is illustrated in Fig. 13.4. Pressure decay is usually less steep and better modeled in research settings by nonlinear fitting methods applied to high-fidelity pressure recordings. Relaxation can be assessed from pressure fall by monoexponential decay, exponential decay to pressure asymptote, or logistic fittings. These methods optimize fitting of pressure decay during isovolumic relaxation as a function of time from aortic valve closure onwards, or from peak pressure fall (dP/dt_{min}) as a surrogate to aortic valve closure. A time constant, τ, is derived such that lower values translate to steeper pressure fall and faster relaxation while higher values mean slower relaxation. This is illustrated as the dashed region in LV pressure decline in Fig. 13.4. The simple monoexponential method first proposed by Weiss assumes pressure fall to zero pressure, whereas the later extension by Glantz introduces a more physiological pressure fall to a positive pressure asymptote. Further refinement by Matsubara provides more robust fits in the extremes of cardiac performance where a clear deviation from exponential decay is observed.[20] Of note, the time resolution of fluid-filled catheters is usually not enough for accurate τ estimation, which warrants solid-state catheters (see below).

As for compliance, even static end-diastolic pressure acquisitions coupled with end-diastolic volume determination can only provide a rough estimate of compliance because the end-diastolic pressure-volume relationship is nonlinear. Titin's elastic behavior within the physiological range and connective tissue at higher sarcomere lengths dictate a steeper rise of pressure at higher volumes.

The pressure-volume loop

Suga and Sagawa developed in ex vivo isolated heart preparations the construct of pressure-volume loops, which conceives the heart as a constantly moving spring with time-varying elastance (pressure/volume) that alternates between high-elastance and low-elastance states during systole and diastole, respectively[21] (Fig. 13.6).

Combined with the development of technology for continuous real-time monitoring of ventricular volume, the pressure-volume construct allowed in vivo assessment of intrinsic myocardial performance, but mostly restricted to animal research due to the invasive nature of the methods. Pressure-volume loops inform us on pressures, volumes, chamber elastance, and stroke work. The same approach can also be applied to regional function by constructing "pressure (or wall stress)—segment length" loops.[22]

FIGURE 13.6   The pressure-volume loop according to Suga and Sagawa. The ventricles are viewed as elastic springs that alternate between low and high-elastance states while performing pump work. Elastance varies with time (E_t) as a function of pressure (P_t) and volume (V_t) as depicted in the left panel according to the equation $E_t = P_t/(V_t-V_0)$ where V_0 is the volume at zero pressure, which can be either extrapolated or determined ex vivo in the unloaded chamber. An alternative view is the pressure-volume loop plotted on the right panel, where the alternance between high and low-elastance states is highlighted as well as the stages of the cardiac cycle and timings of valve opening and closure (see Fig. 13.2). The pressure-volume loop is a highly informative visual representation of the cardiac cycle. Indeed, stroke work (the area within the loop), stroke volume (volume range), end-diastolic volume and ejection fraction (stroke volume/end-diastolic volume) can easily be appraised. Maximal elastance (E_{max}) is a load-independent index of pump function, rather than contractility.


Admittedly, this approach looks at the heart or the segment as a pump and excludes by its design the analysis of time-varying phenomena. As a consequence, it is not suited for evaluating time-varying myocardial contractility and lusitropy. In the research setting, solid-state transducers bring the membrane from the Wheatstone bridge circuit inside the patient, at the tip of the catheter, enabling high-fidelity and high-temporal resolution recordings with minimal artifacts. These measurements, however, still are subject to zero-line shifting. Volume recordings are achieved by applying alternate low voltage currents to cardiac chambers and recording conductance or impedance readings that, upon suitable calibration, estimate cavity volumes continuously in real-time and with high-temporal resolution. The pressure-volume plane has also been used to assess ventricular-arterial coupling, although this approach has significant limitations for this purpose, as discussed in detail in Chapter 15.

Deriving performance indexes from acute load manipulation

High-fidelity pressure recordings with solid-state micro-manometers coupled to synchronous real-time recordings of chamber volume enable gauging intrinsic myocardial performance by indices derived from multiple heartbeats at constant heart rates and varying preload and afterload. This is usually achieved with short *transient inferior vena cava occlusions* either with a snare or an intravascular balloon occluder, or, alternatively, by imposing *transient afterload increases* with aortic clamping. Intrinsic performance can only be appraised if these load interventions are very transient, optimally spanning one or just a few more beats, to avoid influences from neural and endocrine responses.[23] The experimental setup along with an inferior vena cava

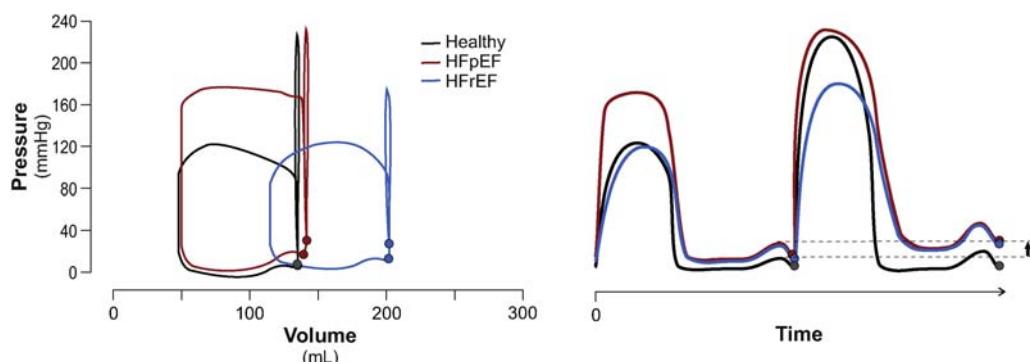
occlusion recording and representative tracings of HFpEF and HFrEF are illustrated in Fig. 13.7.

Still, we must underscore that external forces such as *ventricular interdependence*, intrathoracic pressure, and pericardial restraint can only be minimized in open-chest and wide-pericardiotomy experimental preparations which clearly deviates from physiology. Indeed, with intact pericardium, sudden preload reductions will show a biphasic course. First a decrease of RV volume and pressure, distorting LV end-diastolic pressure-volume relationship, will show an initial decrease in LV pressure without LV volume reduction (due to reduced pressure transmission across the interventricular septum) and only later, at lower pressures, will conform to the usual exponential fit. Fitting end-systolic pressure-volume relationships or stroke-work end-diastolic volume relationships at varying preloads provides indices of overall myocardial contractile performance whereas end-diastolic pressure-volume relationships provide indices of myocardial compliance. Some of these indices may be refined by normalization to ventricular mass or cardiomyocyte cross-sectional area. These have been considered for decades to be the gold standards for in vivo evaluation of cardiac function. Nevertheless, from the previous discussion, it becomes obvious that a clear-cut distinction between the effects of any physiological response, pharmacological or mechanical intervention on *heart rate, preload, afterload, and intrinsic myocardial performance* is not possible because these are all highly interdependent. Moreover, responses may vary with time from intervention. Additionally, complexity increases when we consider that pump performance is also governed by perfusion and that regions within the myocardium may behave quite distinctly (nonuniformity). Actually, overall performance is merely the sum of contributions from each myocardial region and ultimately each cardiomyocyte.

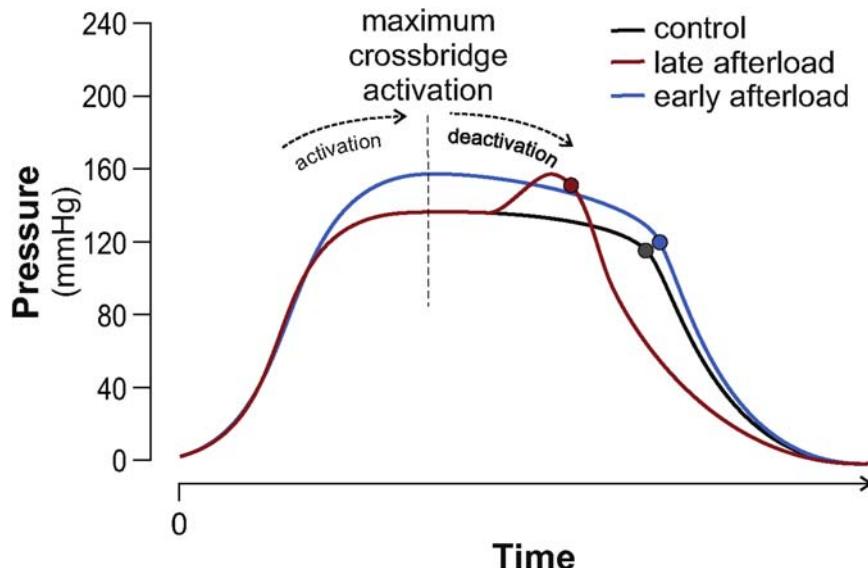
FIGURE 13.7   Pressure-volume loop acquisition of an inferior vena cava occlusion recording. The complex invasive set-up is depicted in the upper panel, namely a pulmonary artery (Swan-Ganz) catheter for continuous cardiac output monitoring through a thermistor (yellow), a pressure-volume catheter with solid-state high-fidelity pressure sensor and multiple electrodes for conductance recording (blue), a balloon occluder catheter placed in the inferior vena cava to enable sudden preload decreases and a snare in the ascending aorta for sudden or beat-to-beat afterload elevations. An inferior vena cava occlusion recording in a healthy heart is shown in the lower left panel. Cardiac performance indexes can be derived from the end-systolic and end-diastolic pressure-volume relationships. Contractility is appraised by the slope of the end-systolic relationship, end-systolic elastance (E_{es}), while compliance is quantified by the chamber stiffness constant (β) derived from fitting the end-diastolic relationship. In the lower right panel, pressure-volume loops and end-systolic and end-diastolic relationships are depicted in the healthy heart, HFpEF and HFrEF). HFpEF is characterized by diastolic stiffness (upward shift in end-diastolic pressure-volume relationship) with preserved E_{es} and ejection fraction whereas HFrEF shows decreased Ees and ejection fraction, higher compliance but steep elevations of end-diastolic pressure for further end-diastolic volume elevation. *AV*, aortic valve; *IVC*, inferior vena cava; *LV*, left ventricle; *MV*, mitral valve; *PA*, pulmonary artery; *PV*, pulmonary valve; *RA*, right atrium; *RV*, right ventricle; *SVC*, superior vena cava; *TV*, tricuspid valve.

As mentioned, transient afterload elevations by beat-to-beat or single-beat aortic occlusions have been employed to assess both systolic and diastolic performance as an alternative to sudden preload reduction.[24] They enable assessing relaxation (by pressure decay) at varying load conditions as well as the impact of afterload on end-diastolic pressure. These interventions provide insight on intrinsic myocardial properties. A healthy heart swiftly develops an elevated and early peak wall stress[25] and will have an elevated first-phase ejection fraction.[26] As a consequence of rapid early ejection and according to Laplace's law, systolic fiber stress quickly drops early in systole. This leads to shortening deactivation and fast relaxation. The young and healthy heart has an extraordinary reserve capacity for matching

challenges such as stress and exercise. Even independently from increased heart rate, increased venous return and filling volume (preload), increased contractility and neurohumoral adjustments, the heart has an intrinsic and readily available capacity for facing increased afterload. At rest, the young and healthy works up to 30% of its peak isovolumetric afterload. This heart can develop beat-to-beat pressures up to 300 mm Hg and more, without delaying relaxation and without increasing filling pressures.[24] This is the *afterload reserve* of the healthy heart.

In aged or diseased hearts, afterload reserve will decrease, closely reflecting impaired contractility.[27] When cardiac function deteriorates and/or when filling pressures are higher, load dependence of diastolic function increases, leading to more congestion.[7] Hypertensive patients with diastolic dysfunction exhibit reduced first-phase ejection fraction (i.e., ejection fraction during the initial 1/3 of systole), which may impair shortening deactivation and sustain myocardial contraction, preserving systolic ejection fraction at the expense of impaired diastolic function.[26] In an experimental model of HFpEF with combined obesity and hypertension, dependence of diastolic function on afterload similarly is enhanced.[28] A heart with diastolic function impairment will show slower relaxation and end-diastolic pressure elevation, or afterload-induced diastolic dysfunction, even following mild increases in afterload. In HFrEF, even a slight increase in systolic blood pressure will delay relaxation and increase filling pressures,[7] while a decrease in blood pressure will accelerate relaxation and improve congestion.[29] The behavior of the healthy and failing heart are depicted in Fig. 13.8.


Time-varying afterload, wave reflection, and their toll in the heart

Preload in vivo easily equates with concepts from experimental settings. Preload is the volume in the chamber (length of a muscle segment, fiber, sarcomere) immediately before contraction starts. Afterload, however, assumes further complexity in vivo. While ex vivo it is the constant load the myocardium must bear during shortening, in vivo, because of changing geometry, arterial properties and resulting pressures, afterload continuously varies throughout systole. Thus, afterload is a time-varying function, which cannot be reduced to a single number. Cardiovascular filling, contractile properties of the LV, geometry of the outflow, aortic and arterial elasticity, vasomotor tone, peripheral vascular resistance, forward and backward traveling pressure waves all contribute to *time-varying afterload*. The effects of afterload on myocardial function are therefore also time-dependent.


A clamp-increase in systolic pressure, applied early, accelerates relaxation. A similar intervention timed later during ejection (and occurring after the transition from contraction to relaxation) delays relaxation.[30,31] The later in time a given load challenge is applied to the heart, the more it delays myocardial relaxation. This behavior is based on the molecular interaction between actin, myosin, troponin, and titin. In the healthy heart, the calcium transient, activating crossbridge formation and cycling, is over soon after aortic valve opening. This corresponds to the transition from muscular contraction to relaxation. Before the transition, calcium availability is adequate to permit recruitment of additional crossbridge formation so that the resultant stress on individual crossbridges remains physiological. After the transition, the availability of calcium is reduced, limiting the formation of additional crossbridges so that the stress on individual crossbridges increases, causing back-rotation of the myosin head[27,32] and delayed crossbridge inactivation. The effects of early and late systolic load on diastolic function are depicted in Fig. 13.9.

When afterload delays relaxation in the diseased heart, this points toward elevated load beyond the transition to

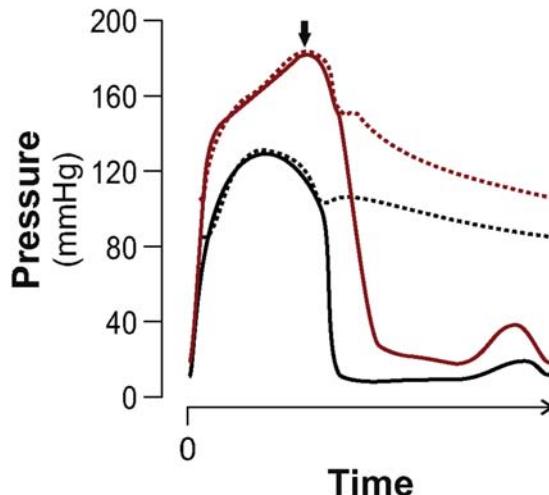
FIGURE 13.8 **Afterload-induced diastolic dysfunction.** When the aortic snare in the upper panel of Fig. 13.3 is occluded for a single beat, an isovolumetric beat is achieved. Acquisitions can be depicted either as pressure-volume loop, left panel, or simply as a pressure tracing, right panel. While the healthy heart can develop high isometric pressures with enhanced relaxation and no elevation in end-diastolic pressures, the failing heart will show delayed relaxation and an upward shift in end-diastolic pressure (marked by an arrow) both with HFpEF and HFrEF. Distinctively, in HFrEF maximum developed isometric pressure is decreased denoting markedly impaired contractility.


FIGURE 13.9 Differential effects of early and late afterload on diastole. The image displays a control beat and subsequent test beats where the same afterload magnitude was imposed either during early and late left ventricular pressure development (before and after maximum crossbridge recruitment, respectively, as signaled by the dashed vertical line). An early pressure clamp increases the number of interacting crossbridge, by cooperative activity, thereby matching systolic load, lengthening active pressure development and delaying left ventricular pressure fall (marked with a circle) while accelerating relaxation whereas a late pressure clamp induces a mismatch between load and available crossbridges with additional stress imposed on crossbridge, anticipation of left ventricular pressure fall (marked with a circle) and delayed relaxation due to slower crossbridge inactivation.

muscular relaxation. In HFrEF, this transition may even occur before aortic valve opening. As a consequence, in severe HFrEF, afterload inevitably contributes to load-dependent diastolic dysfunction[29] The time-dependent response of relaxation to load is a marker of diastolic dysfunction and of long-term effects of load on the myocardium. Timing of load modulates the hypertrophic response of the myocardium. While early systolic load (contraction load) triggers *physiological hypertrophy*, late systolic load (relaxation-load) is more likely to induce *maladaptive hypertrophy*.[25,33]

Throughout the ejection, the LV interacts with the vascular tree. The time-varying mechanical load (wall stress) on the myocardium is determined by complex interactions between myocardial contractile elements, instantaneous LV geometry, and the time-varying hydraulic load imposed by the arterial tree.[34] Early versus late systolic myocardial wall stress demonstrates finite relationships with specific arterial properties.[35] Systemic vascular resistance is a strong determinant of both early and late wall stress, aortic characteristic impedance determines ejection phase systolic wall stress, whereas wall stress at the end of systolic is also related to reflection magnitude. *Reflected waves* in patients with a stiff vascular tree may contribute to impaired LV relaxation and worsening diastolic dysfunction, which is illustrated in Fig. 13.10.

This underlies the relationship between wave reflections and late-ejection wall stress with systolic and diastolic dysfunction,[25] with left atrial function, maladaptive

FIGURE 13.10 Incremental impact of hypertension and wave reflection on diastolic function. The image displays superimposed aortic pressure (dashed) and left ventricular pressures (solid) from a healthy patient (black) and a hypertensive patient (red) with increased late systolic pressure (marked by arrow). This late systolic increase in pressure is attributable to stronger and earlier wave reflections. Note the delayed onset and slower rate of relaxation, the increased filling pressures and the big atrial contraction wave. Increased afterload delays the onset of relaxation. We may assume that decreased first 1/3 EF contributes as well to delayed relaxation and increased sensitivity to wave reflections (Gu). Late systolic afterload due to faster and enhanced wave reflections from a stiff vascular system further delays relaxation, as appraised by the less steep drop in left ventricular pressure during isovolumic relaxation. In HFpEF, this may jeopardize early filling thereby raising the importance of atrial contraction. During effort, when both left ventricular loading and heart rate increase congestive symptoms and fatigue arise.

hypertrophy, and outcomes. The impact of early and late systolic load on the myocardium is discussed in more detail in Chapter 16.

Conclusions

The heart is a biological pump with complex active ejection and filling. These functions are achieved with phased activation of atria and ventricles, contraction and relaxation of myocardial cells. The tight balance between intracellular molecular mechanisms, metabolism, and bodily needs implies close functional coupling between the heart and the arteries. This cardiovascular system interacts with renal, pulmonary, hematopoietic, and endocrine systems for achieving extraordinary adaptions throughout lifetime and to performant responses to various forms of stress. Aging and lifelong insults form systemic arterial hypertension, atherosclerosis, coronary artery disease, diabetes mellitus, and many other risk factors and pathologies will nevertheless threaten this highly resilient pump of the young healthy human. Unsurprisingly cardiovascular health and research remain among the major front battles in medicine and healthcare.

Chapter 14

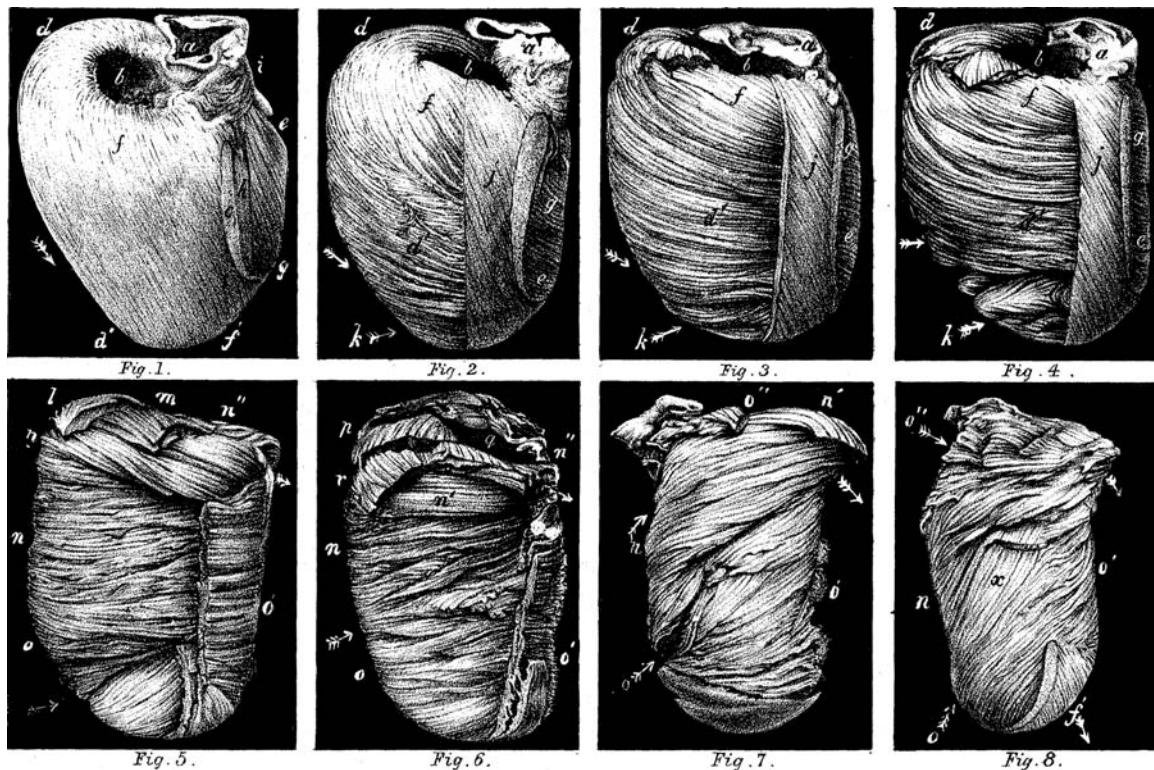
Systolic−diastolic coupling

Per M. Arvidsson[1] and Sándor J. Kovács[2]

[1]Clinical Physiology, Department of Clinical Sciences Lund, Faculty of Medicine, Lund University, Lund, Sweden; [2]Cardiovascular Division, Department of Medicine, Washington University in Saint Louis, School of Medicine, Saint Louis, Missouri, United States

Historical background

In this chapter, we will delve into the previously introduced features of ventricular and myocardial physiology to cover the functional interplay between the ventricles and their immediate surroundings, including the entire content of the pericardial sac. We will review cardiac embryology and examine a set of functional propositions relating the macroscopic structure of the heart to its purpose in the circulatory system, evaluate these propositions using the best available data, and finally incorporate the systolic and diastolic properties of the heart including systolic−diastolic coupling, into a model capable of explaining commonly observed cardiac phenomena.

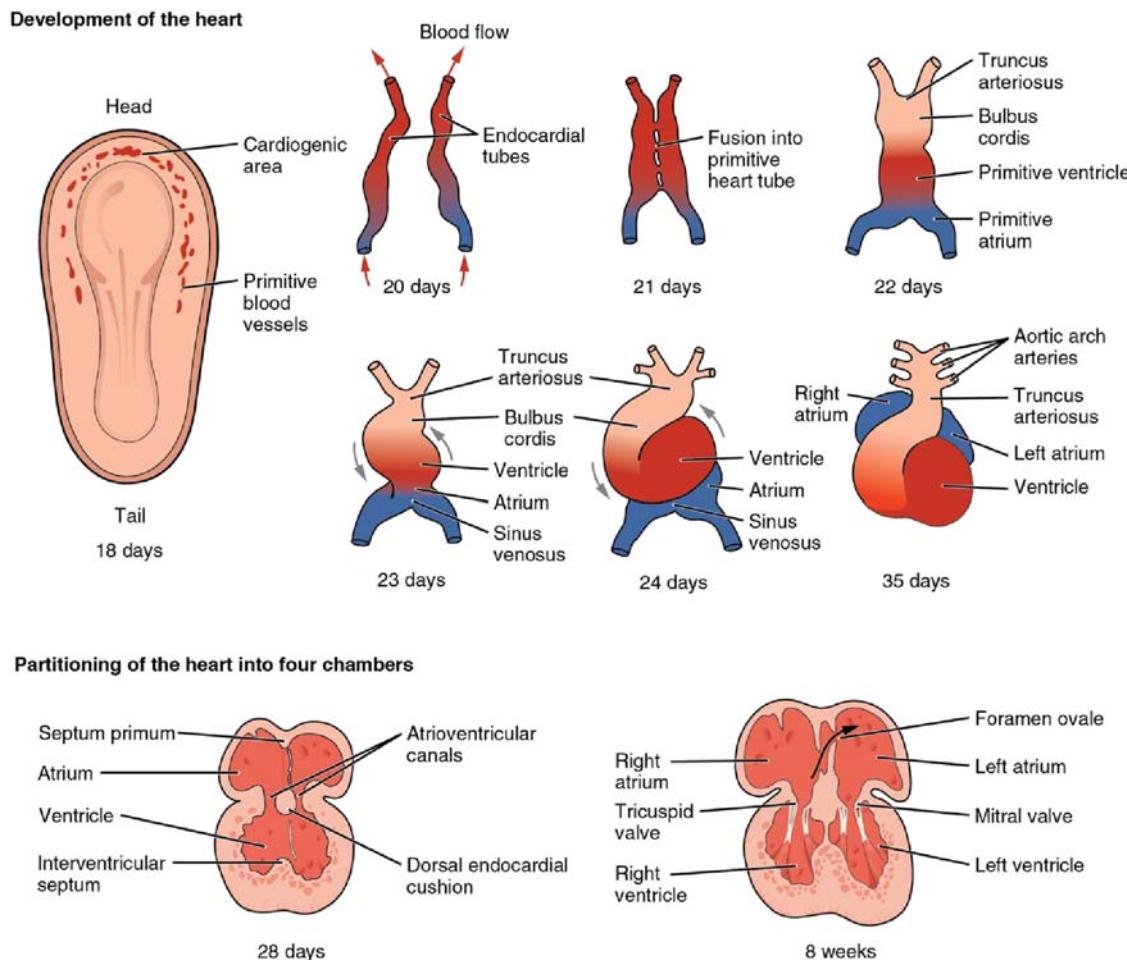
The understanding of the cardiovascular system as a closed-loop system is fundamental, and was first proposed by William Harvey in his 1628 landmark book *De Motu Cordis*. Before Harvey, many anatomists and physicians had unsuccessfully attempted to uncover the role of the heart in maintaining a proper balance of spirits *(pneumata)* in the body, typically reasoning within a fundamentally Platonic framework. Harvey was able to break through such barriers by incorporating a translational approach to cardiovascular research; he successfully combined hypotheses, experiments, observations, interspecies comparisons, and interpretations to produce a rudimentary closed-loop model of the circulatory system. Following on these observations, Richard Lower in 1669 excised strips of cardiac muscle from animals and demonstrated that the contractile feature of cardiac tissue remained for a while even in the absence of blood. Lower also described that the muscular cells of the heart had a weave, and were arranged in a spiral-like pattern whose direction varied with its location within the ventricular wall. He suggested that this arrangement was responsible for the observed "wringing" contractile pattern of the open chest, beating heart.


Building on this finding, James Bell Pettigrew studied the structural arrangement of the heart in fish, birds, mammals (including baleen whale, armadillo, and giraffe), and humans. Through a series of meticulous dissections carried out around 1858, he described a gradual change of directional alignment of muscle fibers in the ventricular myocardium, from the endocardium to the epicardium. An example of his findings is shown in Fig. 14.1. The helical and progressive arrangement of cardiomyocytes would later turn out to be crucial both for generation of the blood pressure (pressure pumping) needed in the systemic circulation,[1] and for efficient emptying and filling of the ventricles (volume pumping) despite limited shortening of the individual myocytes.[2] Indeed, the combination of longitudinally and circumferentially aligned myocytes in the human heart enables it to pressure- and volume-pump blood with remarkable efficiency, and elegantly solves what are potentially the two most difficult conceptual physiologic problems in cardiac pumping: (1) how does the chamber achieve an left ventricular (LV) ejection fraction of 60%−70% while individual myocytes shorten by only 10%−15% and (2) how does the chamber achieve adequate (optimal, low pressure) filling over the physiologic range of heart rates and loads that defines diastolic function. To understand how this is achieved, we must examine the anatomy of the heart from a functional and kinematic perspective.

Gross cardiac anatomy, ventricular myocyte orientation, and mechanism of contraction

Anatomy of the heart

Embryologically, the heart evolves from the heart tube that requires looping and development of septa and valves that ultimately establish a four-chamber configuration (Fig. 14.2). The human heart begins to beat at about 22−23 days, with blood flow commencing in the fourth week. By the end of the ninth week, the fetal heart has

FIGURE 14.1   Posterior view of sheep heart dissected by James Bell Pettigrew. Note the transition in the alignment of cardiac muscle fibers from the left-handed epicardial layer (top left), via the circumferential middle layer, to the right-handed endocardial layer (bottom right). *Image courtesy of The Royal Society.*


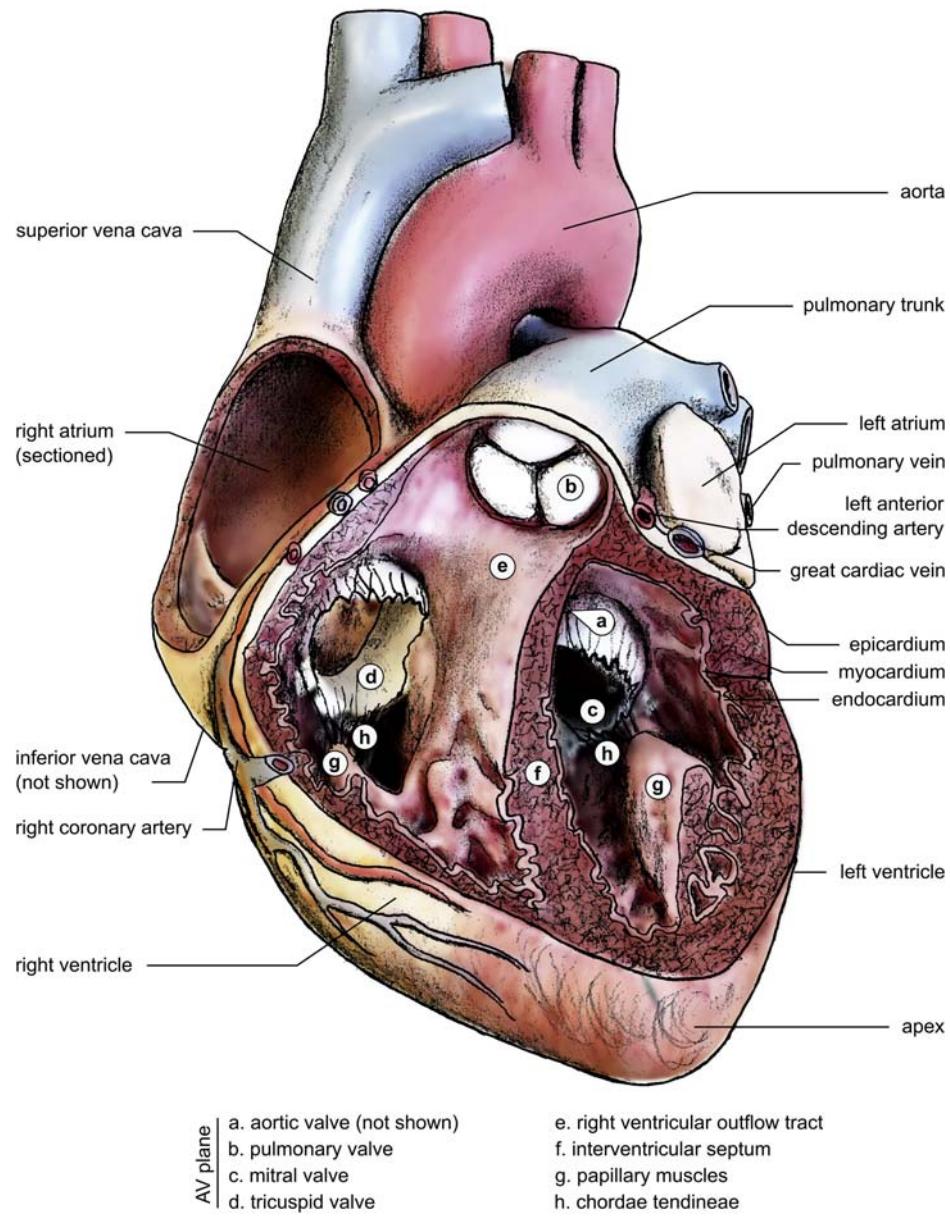
developed septa, valves, and has four chambers. Typical heart rates at this stage of development are 155−195 bpm. Suitable preprogrammed developmental features assure initial establishment of the fetal circulation that obtains nutrition and oxygen through the placenta, while eliminating metabolic waste and CO_2. The fetal circulation diminishes within a few days after delivery, resulting in the complete separation of venous and arterial circulations. Accordingly, circulation proceeds in series, involving the left heart, the periphery, venous return, right heart pumping to the lungs, and arrival of oxygenated blood in the left atrium for systemic perfusion. Therefore, the heart is one of the earliest organs to differentiate and function.

The human heart with pericardium removed, shown in Fig. 14.3, is located in the mediastinum within the thoracic cavity, above the diaphragm and enclosed in the pericardial sac. The pericardium is a soft but essentially nondistensible serous membrane that contains a small amount of pericardial fluid, which acts as a lubricant and permits the surface of the beating heart (visceral pericardium) to contract freely and slide essentially without resistance relative to anatomically fixed pericardial sac (parietal pericardium). The visceral side of the pericardium adheres to the left ventricle, left atrium, right ventricle, and right atrium, as well as the aortic root. The sum of these parts (the contents of the pericardial sac) constitutes the *total heart volume*.

The left ventricle supplies the systemic circulation with oxygenated and pressurized blood, and the right ventricle feeds oxygen-depleted venous blood through the pulmonary circulation to enable gas exchange with the surrounding air. Flow is generated when the systolic pressure of the contracting right ventricle overcomes the pulmonary vascular impedance (such of resistive and pulsatile load). For detailed descriptions of the steady and pulsatile components of arterial load, the reader is referred to (Chapters 1, 3, 17). For a specific detailed discussion of the pulmonary arterial load, the reader is referred to Chapter 57. Here, we will provide a simplified discussion related to vascular resistance only (steady components of load), which can be expressed by the analog of Ohm's Law,

$$Q = \frac{\Delta P}{R}, \tag{14.1}$$

where Q is the flow [ml/sec], ΔP is the pressure difference (mmHg) between the inflow and outflow locations of the resistive circuit, and R is the resistance [mmHg/(mL/ sec)]. Under normal conditions, the resistance in the pulmonary circulation is approximately one-fifth of that in the systemic circulation. For the two ventricles to pump the same volume of blood—in a time-averaged sense—the left ventricle therefore has to apply a driving force (systolic pressure) that is about five times greater than the driving

FIGURE 14.2 Development of the human, four-chambered heart is essentially complete by the eighth week, when the embryo is about 10—12 mm in size.


force generated by the right ventricle. This difference in LV versus right ventricular (RV) workload and wall tension requirement is reflected anatomically in that the left ventricle has a significantly thicker (about 1—1.5 cm) myocardium than the right ventricle (0.3—0.8 cm). Cardiac pumping is an energy-demanding process, and oxygenated blood is supplied to both ventricles and atria via the coronary arteries, which originate in the left and right aortic cusps in the aortic root.

Forward flow is ensured by the valve apparatus, i.e., the aortic and pulmonary valves (also called *semilunar valves*), and the mitral and tricuspid valves (*atrioventricular valves*) that separate the ventricles from the atria.

The atria receive blood from the pulmonary and caval veins, which also serve as anchor points for the posterior (basal) aspect of the heart. The left and right sides of the heart are separated by the interventricular septum and the

atrial septum (see Figs. 14.2 and 14.3). The ventricles are separated from the atria by a fibrous structure known as the *atrioventricular plane* (AV plane). This effectively means that the atria and ventricles are functionally interconnected: whenever the ventricles contract, this will affect the atria and vice versa. As we shall see, this is of great importance for cardiac pumping.

The AV plane serves as the anchoring point for the AV valves as well as the aortic root and aortic valve. The AV valves are also connected to the ventricular myocardium via the chordae tendineae, which together with the papillary muscles prevent the valve leaflets from prolapsing into the atria during ventricular contraction. The atrioventricular valves must resist the systolic blood pressure without allowing any backward, regurgitant flow, and they must be compliant enough to permit fast and unobstructed inflow during cardiac filling, which normally occurs at low blood pressure.

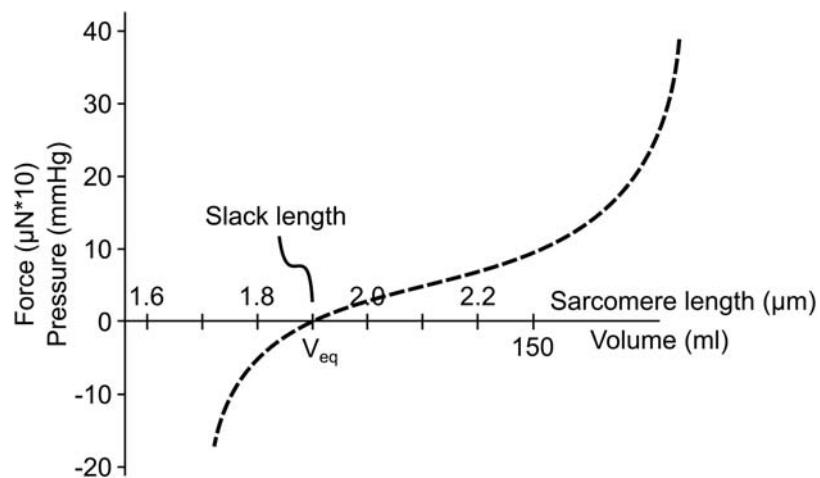
When functioning properly, cardiac valves can be thought of as physiological rectifiers or diodes. It is important to understand that all cardiac valve leaflets are entirely passive structures, and their motion is dictated by the motion of the surrounding blood. While intraventricular, ventriculoaortic, and atrioventricular pressure gradients accelerate the blood, this acceleration force is always opposed by the inertia of the blood. Recall that flow occurs only when resistance is overcome by a force, i.e., a pressure gradient, which develops gradually (over tens of msecs). Valve states (open/closed) therefore always lag behind pressure changes and are ultimately effected by actual blood and tissue motion.[4] It also follows that all valves have some degree of insufficiency (leakiness), as they only begin to close—i.e., coaptation of leaflets to form a leakproof seal—when subjected to retrograde flow, and the closing is gradual (msecs) as opposed to instantaneous. Whether a valve is considered leaky (regurgitant) or not depends on the severity of the insufficiency (quantified as the regurgitation fraction, 0%—100% of forward flow, the latter figure being incompatible with life) and on the clinical consequences (atrial distension, pulmonary edema, and exercise intolerance, to name a few).

Contractile function of myocytes

Let us now briefly turn to the basic function of the *myocyte*, described in greater detail in the preceding chapter. The contractile function of each individual cell arises from the interaction of two sets of intracellular filaments, composed of *thin filaments* (composed of *actin*, *tropomyosin*, and *troponin*) and *thick filaments* (*myosin*), respectively. These filaments are arranged in an interlocking pattern within

each sarcomere along the long axis of each myocyte. Myocyte shortening occurs because within each sarcomere myosin "walks" along the actin filaments, pulling the ends of the myocyte toward its center (Fig. 14.4).

Whenever a cardiomyocyte is depolarized, i.e., its membrane potential is lost, it will respond by increasing its permeability for Ca^{2+}, leading to influx of such ions. Through the ryanodine receptor system, this triggers additional rapid calcium-dependent release of stored

FIGURE 14.4 Structural layout of an individual cardiomyocyte and its contractile subunit, the sarcomere—a molecular motor. Cardiomyocytes are dominated by the contractile elements which are arranged in myofibrils. Myofibrils are surrounded by mitochondria and the sarcoplasmatic reticulum, which is coupled to the exterior of the cell through the T-tubules. Bottom: the sarcomere is understood as a system of sliding filaments, which alternate between relaxed (crossbridges are essentially uncoupled) and contracting (crossbridges are mostly coupled) states depending on the Ca^{2+} concentration—which varies by about a factor of 1000 during each cardiac cycle. Titin is anchored to the Z disk and M line and is a *bidirectional spring*; it is compressed—and stores elastic energy—because of contraction; it then provides a restoring (recoil) force upon cessation of contraction (crossbridge uncoupling) and onset of relaxation.


intracellular Ca^{2+} from the sarcoplasmic reticulum—a storage compartment for Ca^{2+} ions. Part of this Ca^{2+} binds to troponin, a protein coupled to the actin filaments, causing it to undergo conformational changes which unmask myosin binding sites in the actin filaments. The subsequent attachment of myosin to actin is called *crossbridge formation*. In the presence of adenosine triphosphate (ATP), myosin then undergoes additional conformational changes causing it to exert a "pull" on actin. This leads to shortening of the sarcomere. During systole, sarcomeres shorten by about 15% from 2.1 to 1.7 microns. ATP is also required to break the actin-myosin crossbridge and restore myosin to its relaxed state, preparing it for repeated crossbridge cycling. Cycles continue for as long as the intracellular space is flooded with Ca^{2+} and while ATP remains available. During a single systolic contraction, an individual sarcomere attaches, shortens, and detaches multiple times (crossbridge cycling). Sliding filament dynamics should be viewed as the result of an astronomical number of crossbridges cycling, governed by a probability distribution modulated by Ca^{2+} concentration.

As the sarcomeres shorten, the cell also thickens, since the intact cellular membrane implies volume conservation at the individual cell level. Total shortening is dependent on the contractile (inotropic) state but is usually in the 15% to 20% range; thickening is markedly less, since the myocyte is longer (≈ 100 microns) than it is thick ($10-25$ microns in diameter).

Importantly, a third filament-like protein is also present within the sarcomere: the giant protein *titin* connects the M line with the Z disk, providing structural continuity along the entire sarcomere. Apart from acting as a scaffold for the contractile elements, titin also contains several spring-like domains which modulate the physical tensile properties of the sarcomere. During systolic contraction, the spring is gradually compressed, storing elastic energy. Once relaxation commences, the titin springs release their stored strain energy and restore the myocyte to its slack length.[5] In other words, during diastole myocytes can actually push! Conversely, titin also resists stretching of the sarcomere during diastole, and is the major intracellular contributor to myocardial passive tension at physiological sarcomere lengths.[6] Taken together, this means *titin acts as a bidirectional spring*. In simple physical terms, titin has an equilibrium length say Lo, (likely during diastasis); if compressed below Lo (LV at end-systolic volume), it stores elastic strain energy, and when crossbridges detach, it lengthens the sarcomere toward Lo. If it is stretched beyond Lo (likely, in normal sinus rhythm, at end diastole after the atrial kick), titin is stretched beyond Lo, and if no systolic contraction ensues, it shortens toward Lo. Recall that *tension* is defined as the amount of force resisting length changes of the relaxed myocyte. In the experimental setting, this can be measured by attaching a relaxed and isolated myocyte to a force measurement device and gradually extending it from its slack length (equilibrium). This produces a highly nonlinear force-length curve (Fig. 14.5), representing the cell-specific stiffness which can be understood as the sum of forces acting to restore the cell to its slack length.

The concept of passive tension can be translated to the three-dimensional organ level, where the sarcomere length is replaced with ventricular volume, and force is replaced with pressure. The sarcomere length is thus equivalent to

FIGURE 14.5 Passive and active tension properties of myocardium. Myocytes resist length changes due to their elastic properties. When stretched from slack length, the amount of restoring force is initially small. At the organ level, this facilitates filling of the ventricle. As the cell becomes more stretched, the restoring force becomes more pronounced, which prevents overstretching of the ventricle. Note that in the 1.8 to 2.1 micron (physiological) range, the curvilinear relationship is essentially linear, justifying the approximation that the system behaves kinematically as a linear, bidirectional spring. During systole, sarcomeres shorten by about 15% from 2.1 to 1.7 microns. Conversely, shortening below slack length results in a restoring force acting to lengthen the cell.

cardiac preload; slack length is equivalent to the *equilibrium volume* (V_{eq}), which is attained during diastasis when the myocardium is fully relaxed, and wall motion ceases. Total stress on the ventricular wall is minimized, but not completely eliminated, at V_{eq}.[7] It therefore follows that the passive tension curve describes the tendency of the ventricle to resist volume change away from V_{eq} (Fig. 14.5). Whenever ventricular volume is below V_{eq}, the *restoring forces contribute to filling of the ventricle* by facilitating ventricular expansion toward its resting (diastatic) volume. On the organ level, titin-mediated passive tension is further compounded by intermediate filaments, extracellular collagen, and external mechanical factors which will be discussed later.

Active tension describes the capacity of the myocyte to generate force by contraction. Cardiomyocytes will generate different amounts of contractile force depending on the initial conditions of the sliding filaments. If cells are stretched, the contractile elements become more sensitive to Ca^{2+}. The mechanisms are unclear, but the result (within limits) is a stronger contractile force for initiation of shortening when starting from increased sarcomere lengths. On the organ level, this has the effect of providing an instantaneous compensatory mechanism for handling different ventricular filling volumes (preload). Increased inflow to the heart is responded to by a stronger contraction, i.e., the heart pumps what it receives. This is called the *Frank—Starling law of the heart*. The potential to generate force is maximized at sarcomere lengths around 2.2 μm. At even higher lengths, the filaments start to slide apart, and fewer active sites are available for crossbridge formation, leading to decreased active tension.

The active tension curve describes the maximum attainable force for a certain level of sarcomere stretch or ventricular filling. This explains why atrial fibrillation leads to decreased ejection fraction. Under normal conditions, atrial contraction (Doppler A-wave of transmitral flow) leads to additional filling of the ventricle, i.e., presystolic stretching of myocytes. The most important contribution, however, is the added stretching of the myocardium because the atria pull the AV plane up toward the base, thereby increasing the subsequent force of ventricular contraction. When atrial contraction is lost, as in atrial fibrillation, the ventricle does not fill beyond V_{eq}, and ventricular contraction occurs at a lower level of precontractile stretch. As a result, ventricular ejection fraction is diminished. Since ventricular contraction pulls at the AV plane and is opposed by it structurally, it also follows that increased stiffness of elastic structures being tugged at—predominantly the atria and great vessels—will likely affect both the end-systolic position and the diastolic return to V_{eq}. Increased stiffness may result from fibrosis, calcification, and other disease processes.

The shape of the active tension curve can also be altered, by adjusting the level of sympathetic tone from the autonomic nervous system and the presence of cathecholamines (primarily adrenaline). The capacity to regulate the contractile force for a given preload is called *inotropy*. Importantly, this differs from the Frank—Starling mechanism by altering the slope of the active tension curve instead of responding to variations in preload.

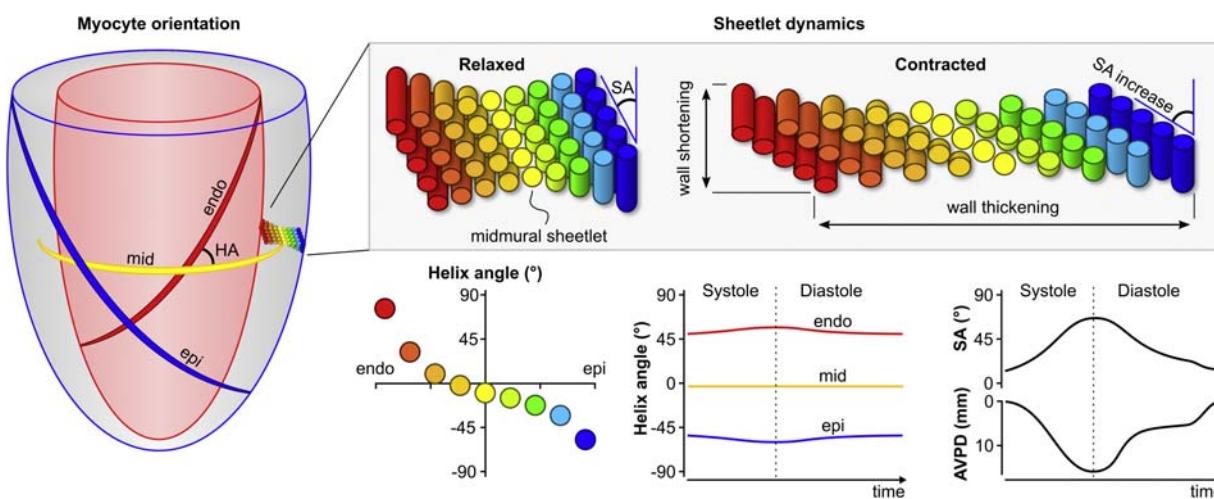
For a fixed afterload (vascular resistance), increasing the force of contraction (positive inotropy) will lead to more complete emptying of the ventricle. The end-systolic volume will therefore be further below the V_{eq}, resulting in a stronger restoring force of recoil (titin) during early diastole. This is one of the key physical mechanisms of systolic—diastolic coupling, by which systolic function directly influences diastolic performance. Indeed, it is impossible to optimize diastolic function in the presence of systolic dysfunction.

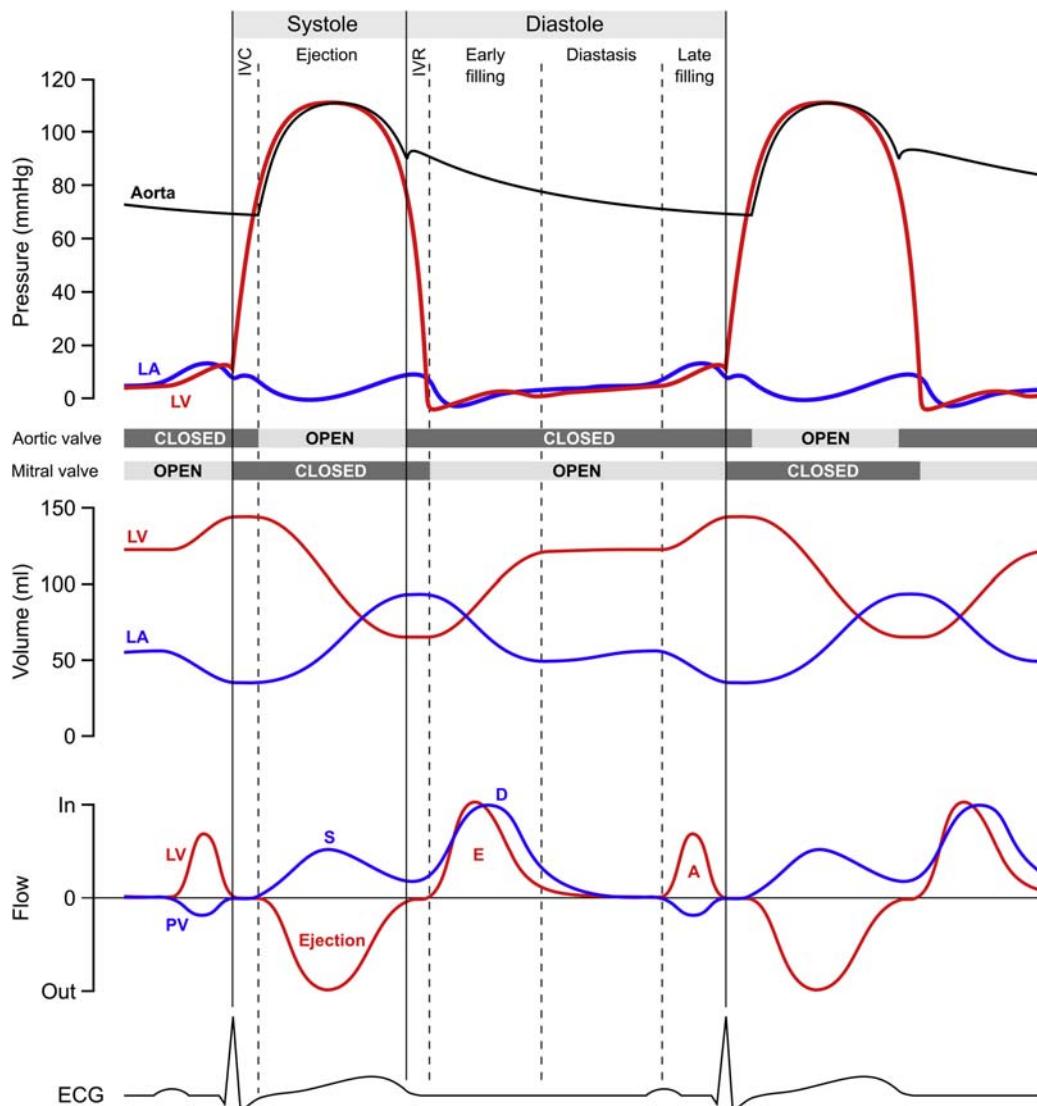
Physiologically, the Frank—Starling mechanism and inotropic regulation address fundamentally different challenges. The Frank—Starling mechanism ensures a steady output of blood flow (volume pumping) under varying preload levels, while inotropy is adjusted to ensure a sufficient ejection force to overcome the peripheral resistance (pressure pumping), equal to different afterloads. Increasing inotropy at rest therefore only lowers the end-systolic volume and increases the ejection fraction but does not increase cardiac output. In contrast, during vigorous exercise, the increase in heart rate and cardiac output is greater than the decrease in peripheral resistance resulting from compensatory vasodilation in working skeletal muscle; as a result, blood pressure (afterload) typically increases by at least 50%. The ability to increase the contractile force is crucial to overcome this increased afterload, which is continuously generated by the working heart. Inotropy is therefore not a mechanism by which cardiac output is increased, but rather maintained at varying afterloads. The utility of the association between increased contractile force and augmented diastolic function will become apparent in the following section.

Ventricular myocyte orientation and function

When examining myocardial tissue, the myocytes exhibit an obvious weave, a directionality. The commonly used term "fiber direction" is somewhat misleading because there are no continuous fibers of myocytes in the myocardium, unlike in skeletal muscle; cardiomyocytes instead branch and interconnect continuously, creating a syncytium (a functional unit of cells). Furthermore, the myocytes are embedded in a three-dimensional extracellular matrix composed primarily of collagen and elastin. Despite this, we can appreciate directional patterns which are visible to

the naked eye, as evidenced by the aforementioned experiments by Lower and Pettigrew.

The overall arrangement of cardiomyocytes is commonly described as helical, albeit with a gradual and smooth change in alignment as a function of their position between the epicardial and endocardial aspects of the myocardial wall. The angle between the myocyte long-axis direction and the LV equatorial (short-axis) plane constitutes the primary pattern of organization in the myocardium, and is referred to as the *helix angle* (HA, Fig. 14.6). Multiple modalities have been used to demonstrate that the endocardial myocytes follow a left-handed helix, while midmural cells are circumferentially aligned, and epicardial cells are arranged in a right-handed helix; the difference in HA between the extremes is around 120 degrees.[9,10] Taken together, the shortening of individual myocytes will therefore cause ventricular long-axis shortening (due to the epicardial and endocardial cells), narrowing (due to the midmural cells), and twisting (torsion) of the ventricle (due to the differences in HA between as one traverses the wall, from endocardium to epicardium).[11]


Cardiomyocytes are secondarily organized in microstructures termed *sheetlets*. A sheetlet is a laminar group of parallel myocytes, 5–10 cells in thickness. While the HA describes the relationship between the individual cellular shortening direction and the ventricle, the *sheetlet angle* refers to the cross-sectional alignment of sheetlets in relation to the local epicardial aspect of the ventricle (SA, Fig. 14.6). The sheetlet angle drastically increases during systolic contraction, implying that the myocardium undergoes a significant shear deformation. Indeed, this constitutes the predominant mechanism causing systolic LV wall thickening[12] in contrast with the HA, which changes very little over the cardiac cycle.


The cardiac cycle

Having established the principal modes of action of the myocardium, let us now consider the filling and emptying dynamics of the heart. The cardiac cycle can be visualized using a Wiggers diagram (Fig. 14.7), named after its inventor, Carl J Wiggers. For simplicity, we will only consider the left side (LA and LV) of the heart; the principles discussed below apply to the right heart (RA and RV) as well, with variations mainly in pressure levels.

The cardiac cycle begins with the spontaneous depolarization of the sinus node (P-wave in the ECG). This causes the atrium to contract and pull the mitral annulus upward, lengthening the chamber and ejecting atrial blood. The atrium has five orifices, four inlets (pulmonary veins, about 1 cm^2 cross-sectional area for each of the veins) and one outflow orifice (mitral valve having a cross-sectional area of 5–6 cm^2). Atrial contraction inscribes the Doppler echocardiographic A-wave of transmitral flow, and pushes blood into all five orifices! Blood flows into the relaxed LV via the large open mitral valve and simultaneously, a small amount of blood is pushed back into each of the pulmonary veins. It is self-evident that the duration of antegrade (into the LV) versus retrograde (back into the PVs) flow and the antegrade versus retrograde volumes are determined by the relative compliance of the LV chamber relative to the compliance of the pulmonary veins themselves. Indeed,

FIGURE 14.6 Patterns of myocyte organization. The primary pattern of myocyte organization is that of a helix whose angle varies across the ventricular wall. The epicardial and endocardial layers are longitudinally arranged, resulting in a systolic long-axis shortening of the ventricle. Relative to a spatially fixed epicardial apex, this is quantifiable as atrioventricular plane displacement (AVPD). Secondarily, myocytes are arranged in sheetlets which undergo systolic shear deformation; this is the main mechanism for wall thickening. Recall total tissue volume is conserved between systole and diastole. The shear deformation also implies cyclical alterations to the space surrounding the myocytes, where the capillaries are situated, which may contribute to perfusion of the myocardium.[8]

FIGURE 14.7 Modified Wiggers diagram, showing pressure, volume, and flow variations over the cardiac cycle. Note that while the atrioventricular and ventriculoaortic pressure gradients are small (1−3 mmHg) in comparison to the absolute pressures, they are sufficient for diastolic volume pumping, i.e., to drive flow.[13] Also note the temporal matching of inflows and outflows, visible both in the volume and flow curves. Note that LV ejection (aortic stroke volume) is not fully compensated by the simultaneous pulmonary vein S wave entering the left atrium. This discrepancy between left heart outflow and simultaneous inflow causes slight (about 5%−8%) total heart volume variation, which is restored by the pulmonary vein D wave.

the duration of antegrade flow (duration of Doppler A-wave in msec) compared to the duration of retrograde PV flow is a measure of end-diastolic LV chamber stiffness.[14]

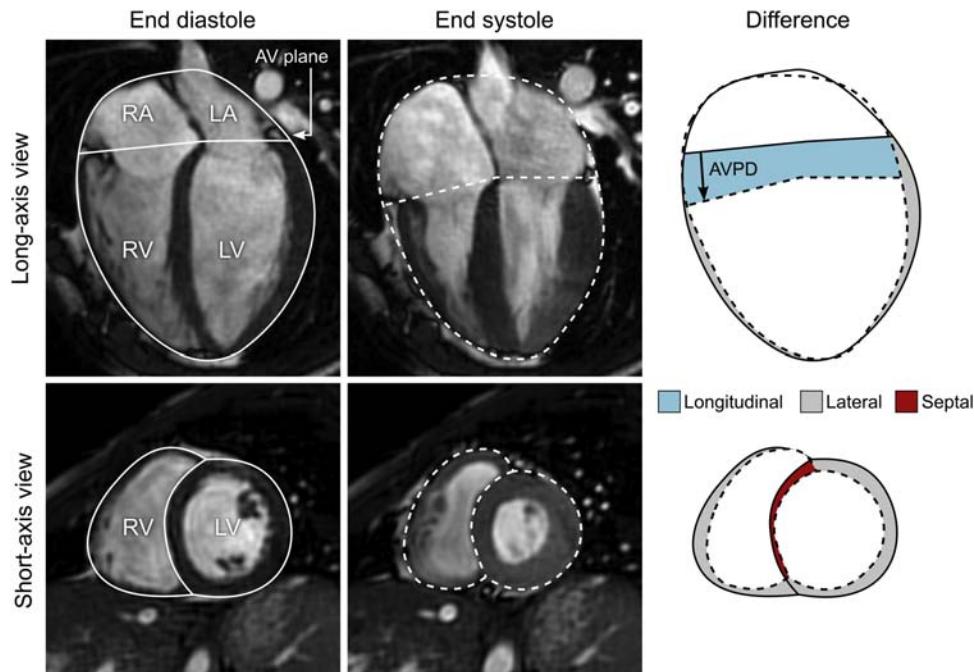
Atrial contraction pumps blood into the LV while simultaneously pulling the AV valve plane upward, lengthening the chamber, whose epicardial apex remains spatially fixed. This action generates a prestretch of myocytes and "primes" the ventricles for more efficient subsequent ejection through the Frank−Starling mechanism.

After atrial depolarization, the atrioventricular node introduces a slight temporal delay (P-Q interval in the ECG, equivalent to duration of the transmitral Doppler A-wave) before the Purkinje fiber network's depolarization wavefront reaches the ventricles. Once the ventricle starts to depolarize (QRS complex in the ECG), its contraction causes ventricular pressure to increase sharply. The increase in pressure forces blood toward the base of the ventricle, causing the mitral valve to close. Due to the closed mitral and aortic valves, ventricular volume remains constant—this period (30−60 ms) is referred to as isovolumic contraction and is characterized by rapid pressure buildup, usually quantitated by the peak slope of the rising pressure, denoted peak + dP/dt. Once ventricular pressure exceeds aortic pressure, (LVP > AoP) the aortic valve opens, LV pressure continues to rise for a brief interval as blood is accelerated into the aorta—the ejection phase begins.

After opening of the aortic valve, rate of LV pressure increase slows, and approximately halfway through ejection, LVP starts to decrease. The ventricle has now started its repolarization process (T wave on ECG). Aortic pressure now exceeds ventricular pressure and flow starts to decelerate; however, outflow continues for a while due to the inertia of the outflowing blood.[4] In healthy hearts, ejection imparts enough momentum on the outflowing blood to significantly contribute to emptying of the ventricle even in late systole, when contraction has ceased.[15] This leads to a smaller end-systolic volume and hence stronger restoring (recoil) forces, improving subsequent filling.

Eventually the pressure gradient between aorta and ventricle changes sign (LVP < AoP) and causes flow reversal, which quickly closes the aortic valve, ending ejection. The period from closure of the mitral valve to closure of the aortic valve is one definition of (mechanical) *systole*, the ejection phase. The duration of mechanical systole closely corresponds to the QT interval on the normal ECG and is a function of heart rate.[16]

As the ventricle repolarizes, its pressure continues to decrease through the process of isovolumic relaxation (IVR = 70−100 msec) to a point where it undershoots (LVP < LAP) the atrial pressure.[13] This causes the mitral valve to open and the LV begins to fill, while pressure is still decreasing. Because pressure continues to drop as the chamber volume increases, the wall must be springing apart faster than the chamber can fill, which effectively turns the ventricle into a mechanical suction pump that opens the mitral valve and aspirates blood from the atrium.[17,18] Therefore, after mitral valve opening, dP/dV is briefly <0! The "early rapid filling phase" of the LV commences, usually echocardiographically quantified as the transmitral Doppler E-wave. During the acceleration portion of the E-wave, LVP < LAP (suction), after the peak of the E-wave, at pressure crossover, when LVP = LAP, blood continues to flow into the LV due to inertia and continued relaxation of the myocardium, but eventually flow decelerates because LVP > LAP.

Once the pressure gradient between atrium and ventricle is eliminated after the E-wave, and the myocardium is fully relaxed, the chamber enters a temporary state of equilibrium where tissue motion ceases, all forces are balanced (but not zero), and there is no wall motion. The forces balanced interval is called the *diastasis*. Diastasis corresponds to the aforementioned equilibrium volume V_{eq} and therefore conveys information regarding the passive stiffness of the ventricle.[19] Diastasis is concluded when the sinus node depolarizes anew, which again leads to atrial contraction, inscription of the transmitral Doppler A-wave, and the end of the A-wave marks the beginning of a new cardiac cycle. The time spent by the relaxing and filling ventricle, from the isovolumic relaxation until the end of the late filling phase, is collectively called *diastole*. Expressions for the duration of diastole, and its phases (E-wave, diastasis, A-wave) or equivalently on the ECG


(RR duration minus the QT duration), as a function of heart rate have been proposed and validated.[16]

Atrioventricular valve plane displacement: give and take

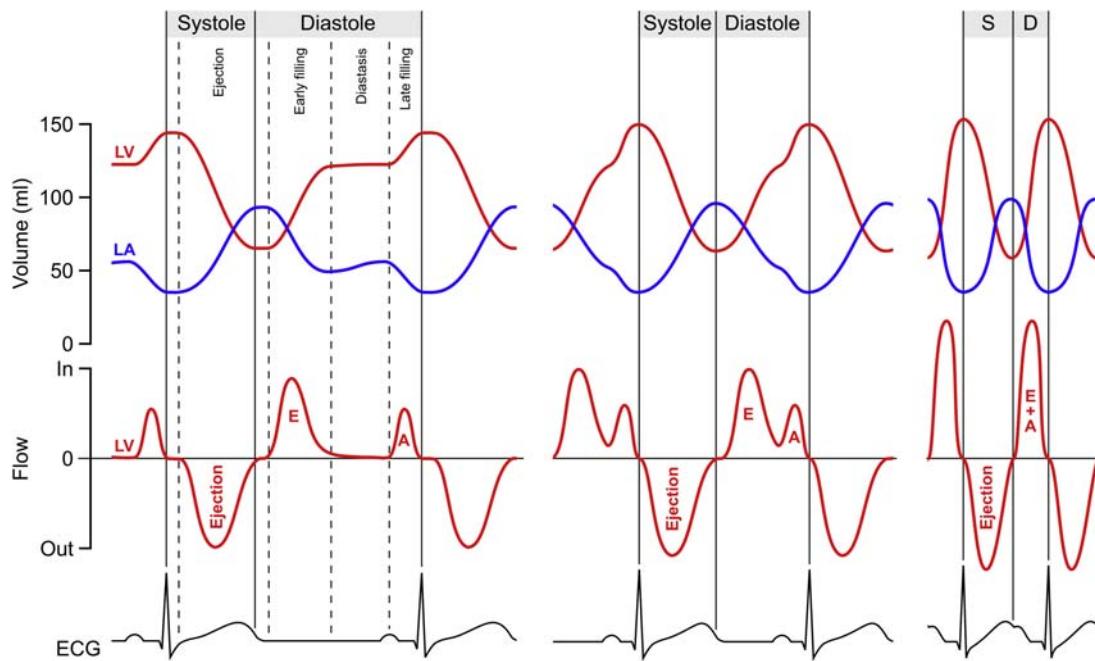
With the Wiggers diagram fresh in mind, let us now revisit the anatomy of the heart from a functional perspective. During systole, myocyte shortening will lead to ejection of ventricular blood and subsequent long-axis shortening and short-axis (transverse) narrowing of the ventricles. Due to the predominantly longitudinal arrangement of the myocardium, long-axis shortening will dominate over transverse narrowing. The epicardial apex of the heart remains spatially stationary, since the pericardium is attached to the thoracic wall. Similarly, the base of the heart is anchored to the pulmonary and caval veins, the mediastinum as well as the great arteries. Therefore, ventricular long-axis shortening acts to pull the AV valve plane toward the fixed apex, simultaneously enlarging the atria whose posterior portion is anchored by the PVs. Hence the apically directed motion of the AV plane and its closed valves mechanically acts much like a plunger on a syringe, creating a pressure gradient which aspirates pulmonary and caval venous blood into the atria. Ventricular ejection is therefore temporally and mechanically coupled to atrial filling (Fig. 14.7). This reciprocal action is the main example of *systolic−diastolic coupling* reflected in the ventricular and atrial volume curves: as the LV empties, the LA fills, and vice versa.[20] The only exception to this rule may be during diastasis, when atrial filling may slowly continue due to the pressure head from the pulmonary veins.

In this view, the four-chambered heart acts as a piston (volume) pump that ejects blood through atrioventricular plane displacement (AVPD), a mode of pumping which simultaneously leads to atrial filling, ensuring that an adequate amount of blood is available for the subsequent filling phase. In fact, this effect extends beyond the confines of the heart: venous return to the heart is amplified by AVPD even in distal parts of the vasculature.[21] Now, if AVPD was the only mechanism for cardiac pumping, we should expect a 1:1 relationship between ventricular stroke volume leaving the pericardial space via the aorta and simultaneous atrial filling (pulmonary vein S wave). We should also expect a perfectly constant total heart volume, since the volume removed from the ventricles should be balanced by a corresponding increase in atrial volume. This is an appealing concept since it means no work is wasted displacing adjacent tissues.[22]

How significant, then, is the longitudinal contribution to stroke volume, compared to radial contribution? Studies using cardiac MRI have found that the healthy LV produces approximately 60% of its stroke volume by AVPD, while the rest results from radial narrowing (Fig. 14.8).[23,24] The right ventricle has a larger proportion of longitudinally

FIGURE 14.8   Principles of cardiac pumping require systolic—diastolic coupling. Left: MR images of a normal heart at end diastole shown in long-axis and short-axis views. The atrioventricular plane and epicardial boundaries have been delineated. Middle: end-systolic phase. Note that the AV plane has been pulled downwards toward the apex. Right: superposition of end-diastolic and end-systolic epicardial contours reveals the three principal modes of pumping. The longitudinal contribution to ventricular stroke volume is shown in blue. Note that RV AVPD exceeds LV AVPD. The lateral component is shown in gray. Note that this area corresponds to the outer volume changes of the heart. The septal component is shown in red. Normally, septal contraction contributes to LV pumping, and detracts slightly from RV pumping. The radial contribution to pumping is calculated as the sum of lateral and septal pumping.

oriented myocytes and lacks the midmural circumferential layer needed to generate high pressures, i.e., its primary role is to be a volume-pump. As a result, AVPD produces approximately 80% of RV stroke volume.

Radial pumping ejects a volume that will not be reciprocally filled into the atria, and explains why the pulmonary vein S wave filling the atrium is always smaller than the simultaneous stroke volume.[25,26] Total heart volume reaches its lowest point just before end-systole,[27] and the volume is largely recovered during early diastole through the pulmonary vein D wave. Additional total heart volume variation arises from a slight venous backflow in late diastole, resulting from atrial contraction.


In summary, the four-chambered heart can be described as a *near*-constant volume pump whose total volume (about 800 mL) changes by 5%—8% (40—60 mL) over the cardiac cycle, and whose mode of operation is mainly through longitudinal shortening.[25,28]

Locked and loaded: recovering elastic energy during diastole

Thus far we have concentrated on how ventricular contraction manages to eject blood, but let us now turn to the problem of filling the ventricle. At rest, approximately one-third of the cardiac cycle is spent ejecting blood, a process which accounts for the vast majority of the heart's energy expenditures. The remaining time is spent filling the heart (in normal sinus rhythm) in a biphasic pattern: the E-wave (early rapid filling) is followed by the A-wave (atrial kick, late filling), separated by diastasis. With increasing heart rate, diastasis is gradually shortened and disappears completely at moderately elevated heart rates.[16] At even higher heart rates, the E- and A-waves merge to form a single filling wave, and diastole is *shorter* than systole (Fig. 14.9). Filling (volume pumping) must therefore involve higher levels of acceleration than emptying, despite occurring at much lower pressures. How is this possible?

Recall that systolic contraction below the equilibrium volume V_{eq} results in restoring forces building up in the myocardium. These forces are released upon cessation of systolic contraction, releasing the restoring forces and creating what is known as *diastolic recoil*. Diastolic recoil means that the ventricle rapidly springs back toward V_{eq}, seen in the Wiggers diagram as a rapid pressure decrease during isovolumic relaxation. The pressure decline continues briefly after mitral valve opening during the initial, early rapid phase (Doppler E-wave). As long as ventricular pressure drops while the ventricle fills, the chamber must be mechanically expanding faster than it can fill, hence, the

FIGURE 14.9 Gradual changes in filling dynamics with increasing exercise intensity. Left: At rest, the transmitral E- and A-waves are separated by diastasis. Middle: At moderate exercise, diastasis disappears, but E- and A-waves remain discernible. Right: At intense exercise, E- and A-waves merge into a uniphasic filling wave. The uniphasic waveform means that the LV is sucking at the same time that the atrium is pushing! The result is a sinusoidal filling/emptying pattern, reflected in the reciprocal LA/LV volume curves. Note also that at high heart rates, diastole is shorter than systole.

ventricle by definition functions as a mechanical diastolic *suction pump*. This fulfills the original criterion for ventricular suction defined by Katz:

$$\frac{dP}{dV} < 0,$$

regardless of absolute pressure level. Recall that the definition of chamber stiffness is *dP/dV*, the instantaneous slope of the pressure-volume relation. When the ventricle sucks *dP/dV* is negative, and the LV has negative stiffness! It is important to recall that the definition of suction is that LVP drop below the pressure in the chamber that is the source for filling, i.e., the left atrium. Diastolic suction therefore does not mean that the pressure in the LV is below atmospheric pressure, rather, suction is defined relative to the source pressure for filling. Also note that transmural wall pressure gradients are immaterial to this kinematic definition and need not be considered, as long as atrial pressure is known. This *dP/dV* < 0 definition for suction is also valid regardless of heart rate; ventricular suction contributes to filling even with a simultaneously contracting atrium. In fact, the basally directed "pull" of the atria serve to amplify the relaxation and expansion of the ventricle.

Diastolic relaxation is an active process, dependent on at least three critical events at the cellular level: quick removal of intracellular Ca^{2+}, thin filament deactivation, and crossbridge cycling.[29] To complicate matters further,

these processes are interdependent and influenced by many intracellular processes and factors such as the presence of ATP, changes in gene expression, intracellular sodium levels, and so on. And finally, the modulation of diastolic relaxation (*lusitropy*) occurs through organ-level changes in heart rate, preload, and sympathetic tone, which in turn are also interconnected. When relaxation works properly, it enables quick release of stored elastic strain energy; whenever it is impaired, diastolic suction will be attenuated, and filling impaired as a result.

Impaired diastolic function is a typical finding in heart failure and may precede systolic impairment. As such, it is often seen in heart failure with preserved ejection fraction. Conversely, whenever systolic dysfunction is manifest, as a result of *systolic–diastolic coupling*, it follows *by necessity* that diastolic function is also disturbed. Clinical quantitation of diastolic function seeks to determine whether relaxation abnormality or increased stiffness is present, and whether cardiac filling pressures have become elevated as a compensatory mechanism. In concise terms, the determinants of diastolic function are stiffness, relaxation, and load.

The evidence for diastolic suction has accrued gradually. Early studies in animal models found that clamping the mitral valve at end-systole resulted in negative (subatmospheric) LV pressures, in the open chest, pericardial cradle experiments.[18,30] Using invasive pressure-volume catheters, later studies (closed chest) have demonstrated

the presence of early diastolic intracavitary and atrioventricular pressure gradients whose properties match the dynamics of the E-wave.[13] These pressure gradients are attenuated in myocardial ischemia, with increasingly diminished diastolic suction seen with worsening systolic function.[31] To further underscore the significance of *systolic—diastolic coupling*, incorporating the spring-like characteristics of diastolic function, the effects of the relaxing myocardium on the resulting inflow patterns have been formulated kinematically, and viewed as an inertial cardiohemic oscillation. Accordingly, E-wave contours are generated by this process and must obey the laws of motion. It can be described using a mathematical framework in analogy to damped harmonic oscillatory motion as detailed in the *parametrized diastolic filling formalism*.[32] This model that employed a linear, bidirectional spring was introduced many years before the actual linear, bidirectional molecular spring—titin[14]—was uncovered, demonstrating the fundamental predictive utility of kinematic modeling of the heart.[5]

The presence of a pulmonary venous D wave is key to understanding diastolic suction. It tells us that whichever mechanism normally causes blood to flow from the atrium into the ventricle must reside at the ventricular level. If ventricular filling is increasingly driven by elevated atrial pressure, and diastolic suction is impeded, we expect a diminished D wave, which is exactly what is observed. Furthermore, the volume displaced by radial pumping (epicardial volume change) corresponds to the D wave and atrial conduit volume, as evidenced using both echocardiography and MRI.[33—35] This volume is also equivalent to the difference between the stroke volume exiting the pericardial volume and the simultaneously entering pulmonary S wave volume.[36] Ventricular suction must be present whenever ventricular volume is below V_{eq}, since this implies the presence of restoring forces acting to lengthen the myocytes. In the overstretched ventricle (as in congestive heart failure or acute volume overload), restoring forces may actually counteract ventricular filling since adding more volume implies moving further away from V_{eq}.

Summary

In this chapter, we have examined the functional consequences of both cardiac anatomy, with a focus on atrioventricular interactions, and of the filament model of the myocyte, especially with regards to the spring-like protein titin. Through the helical arrangement of myocytes, systolic contraction mainly leads to shortening of the ventricles, a longitudinal motion of the AV plane which ensures simultaneous filling of the atria. The reciprocation is not perfect, and while the discrepancy between inflow and outflow during systole is caused by radial narrowing of the ventricle, it

also gives rise to the pulmonary vein D wave which is explained by ventricular diastolic suction. At the cellular level, all motion away from slack length or equilibrium will be opposed by restoring forces primarily generated by the spring-like protein titin. It follows that systolic shortening will prime the ventricle for subsequent release of elastic energy—diastolic suction—which serves to bring the ventricle back toward equilibrium. Increasing the deviation from the equilibrium volume, such as after a more forceful contraction, therefore augments diastolic filling both by release of more elastic energy, and by improved atrial inflow during systole. It also follows that patients with systolic dysfunction must always have some degree of diastolic disturbance—but the opposite is not necessarily true.

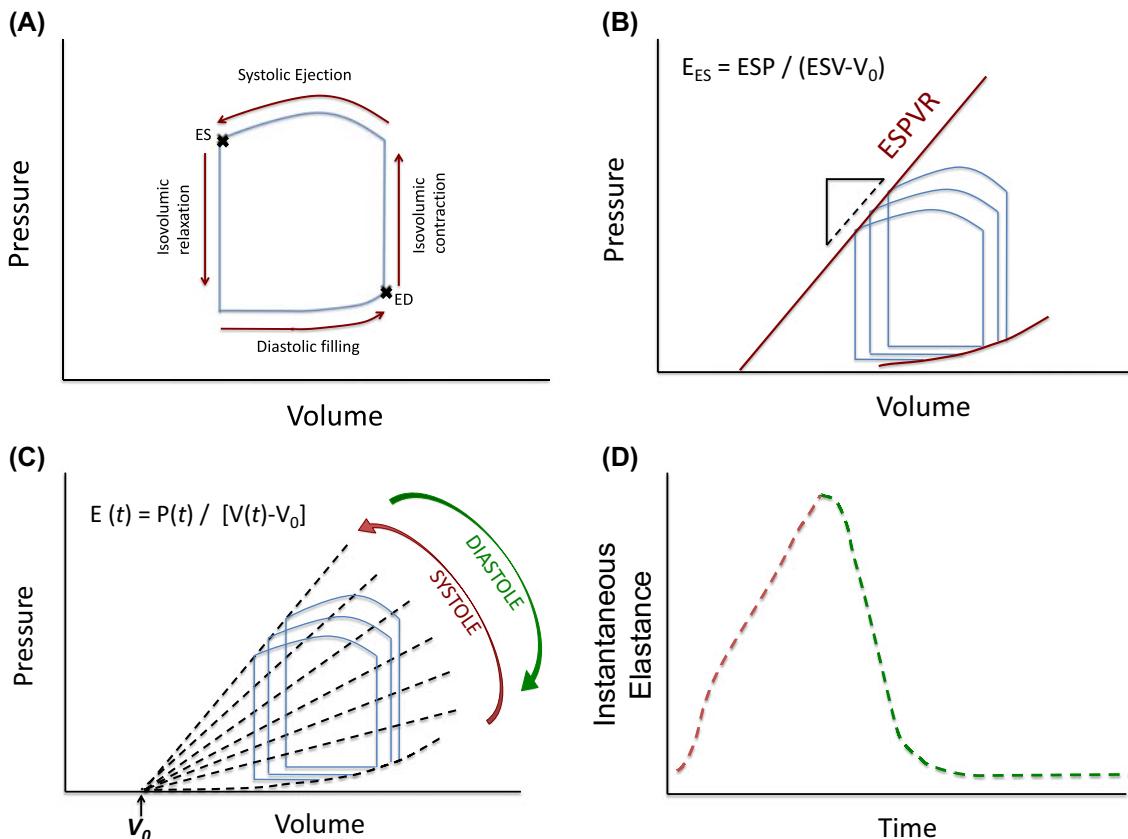
Chapter 15

Ventricular–arterial coupling: the pressure–volume plane

Julio A. Chirinos[1,2]

[1]University of Pennsylvania Perelman School of Medicine, Hospital of the University of Pennsylvania and Perelman Center for Advanced Medicine, Philadelphia, PA, United States; [2]Ghent University, Ghent, Belgium

Introduction

Detailed phenotyping of ventricular–arterial (VA) coupling and arterial hemodynamics provides important insights into the pathophysiology of left ventricular (LV) energetics, remodeling and fibrosis, systolic and diastolic dysfunction in various disease states.[1–6]


The interactions between the LV and systemic arteries are key determinants of cardiovascular function and encompass a broad and complex set of hemodynamic phenomena. VA coupling, defined narrowly to encompass the determinants of stroke volume and the energetic coupling of the LV and the arterial system, has been most frequently assessed in the pressure–volume plane. This approach is widely taught in formal cardiovascular physiology courses, and provides useful information regarding the operating mechanical efficiency and performance of the VA system when the LV ejection fraction (EF) is frankly abnormal (such as in Heart Failure with Reduced EF, HFrEF). However, analyses in the pressure–volume plane have important limitations and are much less informative in the presence of a normal LV EF, such as in Heart Failure with Preserved EF (HFpEF). More importantly, analyses in the pressure–volume plane do not characterize broader aspects of VA cross-talk, particularly those related to pulsatile arterial load, which are highly clinically relevant both among patients at risk for HF and for patients with established HFrEF or HFpEF. Assessment of arterial load and VA coupling via analysis of time-varying pressure-flow relations and myocardial wall stress (MWS) provides important incremental physiologic information about the cardiovascular system. In particular, the systolic loading sequence (early vs. late systolic load), an important aspect of VA coupling, is neglected by pressure–volume

analyses, and can profoundly impact LV function, remodeling, and progression to heart failure.

This chapter deals with relevant technical and physiologic aspects regarding VA coupling assessments in the pressure–volume plane, and is largely based on previous reviews by the author.[1,3,4] Subsequent chapters in this textbook discuss other informative approaches to characterize VA interactions, including time-varying MWS (Chapter 16) and time-varying pressure-flow analyses (Chapters 17; please also refer to Chapters 1, 3, 11). This chapter does not address pulmonary arterial load and right ventricular–pulmonary vascular interactions, which are discussed in section VI of this textbook (Chapters 55 and 56).

The pressure volume plane

As shown in Fig. 15.1, the pressure volume plane is a two-dimensional plot in which pressure is represented in the vertical axis, whereas volume is represented in the horizontal axis. The LV pressure-volume loop is a plot of instantaneous LV cavity pressure and volume data points throughout a full cardiac cycle. When instantaneous pressure–volume data points are plotted from the beginning of systole to the end of diastole, they proceed in a counterclockwise manner, defining a loop, commonly called the LV pressure–volume loop (Fig. 15.1A). The lower right "corner" of this loop represents end-diastole. Isovolumic LV contraction results in an increase in LV pressure without an increase in LV volume (vertical line). After aortic valve opening, LV volume decreases as the LV ejects blood, which results in a leftward shift of the instantaneous pressure–volume points. At the end of ejection, aortic valve closure is normally followed by a drop in LV pressure at constant volume before mitral valve

FIGURE 15.1 (A) Left ventricular pressure–volume relation in a single beat; (B) end-systolic and end-diastolic pressure–volume relations obtained from a "family" or pressure–volume loops; (C) Instantaneous isochrones during the cardiac cycle (note the assumption of a common volume-axis intercept, V_0 for all isochrones); (D) Time-varying elastance curve, obtained from plotting the slope of the isochrones over time. E, elastance; E_{ES}, end-systolic elastance; ESP, end-systolic pressure; P, pressure; (t), point in time; V_0, volume intercept of the pressure volume relation. *Modified from Chirinos JA. Ventricular-arterial coupling: invasive and non-invasive assessment. **Artery Res**. 2013;7.*

opening (isovolumic relaxation), resulting in a vertical line in the PV loop. After mitral valve opening, diastolic suction continues until the end of relaxation, which is followed by passive filling of the cavity with increasing pressure until end-diastole. Late diastolic passive filling follows a nonlinear pattern in the pressure volume plane.

The LV chamber as a time-varying elastance

The concept of the time-varying LV elastance and its role in LV pump function and myocardial energetics were first formulated by Suga and Sagawa.[7–10] When a family of pressure–volume loops are obtained from the same subject during acute preload or afterload alterations *at a constant inotropic state*, the left upper loop corners (end-systolic pressure–volume points) describe the end-systolic pressure–volume relation (ESPVR). The LV end-systolic elastance (E_{ES}) is quantified as the slope of the ESPVR, which is considered to be linear or quasi-linear in the physiologic range. E_{ES} represents an index of LV end-systolic stiffness and contractility. Fig. 15.1B shows a schematic representation of PV loops from a hypothetical subject, obtained during three beats under different preload

conditions. The points corresponding to end-systole can be connected with a line, the slope of which is E_{ES}. V_0 is the volume-axis intercept of the ESPVR, which represents a purely theoretical volume at zero pressure, assuming a linear ESPVR. E_{ES} is an index of the contractility and systolic stiffness of the LV. As such, it is affected by the inotropic state of the myocardium and in the long-term, by geometric remodeling and biophysical myocardial tissue properties (which in turn depend on stiffness of myocardial cells, fibrosis, and various other factors).[11,12]

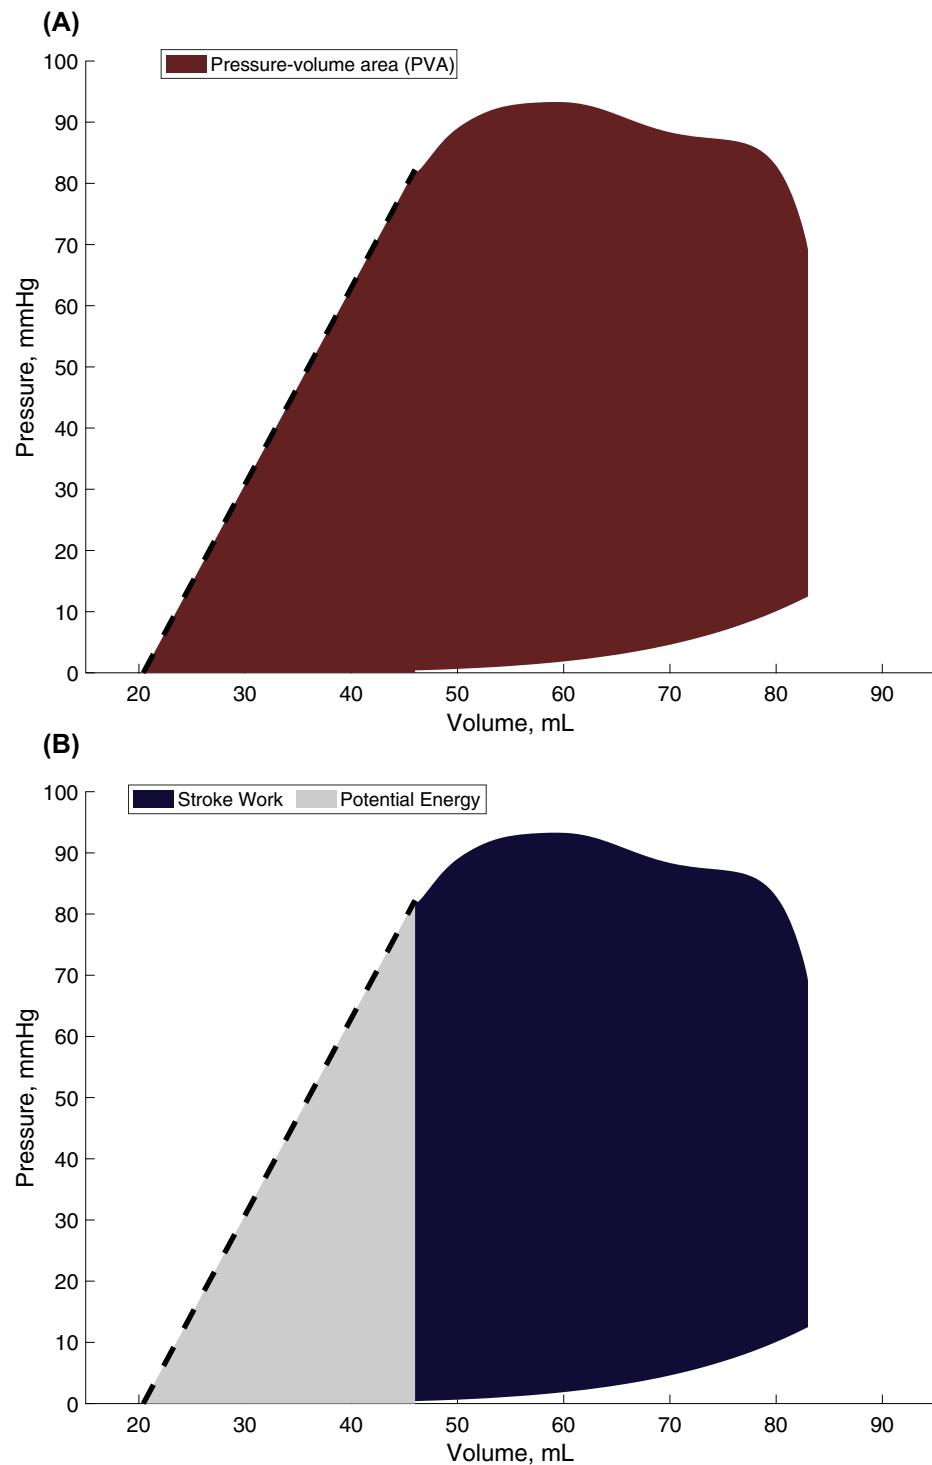
The end-systolic elastance concept is intuitive because it is based on an easily recognizable, well-defined time point in the cardiac cycle. However, it should be noted that a pressure–volume relationship exists at each instant during the cardiac cycle, giving rise to the concept of the "time-varying" elastance (Fig. 15.1C and D). Fig. 15.1C shows a representative family of the LV instantaneous pressure–volume relationships based on joining instantaneous pressure–volume points that occur at similar times during the cardiac cycle in different beats (which are referred to as "isochrones"). The slope of these isochrones increases during systole as the chamber stiffness increases, becoming steepest (i.e., stiffest) toward the end of systole (red arrow),

to then decrease during diastole (green arrow). If the slope of these isochrones is plotted over time (with slope in the vertical axis and time in the horizontal axis), a time-varying elastance [E(t)] curve is obtained (Fig. 15.1D). As will be discussed later, the normalized shape of the time-varying elastance curve tends to be conserved between individuals and disease states, such that the linear E(t) model treats the LV as a spring that stiffens and relaxes along a predictable time course during the cardiac cycle.[9,13] Although the maximal value (i.e., steepest isochrone) of E(t) does not always occur in end-systole (due to inertial influences on pressure and LV outflow before aortic valve closure), in practice this issue is usually ignored and the maximal value of E(t) is considered to be equivalent to E_{ES}.[14]

Key requisites and/or proposed features of the linear E(t) model are:

(**1**) A linear shape of all isochrones (lines connecting equal time points in a P-V diagram of different beats (acquired under different loading conditions);
(**2**) A common intercept of these isochrones with the volume axis (Fig. 15.1C);
(**3**) E(t) is a function of time only, independent of instantaneous and past pressure and volume under a stable contractile state;
(**4**) When normalized for amplitude and time to peak amplitude, the shape of the E(t) curve has a relatively constant shape despite variations in underlying cardiac disease, contractility, loading, and heart rate, particularly during early systole (first 25% to 35% of contraction).

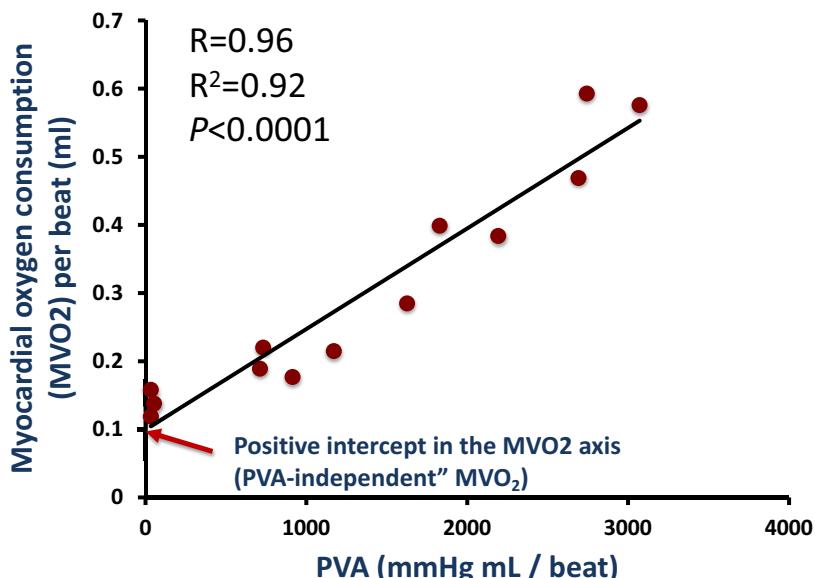
These features and assumptions are important to understand because they are central to the E(t) theory and underlie its main strengths and limitations, which will be discussed later in this chapter. In addition, these features allowed for the development of commonly used methods to approximate E_{ES}, which are based on the derivation of V_0 and E_{ES} from measurements performed in a single heartbeat, without the need for preload alterations.[15,16]

Relationship between the pressure—volume area and LV energetics


For a given beat, the pressure—volume area (PVA) is the area circumscribed by three sides: (1) the end-diastolic pressure—volume relation curve; (2) the end-systolic P-V relation line, and; (3) the systolic portion of the pressure—volume loop trajectory (Fig. 15.2A).[8,17]

The PVA in an ejecting contraction can be divided in two parts: (1) The area enclosed within the pressure—volume loop trajectory, which represents the LV *external work* or *stroke work*; (2) The approximately triangular area enclosed by the linear ESPVR, the left border of a single pressure—volume loop and the end-diastolic pressure—

volume relation (Fig. 15.2B). The latter area has been proposed to represent the end-systolic elastic potential energy built up and stored in the LV wall during systole.

According to the time varying-elastance theory, the PVA represents the total mechanical energy generated by the LV contraction until end-systole. Experiments in excised canine heart preparations cross-circulated with a support dog have shown that, when a single excised heart operates *at a stable contractile state* under various preload and afterload conditions, PVA correlates strongly and linearly with myocardial oxygen consumption (MVO_2) per beat.[8,17,18] (Fig. 15.3). Based on these experiments, it was proposed and it is now widely accepted that the ratio of stroke work (SW) to PVA (the latter considered in this context a surrogate of MVO_2 per beat) represents an index of mechanical efficiency *under specific operating conditions in a given heart*.


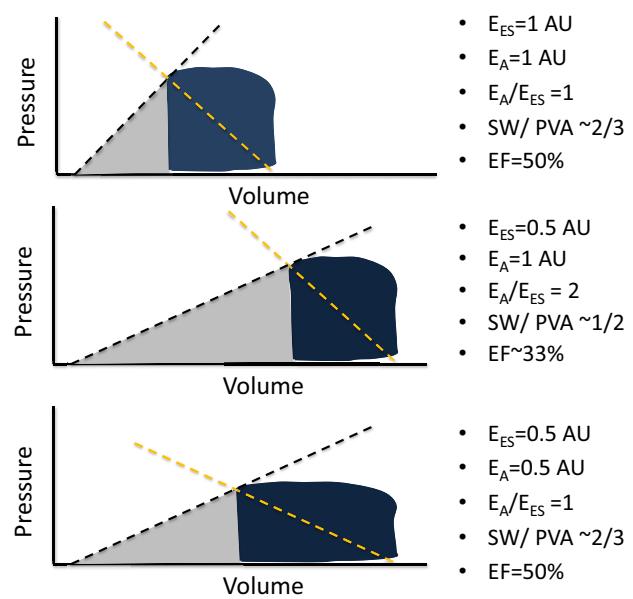
An important point of caution should be considered regarding the use of PVA as a surrogate of MVO_2 in clinical studies, which has become popular due to the relative case of estimating the PVA as opposed to MVO_2 in vivo. Whereas the strong linear relation between PVA and MVO_2 within a given heart is unquestionable, the relationship between measured MVO_2 and PVA within a group of human hearts in vivo is actually much weaker. This can be understood by more closely assessing the nature of the PVA-MVO_2 relation. Within a given heart (Fig. 15.3), the line that relates MVO_2 to PVA demonstrates: (1) A finite slope, which characterizes the efficiency of cardiac chemomechanical conversion in that particular heart in the setting of varying preload and afterload states; (2) A positive intercept with the MVO_2 axis (Fig. 15.3), which can be seen as the "PVA-independent" MVO_2 of that particular heart under that particular inotropic state. The "PVA-independent" MVO_2 is likely related to the energetic costs of excitation—contraction coupling and basal myocardial cellular metabolism. It is important to note that both the slope and particularly, the intercept of this relation are highly variable between different hearts or even in the same heart operating at different inotropic states[19] (for example, positive inotropic interventions generally, but not universally, increase the intercept of the relation and thus shift the entire relation "upward," and vice-versa). Although the variability in the slope and intercept of the PVA-MVO_2 relation appears to be limited between excised hearts operating ex vivo under highly controlled conditions, a more recent reanalysis of invasive human in vivo data[1] reported by Kameyama et al.[19] revealed that the relationship between MVO_2 and PVA is actually much weaker, either at rest ($R^2 = 0.35$) of after phenylephrine administration ($R^2 = 0.16$).[1] This was due to high variability in both the slope and the intercept of the PVA-MVO_2 relation *between* individual hearts, with the slope varying from 2.08 to 3 J/beat, and the MVO_2-axis intercept variability varying

FIGURE 15.2 (A) Representation of the pressure−volume area (PVA) of a single beat; (B) Breakdown of the PVA into stroke (external) work (blue) and potential energy (gray). In both panels, the end-systolic pressure−volume relation is represented by the *black dashed line*. *Modified from Chirinos JA. Ventricular-arterial coupling: invasive and non-invasive assessment.* **Artery Res**. *2013;7.*

over a span greater that an order of magnitude (from 0.04 to 1 J/beat).[19] Therefore, a great deal of caution should be undertaken when using the PVA to assess mechanical efficiency (when the latter is defined as the MVO_2 required to generate a given stroke work), within populations or even within individuals in the setting of interventions that may change the intercept or the slope of the PVA-MVO_2 relation.

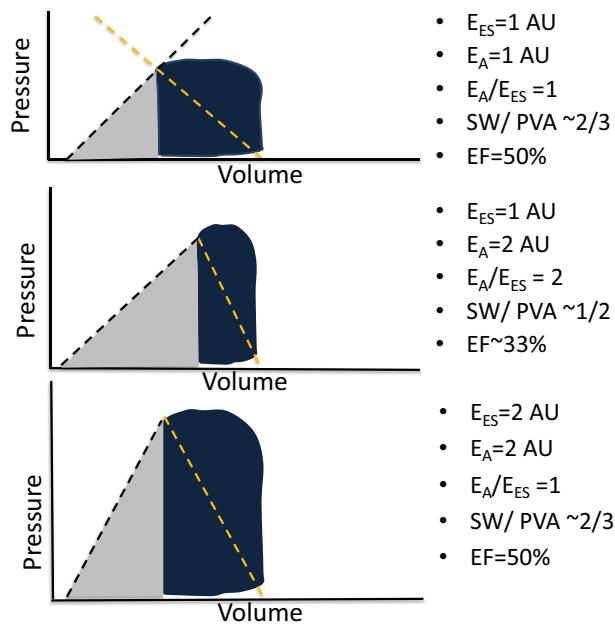
FIGURE 15.3 Panel A shows the strong, linear PVA-MVO$_2$ relation in a single excised heart at a stable contractile state operating under various preload and afterload conditions, as initially reported by Khalafbeigui, Suga and Sagawa. *Modified from Chirinos JA. Ventricular-arterial coupling: invasive and non-invasive assessment.* **Artery Res.** 2013;7.

The concept of effective arterial elastance and assessment of ventricular−arterial coupling in the pressure−volume plane

After the pressure−volume paradigm was developed to characterize LV chamber contractility/stiffness and LV energetics, it was extended to the assessment of VA coupling, primarily to understand the determinants of stroke volume, based on the concept of matching elastances (ventricular and arterial).[20−22] This required expressing the arterial load as a single parameter in units of elastance that could be plotted or readily represented in the pressure− volume plane. The concept was based on the premise that, provided that heart rate, diastolic and systolic duration remain constant, arterial end-systolic pressure changes with stroke volume in a roughly linear fashion (the greater the stroke volume ejected into the arterial system, the greater the generated end-systolic pressure will be). Making multiple simplifying assumptions, Sunagawa et al. derived an equation that relates the slope of this relation to arterial properties and proposed that this slope can be used as a lumped parameter of the impedance that the arterial tree offers to the stroke flow (that is, a lumped parameter of arterial load).[20,23] This slope was called effective arterial elastance (E_A), since it treats the arterial system as an elastic chamber that has a volume elastance (and thus has units of elastance, allowing for an easy comparison to LV end-systolic elastance). With such representation, both the LV and the arterial system are thus treated as elastances and quantified in the same units (change in pressure for a given change in volume; or mm/mL).


Despite the several important limitations of this approach, discussed later in this chapter, some important aspects of VA coupling can indeed be assessed in the pressure−volume plane using the ratio of E_A to LV E_{ES}. Due to geometric considerations, the E_A/E_{ES} ratio roughly correlates with the ratio of stroke work to PVA. Since the stroke work represents the total mechanical energy transferred from the LV to the arterial elastance, whereas the PVA represents the total mechanical energy generated by ventricular contraction (which in turn correlates with MVO$_2$ per beat within a given heart at a specific contractile state as described above), this ratio relates to the operating energetic and mechanical efficiency of the LV in single hearts operating at different loading conditions. It was predicted analytically and shown experimentally in isolated canine heart preparations that the stroke work is maximal when the slopes of LV E_{ES} and E_A are approximately equal to one another (i.e., roughly matched LV and arterial elastances).[23] It should be noted that the E_A/E_{ES} ratio is intimately related to the "effective" EF (ratio of stroke volume to the effective end-diastolic volume, where "effective" end-diastolic volume equals measured end-diastolic volume minus V_0), and this relationship is represented by the following equation: Effective EF = 1/[1+E_A/ E_{ES}]). A value of E_A/E_{ES} equal to 1 implies that the effective EF is ∼50%. The "effective" EF defined in this manner equals the actual LV EF (stroke volume/end-diastolic volume) only when V_0 is zero. Given that V_0 usually has a small positive value, rather than a zero value, this operating state would correspond to actual EF values slightly lower than 50%, which are clearly not the norm in healthy humans, imposing a fundamental problem on the entire paradigm. It was subsequently predicted that, whereas stroke work is maximized when E_A/E_{ES} ∼1, the energetic efficiency (ratio of stroke work to PVA) is

maximized at lower E_A/E_{ES} ratios (which correspond to higher LV EF values).[24] De Tombe et al. studied the dependence of stroke work and mechanical efficiency on the E_A/E_{ES} ratio in isolated blood-perfused canine hearts[25] over a broad range of E_A values. It was shown that on average, stroke work was maximized at $E_A/E_{ES} \sim 0.80$, whereas efficiency was maximal at $E_A/E_{ES} \sim 0.70$. Interestingly, mean E_A/E_{ES} ratios reported in large cohorts of normal humans are $\sim 0.62-0.82$.[26,27] More importantly, De Tombe et al.[25] showed that both stroke work and efficiency were $\geq 90\%$ of their optimal values over a broad range of E_A/E_{ES} ratios (0.3–1.3), which corresponded to a wide range of EFs ($\sim 40-80\%$). The authors concluded that precise optimization of either stroke work of mechanical efficiency is of little consequence in the absence of severe abnormalities in E_{ES} or E_A and that in such circumstances, regulatory systems likely center on control of blood pressure, circulating volume and oxygenation, and can ignore ventricular stroke work or efficiency.[25] In severely abnormal coupling states, however, this homeostasis is lost. In particular, given the close relationship between the E_A/E_{ES} ratio and effective LV EF as described above, markedly "inefficient" E_A/E_{ES} ratios are closely associated with the presence of important reductions in LV EF. In patients with HFrEF, these ratios may rise to as high as 4.0 due to the relative decline in ventricular contractile function (lower E_{ES}) and concomitant rise in E_A. Such coupling is clearly suboptimal from the standpoint of ventricular performance and metabolic efficiency.[1,20,22,25,28,29]

Assessing the consequences of primary LV dysfunction, changes in arterial load and their consequences in the pressure−volume plane


The principles discussed above can be intuitively applied to understand the consequences of primary arterial or myocardial disease on VA coupling. Fig. 15.4 demonstrates some potential consequences of a "primary" reduction in E_{ES}. The top panel represents a normal physiologic state. For simplicity, an E_A/E_{ES} ratio of 1 is assumed to represent "normal" elastance coupling. In this situation, a large proportion ($\sim 2/3$) of the PVA corresponds to stroke work and the LV operates at an effective EF of $\sim 50\%$. The middle panel represents a situation in which, all other factors being equal, E_{ES} has decreased to $\sim 50\%$ of its nominal value and end-diastolic volume has increased, which may occur, for instance, in the setting of a dilated cardiomyopathy. In this situation, a high E_A/E_{ES} ratio is observed, which is accompanied by an increased proportion of the PVA ($\sim 50\%$) corresponding to potential energy, and a reduced proportion (the remaining $\sim 50\%$) corresponding to external work, denoting an unfavorable energetic efficiency state. The high E_A/E_{ES} ratio in this scenario implies that the ventricle operates at an effective EF of $\sim 33\%$, although in

- E_{ES}=1 AU
- E_A=1 AU
- E_A/E_{ES} =1
- SW/ PVA ~2/3
- EF=50%

- E_{ES}=0.5 AU
- E_A=1 AU
- E_A/E_{ES} = 2
- SW/ PVA ~1/2
- EF~33%

- E_{ES}=0.5 AU
- E_A=0.5 AU
- E_A/E_{ES} =1
- SW/ PVA ~2/3
- EF=50%

FIGURE 15.4 Potential consequences of a primary reduction of E_{ES} in energetic aspects of ventricular-arterial coupling. *AU*, arbitrary units. See text for details. *Modified from Chirinos JA. Ventricular-arterial coupling: invasive and non-invasive assessment.* **Artery Res**. *2013;7.*

this particular example, stroke volume is relatively preserved due to the increased end-diastolic volume. The bottom panel corresponds to what may occur with an intervention that, under these circumstances, reduces E_A to 50% of its nominal value. This would theoretically result in normalization of the E_A/E_{ES} ratio, a restoration of the proportions of the PVA corresponding to external work and potential energy, and a normalization of the effective EF. However, this situation is unlikely to be realistic in vivo since the reduction in the intersection point between E_A and E_{ES} in the pressure axis (i.e., end-systolic pressure) is limited by the minimum arterial pressures required for perfusion of peripheral organs. Thus, in hearts with markedly decreased E_{ES}, conditions of near-optimal mechanical efficiency are only achievable at a lower end-systolic pressures than those required to maintain adequate systemic hemodynamics; operating efficiency is thus necessarily decreased relative to the maximally attainable efficiency, in order to maintain acceptable perfusion pressures.

Fig. 15.5 represents the consequences of a "primary" increase in E_A. The top panel again represents a simplified normal physiologic state, with a "normal" E_A/E_{ES} ratio, resulting in a high stroke work relative to PVA and an effective EF of $\sim 50\%$. The middle panel represents a situation in which E_A has increased to twice its nominal value (middle panel), without a change in E_{ES}. A high E_A/E_{ES} ratio is again observed, which is accompanied by an increased proportion of the PVA ($\sim 50\%$) corresponding to potential energy and a reduced proportion (the remaining

- E_{ES}=1 AU
- E_A=1 AU
- E_A/E_{ES} =1
- SW/ PVA ~2/3
- EF=50%

- E_{ES}=1 AU
- E_A=2 AU
- E_A/E_{ES} = 2
- SW/ PVA ~1/2
- EF~33%

- E_{ES}=2 AU
- E_A=2 AU
- E_A/E_{ES} =1
- SW/ PVA ~2/3
- EF=50%

FIGURE 15.5 Potential consequences of a primary increase in E_A on ventricular–arterial coupling. *AU*, arbitrary units. See text for details. *Modified from Chirinos JA. Ventricular-arterial coupling: invasive and non-invasive assessment.* **Artery Res**. *2013;7.*

~50%) corresponding to external work, denoting an unfavorable energetic efficiency state. In this situation, the LV operates at an effective EF of ~33% and systemic arterial pressure is increased. The bottom panel represents an alternative (and more common) situation, in which, in response to the increased E_A, E_{ES} has increased (i.e., the LV demonstrates increased systolic stiffness, due to increased contractility, wall thickness or both). In this situation, the E_A/E_{ES} ratio is normalized, with restoration of the proportions of the PVA corresponding to external work and potential energy and a normalization of the effective EF. However, despite an apparently "favorable" coupling between E_A and E_{ES}, this can be accompanied by systolic hypertension, impaired LV chamber contractile reserve and high sensitivity of blood pressure to preload, thus resulting in blood pressure lability.[28,30] These features tend to be present in older adults with systolic hypertension.

Strengths and limitations of the pressure–volume plane

Analyses of LV and arterial interactions in the pressure–volume plane are valuable and have facilitated our understanding of various physiologic and pathophysiologic states. This simplified approach to VA coupling enables an intuitive evaluation of the specific contributions of ventricular end-systolic properties and some arterial system parameters as determinants of stroke volume and its relation to the overall mechanical energetic cost to the LV (Table 15.1).

Advantages of the pressure–volume plane (Table 15.2) include its well-established relatively intuitive framework, with extensive published data and its ability to represent the LV and arterial systems in the same plane, thus characterizing important mechanical indices that have physiologic relevance from an energetic standpoint. Moreover, although E_{ES} is ideally assessed invasively using data from a family of pressure–volume loops obtained during an acute preload or afterload alterations, "single-beat" methods have also been developed and have undergone limited validation,[15,16] allowing for noninvasive E_{ES} estimations using simple echocardiographic measurements.

Despite its advantages, the pressure–volume approach also has serious limitations (Table 15.2). In particular, E_A has critical disadvantages as an index of arterial load. E_A has been shown to be highly sensitive to heart rate (a cardiac, rather than a ventricular property) and is thus not a pure index of arterial properties.[31,32] More importantly, the commonly made assumption that E_A is a lumped parameter of resistive and pulsatile arterial load, is factually incorrect.[1,31,33,34] Despite its name, E_A is not a true elastance (i.e., the inverse of a compliance) and is mostly dependent on vascular resistance (a microvascular, rather than a conduit artery property),[31,32] while being relatively insensitive to changes in pulsatile arterial load.[31,32] Its strong dependence on resistance is readily explained by the fact that arterial pressure does not increase from zero to end-systolic pressure (as represented in the PV plane) when the stroke volume is injected into the arterial tree, because arterial pressure hovers around a nonzero value (mean arterial pressure, which is in turn entirely determined by peripheral resistance, heart rate and stroke volume).

The almost exclusive dependence of E_A on resistance is a critical limitation of the former, given the importance of pulsatile hemodynamics in the arterial tree. Due to the pulsatile nature of the LV as a pump, arterial load is time-varying, complex, and an attempt to represent it with a single number is unrealistic.[1,35] In fact, E_A has been shown to be minimally sensitive to changes in arterial compliance or to various specific parameters of pulsatile arterial load within physiologically/clinically relevant ranges.[1,31,33,34] Moreover, since the E_A/E_{ES} ratio does not account for time-varying phenomena during ejection,[1] it intrinsically neglects the LV loading sequence (late vs. early systolic load), which is an important determinant of maladaptive remodeling, hypertrophy, diastolic dysfunction, and heart failure risk.[36–43] In particular, E_A was derived using major simplifying assumptions, among which was a "square-shaped" pressure curve in systole, with its upper side corresponding to end-systolic pressure, thus ignoring the contribution of pulsatile phenomena to the contour of the arterial pressure curve above end-systolic pressure. Sunagawa et al. appropriately raised caution regarding the fact that the contribution of these phenomena can become

TABLE 15.1 Key physiologic parameters of in the pressure—volume plane.

Parameter	Definition and interpretation
LV end-systolic elastance (E_{ES})	Slope of the end-systolic pressure—volume relation (ESPVR), obtained by joining end-systolic pressure—volume points from a "family" of left ventricular (LV) pressure—volume loops obtained from the same subject during acute preload or afterload alterations at a constant inotropic state. It can be estimated using single-beat noninvasive methods. Determined by LV contractility and stiffness.
Effective arterial "elastance" (E_A)	Ratio of end-systolic pressure/stroke volume. It is not a true elastance (i.e., inverse of a compliance). It correlates poorly with arterial compliance, but is a quasi-perfect function of the product of systemic vascular resistance (a microvascular property) and heart rate (a cardiac property). Does not capture conduit artery properties, such as stiffness or pulsatile load and does not correlate with large artery stiffness.
Stroke work (SW)	The area enclosed within the LV pressure—volume loop trajectory in a cardiac cycle. Represents the external work provided by the LV to the systemic circulation.
Potential energy (PE)	Approximately triangular area enclosed by the linear end-systolic pressure—volume relation, the left border of a single pressure—volume loop, and the end-diastolic pressure—volume relation. Proposed to represent the end-systolic elastic potential energy built up and stored in the LV wall during systole.
Pressure—volume area (PVA)	Sum of stroke work and potential energy. A surrogate of the total mechanical energy generated by the LV contraction until end-systole. In a single heart a stable contractile state under, PVA correlates strongly and linearly with myocardial oxygen consumption (MVO_2) per beat as preload and afterload varies. However, this correlation does not hold under different contractile states or between different hearts.
SW/PVA	Ratio of external work to PVA, the latter considered in this context a surrogate of MVO_2 per beat. Therefore, this ratio is considered an index of the mechanical energetic efficiency at a given contractile state *specific operating conditions in a given heart.*

important, with a relatively large error in this coupling model when the area under the systolic area of the curve becomes a large fraction of the overall pressure curve (such as occurs with fast heart rates) or when the pulsatile phenomena lead to an increase in the area under the pressure curve above end-systolic pressure, which occurs in the presence of prominent wave reflections.[20,39] The LV pressure curve also markedly deviates from a square-shaped curve in systole in the presence of significant aortic stenosis, which E_A fails to account for (since the transvalvular aortic gradient in end-systole is close to zero). Furthermore, the derivation of E_A as an index of arterial load assumed a constant ejection time, regardless of the loading conditions, whereas it is well known that ejection time can vary with afterload.[39] Even is these simplifications are overseen, the derivation of E_A was performed using a three-element Windkessel model, which does not account for wave reflection.[37,39,44—47]

In a more recent study that aimed to assess the relationship between E_A and pulsatile arterial load,[34] time-resolved central pressure and flow measurements were used to E_A and detailed various parameters of pulsatile arterial load: (1) In a large community-based sample of

middle-aged adults; (2) In a diverse clinical population of older adults; and (3) In response to the handgrip maneuver, a physiologic intervention known to induce pronounced changes in pulsatile arterial load.[48] This series of studies consistently demonstrated that E_A is a quasi-perfect function of the product of systemic vascular resistance and heart rate, with weak, inconsistent and in some cases, erratic/paradoxical relationships with proper measures of pulsatile load, such as aortic root characteristic impedance (Zc), measures of wave reflections, and total arterial compliance. These findings are in full agreement with previous modeling studies,[31] and demonstrate that E_A depends almost entirely on SVR and heart rate, and has very poor sensitivity to the human pathophysiological ranges of pulsatile afterload observed in vivo. Finally, there was no correlation between E_A and carotid-femoral pulse wave velocity, the current reference method to quantify large artery stiffness.[49,50] Current American Heart Association guidelines specifically recommend against utilizing E_A as a measure of arterial stiffness.[49] Given the considerations above, it is incorrect to interpret E_A as an index of arterial "stiffening" or, by extension, to equate a parallel increase in E_A and E_{ES} as a state of "VA stiffening."

TABLE 15.2 Advantages and disadvantages of assessments of ventricular-arterial coupling in the pressure—volume plane.

Advantages

- Widely used, well-established framework
- Extensive published animal and human data
- Relatively simple and intuitive.
- Quantifies left ventricular (LV) chamber contractility/stiffness and arterial load in the same units
- Characterizes mechanical indices that relate to energetics:
  - External mechanical energy
  - Potential energy
  - Energetic efficiency
- Allows us to understand consequences of abnormalities in E_A and E_{ES} on stroke volume, ejection fraction, pressure lability, and some aspects of cardiovascular reserve during exercise.
- Can be assessed noninvasively

Disadvantages

Disadvantages of E_A:
- Is not a pure index of arterial load because it is prominently influenced by heart rate (a cardiac property)
- It is not a true elastance
- Correlates poorly with arterial compliance
- Does not account for time-varying phenomena and neglects the influence of wave transmission and reflections
- Is a quasi-perfect function of resistance (a microvascular property) and heart rate
- Bears no relationship to validated indices of large artery stiffness (i.e., carotid-femoral pulse wave velocity)
- Neglects aortic valvular load in the presence of aortic valve stenosis
- In contrast to metrics of pulsatile arterial load, does not relate to heart failure risk

Disadvantages of E_{ES}:
- Nonlinearity of the end-systolic pressure—volume relation
- E_{ES} demonstrates afterload and some preload dependency
- It does not assess myocardial properties

Disadvantages in the assessment of ventricular—arterial coupling:
- E_A/E_{ES} does not characterize (and indeed neglects) the LV loading sequence
- E_A/E_{ES} and the "mechanical" energetic optimization in the PV plane has unclear relevance in the absence of a frankly reduced ejection fraction, thus providing little unique insights in this situation
- Stroke work does not dissect the importance of systolic pressure versus flow output
- Considers stroke work the only "useful" energy (neglects the value of potential energy deposition in the myocardium that favors diastolic suction)
- The entire paradigm centers of stroke work as "the" variable to be optimized. Yet, stroke work is a limited index of performance and optimization of other factors likely supersede optimization of stroke work in various pathophysiologic situations
- There is a poor correlation between myocardial O_2 consumption (MVO_2) and the pressure—volume area (PVA) in a given population of patients (i.e., between individuals)

To the degree that E_A does not properly characterize arterial pulsatile load, the E_A/E_{ES} ratio is a limited index of VA coupling, even if the important limitations of this approach to assess LV energetics are ignored. This issue is particularly problematic in patients with or at risk for HFpEF, because pulsatile load is highly relevant for VA interactions in these populations. VA coupling encompasses multiple different physiologic aspects that require characterization beyond the pressure—volume plane. These considerations are not purely theoretical, but translate into important limitations to the application of this approach in clinical studies. For example, Goto et al. demonstrated that measures of wave reflection, but not E_A or peripheral vascular resistance, were significantly correlated with the invasively measured time constant of isovolumic relaxation, the gold standard index of diastolic relaxation.[51] Similarly, a recent study demonstrated that E_A did not predict incident HF in the Multiethnic Study of Atherosclerosis (MESA) cohort,[52] whereas indices of reflection magnitude and late systolic load were strong predictors of incident HF in this cohort.[46,53] Finally, a single dose of inorganic nitrate, which has been recently shown to improve aerobic capacity in patients with HFpEF, did not reduce E_A, but substantially reduced wave reflections,[54] and this reduction significantly correlated with the degree of improvement in peak VO_2 in these patients.[55] These findings are consistent with the need to time-resolve arterial load in order to gain clinically relevant insights into VA coupling and the effects of pharmacologic interventions.

Shortcomings of E_{ES} should also be taken into account when interpreting the results of published studies that

applied the pressure–volume paradigm. When subjected to rigorous examination, some fundamental principles of the LV E(t) theory do not hold in vivo. It has been shown that the ESPVR is nonlinear and the degree of nonlinearity depends upon the inotropic state.[56–60] The presence of a V_0 common to all isochrones, a key assumption of the time-varying elastance concept, has also been disproven.[57,61–63] It has been shown that the peak value of the ESPVR decreases with an increase in LV size (preload), even if myocardial contractility is unchanged, which can be accounted for by the lower generated pressure corresponding to a given wall stress in the presence of greater cavity volumes.[64] Furthermore, the ESPVR demonstrates afterload dependency[65,66] and has been shown to be greater on ejecting beats than on isovolumic beats, which is accompanied by a reduced slope of the MVO_2-PVA relation, indicating an increase in metabolic efficiency in ejecting versus nonejecting beats despite an increase in E_{ES}.[56] Both of these phenomena may be related, at least in part, to the greater amount of pressure generation, at identical levels of wall stress, made possible by a greater late systolic wall volume/cavity volume ratio during ejecting beats as opposed to isovolumic beats, as would be predicted by derivations of Laplace's law (see Chapter 16 for a more comprehensive discussion of time-resolved MWS). Another important limitation of the E(t) theory is that it assumes a load-invariant time course of contraction, whereas in reality, the time-course of contraction is load-dependent.[67] Indeed, a fundamental assumption of E_{ES} is that the end-systolic point is reached independently of instantaneous and past pressure and volume.[7–10] This intrinsically neglects the systolic loading sequence, an important determinant of LV dysfunction, LV hypertrophy and failure.[38,40,41,68–75] An additional important limitation is of this approach is that, to the degree that, as shown by De Tombe et al.,[25] nonsevere abnormalities in E_A/E_{ES} are of little consequence to optimization of stroke work and mechanical efficiency, the value of E_{ES}/E_A as a relevant coupling index in the absence of severe disease may be questioned, since it is precisely these energetic aspects of VA coupling that E_A/E_{ES} is meant to characterize. However, E_{ES}/E_A does provide insight into the energetic aspects of VA coupling in the presence of important systolic dysfunction and it is in this situation where it may prove particularly useful in clinical populations. Another important consideration is that, whereas the pressure–volume plane offers insights regarding the energetic efficiency of the system (when the latter is defined as the stroke work generated for any given MVO_2), they are much less reliable to compare the energetic efficiency of the LV-arterial system between individuals or disease populations because, as discussed above, the function that relates the PVA to MVO_2 is highly variable between individuals.[1,8,17,18,76] This results in weak relationships between the PVA and

MVO_2 (and by extension, between PVA-derived efficiency the true underlying efficiency) between individuals. The weak correlation between the PVA and MVO_2 between individuals is in sharp contrast with peak MWS (Chapter 16), which can be evaluated noninvasively and in a large human study, was shown to correlate strongly with MVO_2.[77]

Another weakness of the pressure–volume paradigm is that the use of the stroke work to PVA ratio as an index of energetic efficiency considers the stroke work as the only "useful" energy, thus undermining the value of energy deposition in the myocardium, which favors diastolic suction. An additional limitation of energetic optimization assessed in the pressure–volume plane is that stroke work does not directly dissect the physiologic importance of the flow versus pressure generation. A high stroke volume at normal levels of systemic arterial pressure and a normal stroke volume and high levels of systemic arterial pressure, may thus be characterized by identical stroke work values, despite their vastly different clinical and pathophysiologic implications. Indeed, the latter point leads to more fundamental questions about the role of regulatory processes in cardiovascular status as they relate to the pressure–volume plane. It is likely that the normal cardiovascular control system uses a unique combination of ventricular output, systemic perfusion pressure, heart rate, arterial flow, and impedance patterns, which optimize ventricular performance, energetics, and/or various other cellular processes. However, the pressure–volume scheme treats external stroke work (and its relation to the PVA) as the central coupling variable to be optimized. This does not intrinsically consider the vast differences between different pressure and flow states that may lead to identical stroke work values nor does it address many other cellular of mechanical processes that may require primary optimization on both the ventricle and the arteries. Indeed, Sunagawa et al. pointed out in their early reports from isolated heart preparation studies[20] that their criteria for coupling optimization may not be valid for normally functioning animals or various pathologic states and raised the question of whether the maximum external stroke work is really the crucial criterion that an organism uses for optimizing the operation of the cardiovascular system in physiological circumstances, which likely depends on specific pathophysiologic conditions.

Conclusions

Afterload and VA interactions are important and that they can be characterized with noninvasive techniques. Assessments of afterload and VA interactions offer the potential for a greater mechanistic understanding of normal physiology, early stages of heart and vascular disease, and established heart disease at various clinical stages,

TABLE 15.3 Comparison of the pressure—volume plane versus analyses of pressure-flow relations and myocardial wall stress to assess various aspects of arterial load and ventricular—arterial coupling.

	Pressure—volume plane	Pressure-flow relations and myocardial wall stress
Able to assess left ventricular (LV) pump function in a load-independent manner	Yes	Potentially, but requires further development and validation
Can assess the energetic efficiency of a single heart at various loading conditions	Yes	Yes
Reliable to compare the energetic efficiency between individuals or disease populations	No, although often utilized in this context	Yes
Characterizes and quantifies pulsatile arterial load	No	Yes
Accounts for the time-varying nature of afterload and the LV loading sequence (early vs. late systolic load)	No	Yes
Relationship to diastolic dysfunction	+/−	++
Independently predictive of heart failure risk in the general population	No	Yes
Detects abnormalities in heart failure with preserved ejection fraction compared to age-matched hypertensive controls	No or inconsistently	Yes
Equally useful for heart failure with preserved and heart failure with reduced ejection fraction	No	Likely, although further clinical studies are required
Reliable in the presence of segmental wall motion abnormalities	Yes	Pressure-flow relations are reliable. Myocardial wall stress estimations are unreliable in this situation.
Able to characterize combined arterial and valvular load in aortic stenosis	Not intrinsically, although the paradigm can be partially adapted (see Chapter 37)	Yes, as long as the transvalvular pressure gradient is measured (see Chapter 16)

particularly the continuum of LV remodeling associated with epidemic conditions such as hypertension and obesity and its progression to heart failure. Given the importance of LV afterload and its impact on the heart, afterload and impaired VA interactions should be carefully considered or ruled out as potential mediators or confounders in a wide variety of observed relationships or therapeutic and adverse effects of interventions. The pressure—volume plane remains the reference standard for assessments of LV chamber pump function, and its extension for the assessment of VA coupling is useful as long as the paradigm is adequately interpreted and its significant limitations taken into account. It should be recognized that VA coupling is a broad term that encompasses different physiologic aspects, many of which are not characterized (or are frankly mischaracterized) in the pressure—volume plane. Analyses of VA coupling should thus be complemented by more specific analyses of arterial and myocardial load that can provide additional physiologic information in various disease states, as discussed in the two subsequent chapters. In

particular, analyses of time-resolved proximal aortic pressure-flow relations and time-resolved MWS offer significant advantages to characterize clinically relevant aspects of VA interactions, as shown in Table 15.3 and developed in more detail in Chapters 16 and 17. Despite the apparent complexity of these analyses, they can be readily implemented with contemporary software from signals that can be acquired quickly and noninvasively at the bedside.

Chapter 16

Myocardial wall stress and the systolic loading sequence

Julio A. Chirinos[1,2]

[1]University of Pennsylvania Perelman School of Medicine, Hospital of the University of Pennsylvania and Perelman Center for Advanced Medicine, Philadelphia, PA, United States; [2]Ghent University, Ghent, Belgium

Introduction

Afterload is an important determinant of myocardial function. At the myocardial level, afterload is often expressed as myocardial wall stress (MWS). MWS is directly related to left ventricular (LV) cavity pressure and cavity size and inversely related to wall thickness. Instantaneous MWS during ejection is determined by complex interactions between myocardial contractile elements, instantaneous LV geometry and the time-varying hydraulic load imposed by the arterial tree.[1] All key determinants of MWS, including wall thickness, cavity size, and ventricular pressure (which in turn depends on arterial properties for any given flow delivered against the input impedance of the systemic circulation) exhibit marked variations during ejection. Therefore, although LV/aortic pressure during systole is related to MWS, LV geometric changes that occur during ejection determine profound changes in the relationship between LV/aortic pressure and MWS.[1] Consequently, time-varying MWS estimations need to account for both time-varying pressure and time-varying geometry and are poorly represented by any single time-point measurement (such as end-systolic wall stress, which has been frequently utilized in the literature).

Late systolic load represents an increasingly recognized mechanistic abnormality that can contribute to LV maladaptive remodeling, LV dysfunction, and impaired systolic–diastolic coupling in experimental models. Similarly, multiple studies demonstrate a relationship between late systolic myocardial load and/or arterial wave reflections and LV remodeling, myocardial fibrosis, reduced LV diastolic relaxation, LV and left atrial (LA) dysfunction, and an increased risk of HF in humans. This chapter discusses basic principles regarding time-varying MWS,

the utilization of time-resolved MWS to assess the myocardial systolic loading sequence, and the adverse consequences of late systolic load on the LV.

The chapter is largely based on previous reviews by the author.[2–4] Chapter 15 deals with the pressure–volume plane, whereas Chapter 17 deals with the assessment of ventricular–arterial interactions using time-varying pressure–flow analyses (also refer to Chapters 1, 3, and 11). This chapter does not address right ventricular wall stress, pulmonary arterial load or right ventricular–pulmonary vascular interactions, which are discussed in section VI of this textbook (Chapters 55 and 56).

Myocardial afterload versus ventricular afterload

Although the terms "myocardial afterload" and "ventricular afterload" are often used interchangeably, the relationship between LV and myocardial afterload is influenced by the time-varying LV geometry during ejection, which in turn affects the MWS for any given LV chamber pressure. LV afterload is the hydraulic load imposed by the systemic circulation (aortic input impedance), which depends on the pressure required to generate flow (ejection) into the proximal aorta. In contrast, myocardial afterload is defined as the MWS required to generate fiber shortening. MWS thus reflects the time-varying mechanical load experienced by the contractile elements in the myocardium and the amount of force and work that the myocardial fibers generate during a contraction.

Although MWS is clearly not equivalent to LV afterload, there is a close interaction between the two. As mentioned above, MWS is intimately related to instantaneous LV geometry (cavity size, wall thickness) and LV cavity pressure.

LV afterload is determined by vascular properties (i.e., aortic input impedance; see Chapters 1, 3 and 17) which govern aortic root pressure−flow relations. In the absence of LV outflow tract obstruction or aortic valve stenosis, other than relatively small differences due to acceleration and deceleration of blood in early and late systole, respectively, aortic pressure and LV cavity pressure during ejection are almost identical. Given that, for a given end-diastolic geometry, instantaneous LV geometry during ejection depends on the amount of ejected volume, whereas aortic (and thus LV cavity) pressure depends on aortic input impedance, MWS and aortic input impedance are intimately related. For instance, arterial wave reflections arriving at the LV prematurely (i.e., in mid-to-late systole, rather than diastole), can profoundly impact time-varying MWS (increasing mid-to-late systolic MWS relative to early systolic MWS).

Despite the logical relationship between LV afterload and MWS, end-diastolic LV geometry (wall and cavity volumes) and the LV contraction pattern have an independent impact on MWS, due to their influence on ejection-phase LV geometry. Given the important role of adaptive and maladaptive LV geometric remodeling in health and disease, a careful study of MWS holds promise to better understand myocardial ventricular−arterial coupling in various conditions.

Quantification of myocardial wall stress

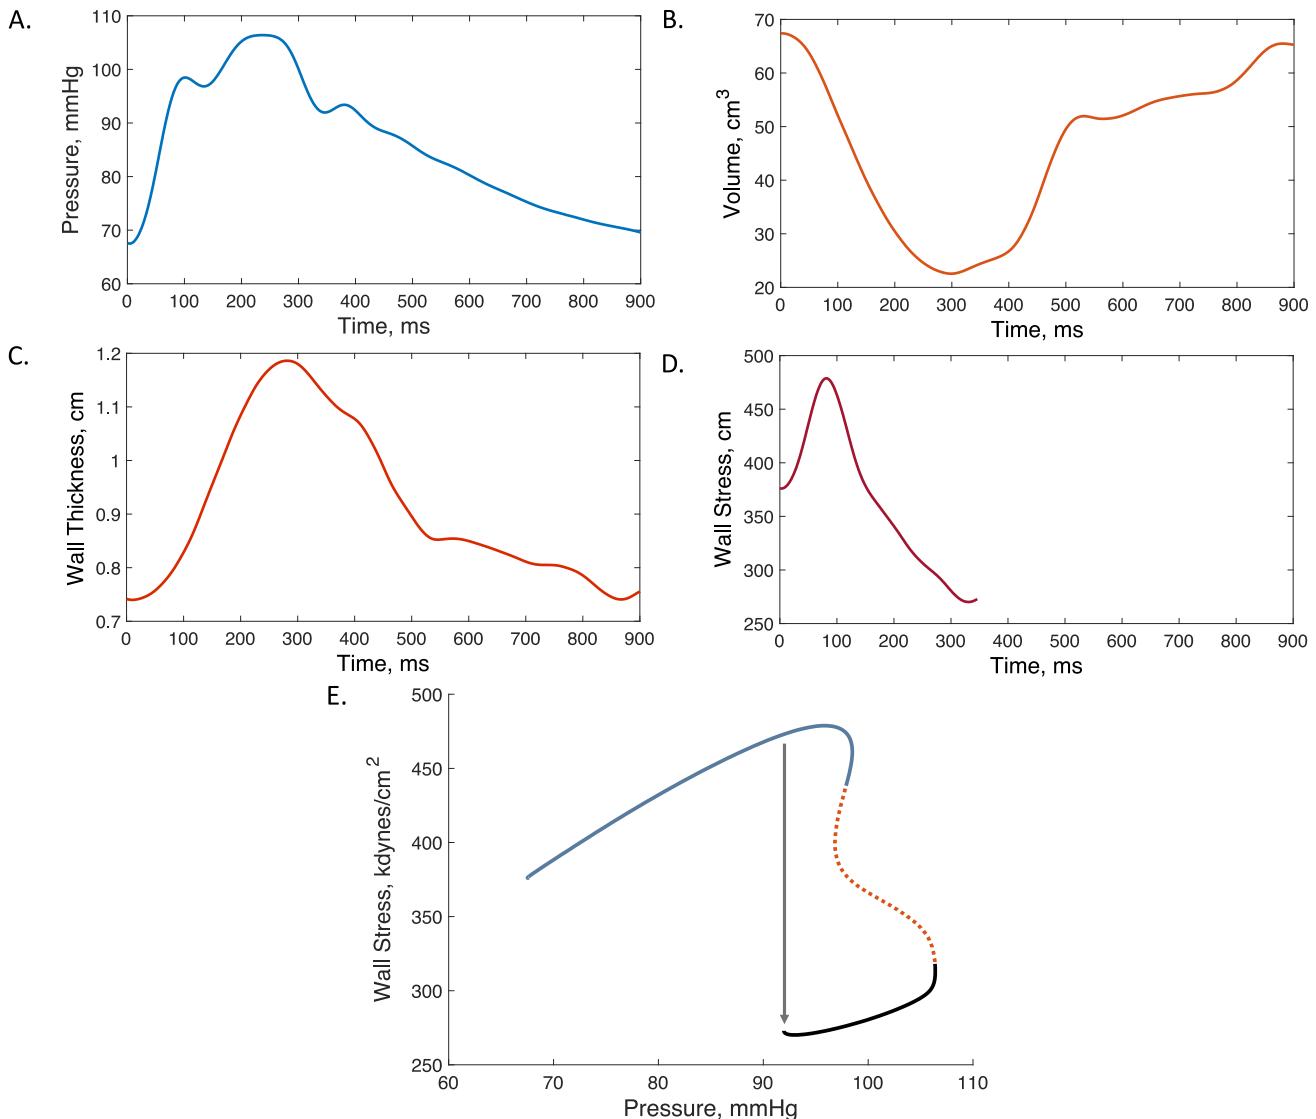
The precise quantification of LV MWS is challenging and in general, MWS in vivo can only be approximated, even in the presence of normal ventricular geometry. In ventricles with more complex geometry (such as the right ventricle, and LVs with regional wall motion abnormalities), the assessment of MWS is even more challenging and often uncertain. For axisymmetric ventricles, a relatively simple formula for the computation of average LV ejection-phase MWS was developed by Arts et al.[5] and can be readily applied using noninvasive measurements of central pressure and LV geometry[3,6,7] (Fig. 16.1). This method does not neglect radially directed forces or forces generated within the wall that oppose fiber shortening, which vary significantly with cavity and wall thickness and can interfere with direct comparisons of myocardial fiber stress at different times during ejection. The formula is based on LV cavity volume (V_{LV}), LV wall volume (V_W), and pressure:

$$Fiber\ \sigma = \frac{P}{\frac{1}{3}\ln\left(1 + \frac{V_W}{V_{LV}}\right)}$$

where P = pressure, ln = natural logarithm, V_W = wall volume and V_{LV} = ventricular cavity volume (computed at each time point).

Time-resolved LV cavity volumes can be measured throughout ejection using various methods, including:

(1) 2D-echocardiography with myocardial speckle tracking, combining apical long axis and parasternal short axis views, and with the application of the area-length method for LV volumes[1,8,9]; this method is generally valid in the absence of important distortions in LV geometry.
(2) 3D-echocardiography, which although widely available, remains challenging due to myocardial endocardial dropout from apical views;
(3) Cardiac MRI cine steady-state free precession (SSFP) images, in which each phase of ejection is carefully segmented.
(4) A practical method to obtain the time-resolved LV cavity volume curve throughout ejection relies on the integration of the proximal aortic systolic flow waveform (Figs. 16.2 and 16.3).[6] The time-integral of the systolic flow waveform represents the cumulative ejected volume at each time point. To improve the correspondence with geometric stroke volume, the ejection-phase flow time-integral can be calibrated to measured stroke volume (computed as end-diastolic minus end-systolic LV cavity volume measured with cardiac imaging). This calibrated flow-time integral can in turn be used to compute the cumulative ejected volume from the onset of ejection to each time point during ejection. The latter value is subtracted from the measured end-diastolic LV cavity volume to compute the time-resolved LV cavity volume at various times points during ejection. LV wall volume can be assumed to be constant throughout ejection,[6,10] and therefore does not need to be measured in every cardiac phase.

Central pressure can be readily measured with arterial tonometry, as discussed in detail in Chapter 2. The pressure and flow waveforms can be aligned to synchronize pressure and geometric measurements at each time point in ejection, and the Arts formula can be readily applied to obtain a time-resolved MWS curve (Fig. 16.3).


The method above assumes that LV pressure and aortic pressure are similar during ejection. This is true only in the absence of aortic stenosis or LV outflow tract obstruction. Interestingly, in the presence of aortic valve stenosis, the time-resolved transvalvular pressure gradient can be derived with continuous wave Doppler acquisitions to measure transvalvular flow velocities and with the use of the modified Bernoulli equation:

$$\Delta P = 4\left(V_2^2 - V_1^2\right)$$

where V_1 is velocity preorifice and V_2 is velocity postorifice. When proximal velocities are low (such as aortic valvular stenosis in the absence of LV outflow tract obstruction), they can be neglected and the equation can be simplified to:

$$\Delta P = 4V^2$$

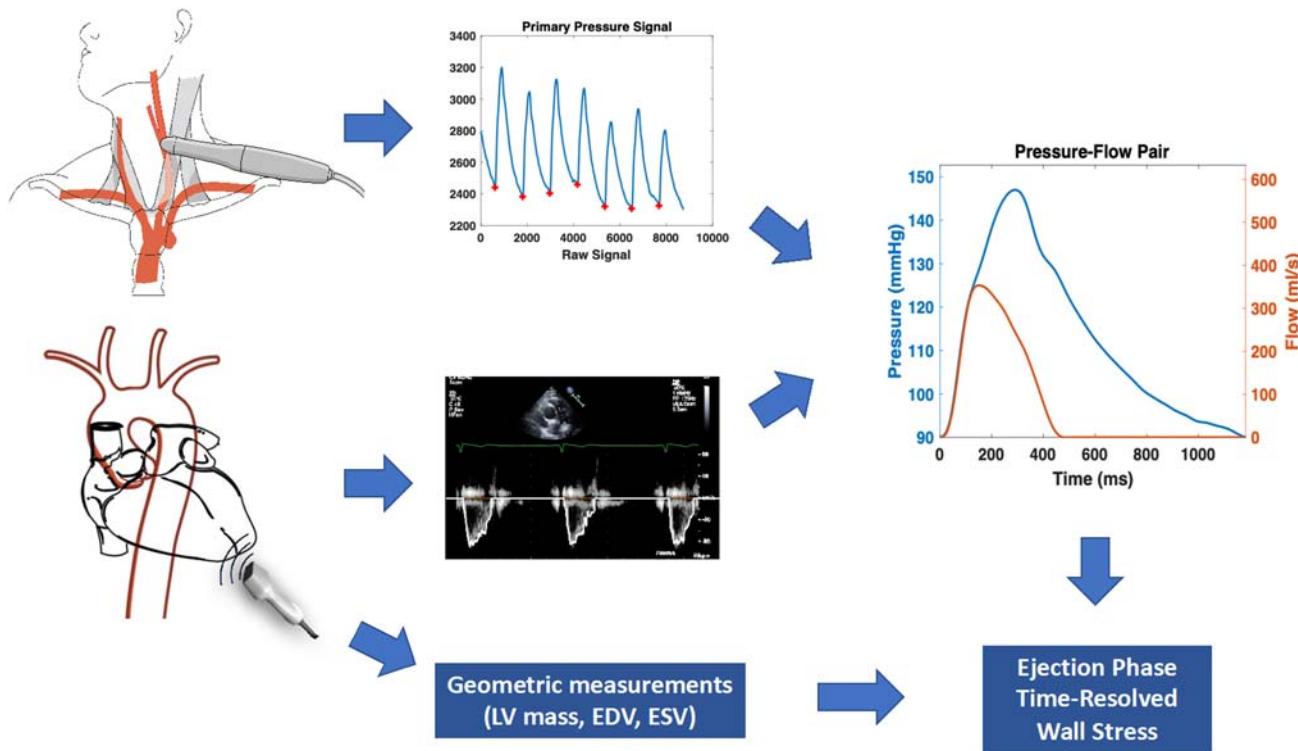
In aortic valvular stenosis, the derived transvalvular pressure gradient can be added to the aortic pressure at each point in time during ejection to derive the LV instantaneous pressure, allowing for a noninvasive approximation of


FIGURE 16.1   Example of assessments of time-resolved ejection-phase myocardial wall stress. Arterial tonometry can provide a time-resolved pressure curve (A), whereas speckle-tracking echocardiography and other imaging techniques can provide time-resolved LV geometry (B: cavity volume; C: wall thickness). One can thus compute myocardial wall stress at each time point and generate a time-resolved stress curve (D). Normally, brisk force development and fiber shortening occur in early systole, resulting in an early peak in MWS and shortening rate, followed by continued LV ejection and a dynamic reconfiguration of LV geometry that results in a mid-systolic reduction in MWS relative to LV pressure. Notice the early systolic MWS peak followed by a rapid decline in wall stress despite rising pressure. Panel E shows a pressure−stress plot, demonstrating a mid-systolic shift of the pressure−stress relation (*gray arrow*) which favors lower stress values in late systole despite rising pressure. This mechanism tends to protect the myocardium against excessive load in mid-to-late systole (a period of increased vulnerability), but may be overcome by pronounced wave reflections during this period and/or intrinsic myocardial dysfunction leading to an abnormal ejection pattern. The mid-systolic reduction in MWS, relative to pressure, is impaired in the presence of a lower LV EF (even within the "normal" EF range), concentric LV remodeling or hypertrophy, and/or reduced early systolic ejection (despite a preserved overall EF).

time-resolved LV pressure (Fig. 16.4), in turn allowing for assessments of time-resolved MWS (Fig. 16.5).

The time course of ejection-phase MW

It is important to recognize the advantages of assessing time-resolved ejection-phase MWS as opposed to end-systolic wall MWS. The latter has been widely utilized in clinical studies due to the relative ease of identification of end-systole with echocardiography, but is not representative

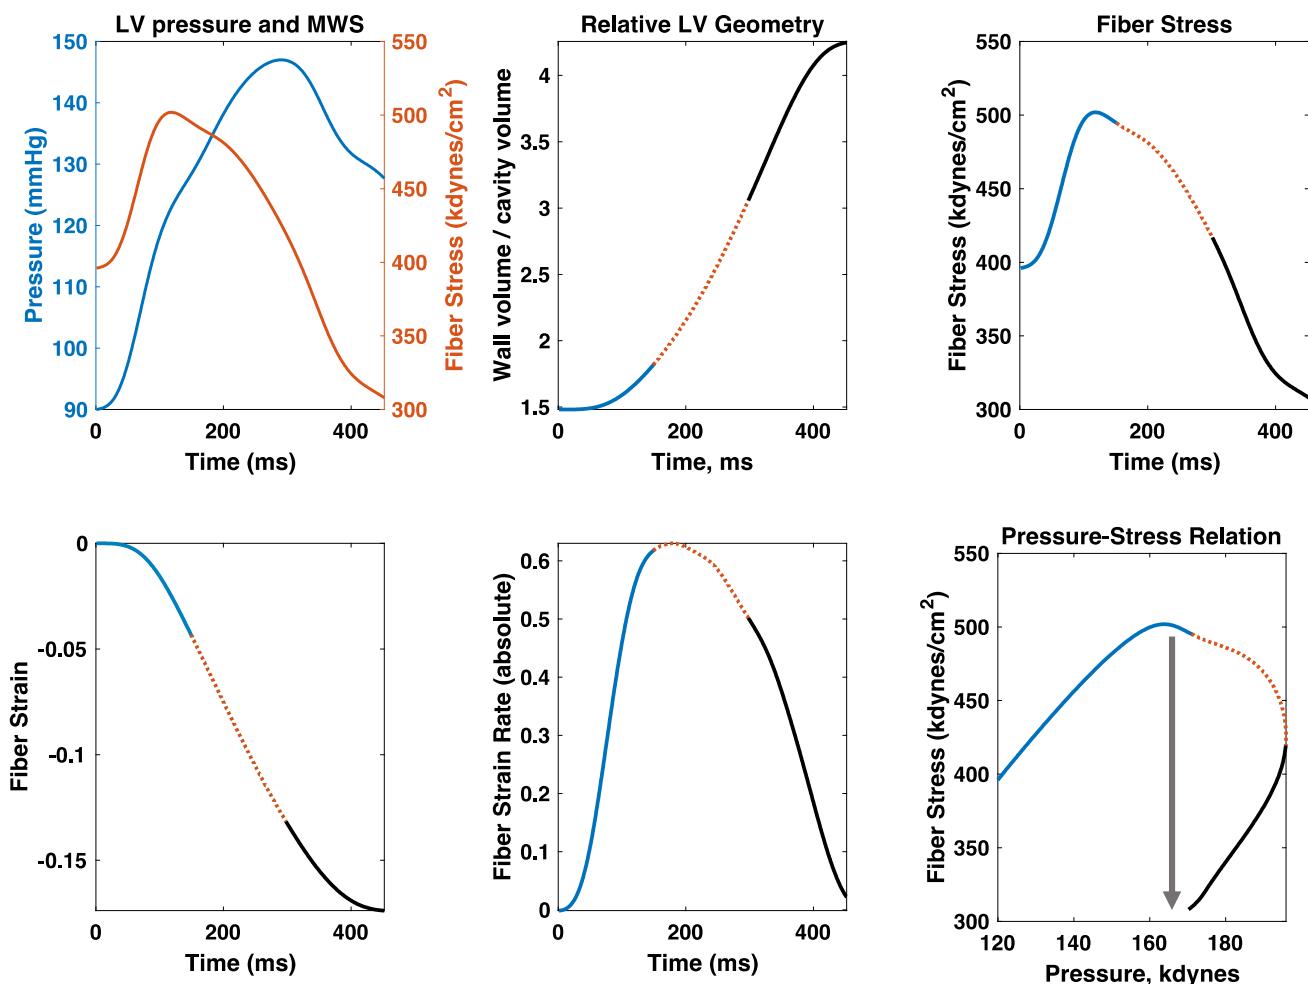
of peak force development or other important events that occur during ejection (Table 16.1). Once a time-resolved ejection-phase MWS curve is derived, various key parameters can be readily computed, including peak (maximum) MWS, the MWS time-integral (i.e., area under the time-resolved wall stress curve) during ejection, and the mid-systolic shift in the pressure−stress relation (Fig. 16.2).[9] A time-resolved MWS curve also allows for characterization of the *myocardial* loading sequence, which can be expressed as a ratio of the stress-time integral in late versus early systole.


FIGURE 16.2 **Assessment of time-resolved wall stress based on arterial tonometry and Doppler echocardiography.** As an alternative to time-resolved geometric left ventricular (LV) measurements, integration of the time-resolved aortic or left ventricular outflow tract flow curve can provide the cumulative ejected volume until any given time point during ejection, therefore allowing for the computation of a time-resolved LV cavity volume curve during ejection. Wall volume can be assumed to be constant. This method can be readily applied using only the pressure−flow pair and basic LV geometric measurements in end-systole and diastole (end-diastolic cavity volume, end-systolic cavity volume, and LV mass).

In order to better interpret the time-resolved MWS curve, it is useful to review the events that take place at the myocardial, ventricular, and arterial levels during early systole, mid-systole, and late systole.

Throughout systole, myocardial fiber activation results in the development of tension (stress) and shortening of myocardial segments, which results in progressive ejection of blood from the LV cavity and wall thickening (Fig. 16.1). During *early* ejection, active development of fiber cross-bridges occurs in the electrically activated myocardium and peak MWS occurs,[1] at a time when systolic pressure co-exists with quasi-diastolic geometry (relatively thin wall and relatively large cavity) (Fig. 16.1A−D). Myocardial fiber shortening and ejection of blood determine a progressive change in LV geometry, which causes a drop in myocardial stress (despite rising pressure) during mid-to-late systole. This can be quantified as a clear "shift" in the pressure−stress relation (Fig. 16.1E) and appears to be ideal for the myocardium to handle the additional load imposed by systolic wave reflections, which are present in most older adults. This shift, however, may be insufficient and/or compromised in the setting of wave reflections of very early onset or of large magnitude[8,12,13] and in the presence of a lower LV ejection fraction.[1,12]

Various indices of LV afterload derived from pressure−flow relations are useful because they characterize the hydraulic load on the LV pump and can provide indices that are purely reflective of arterial properties.[14] However, arterial load should always be interpreted by considering not only the interactions between arteries and the LV as a pump[14,15] but also between myocardial elements and instantaneous LV geometry and the time-varying load imposed by the systemic circulation. As expected from physiologic principles, various arterial properties affect time-varying MWS differently.[8] SVR is a very important determinant of MWS throughout systole, whereas aortic root characteristic impedance (Zc) selectively affects early systolic and peak systolic MWS. In contrast, wave reflections and total arterial compliance correlate with MWS in mid and late systole and significantly influence the area under the stress-curve generated for any given flow output.[8] Interestingly, women seem to demonstrate greater peak and end-systolic wall stress as well as a higher ejection-phase stress-time integral, even after adjustment for arterial properties, which might relate to the differential susceptibility of women to heart failure.[8]

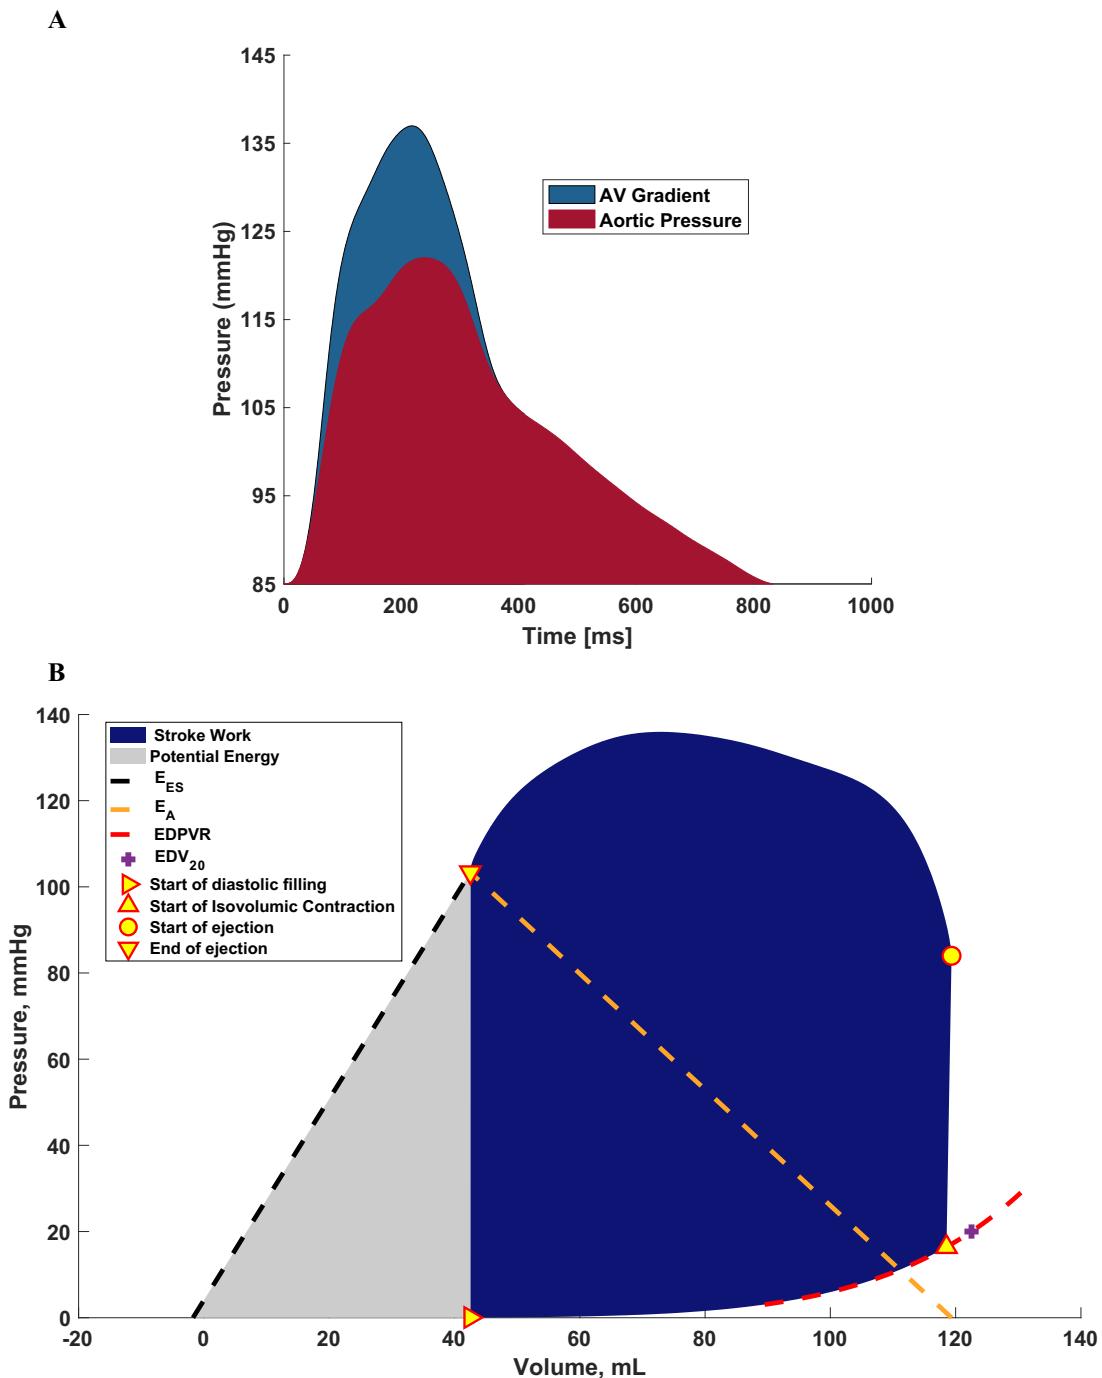
Interestingly, whereas wave reflections selectively increase late systolic wall stress, the LV contraction pattern


FIGURE 16.3 **Assessment of ejection-phase time-resolved wall stress based on arterial tonometry and Doppler echocardiography, using the method depicted in Fig. 16.2.** Time resolved LV cavity pressure (which in the absence of aortic stenosis or LV outflow tract obstruction is very similar to aortic pressure, blue curve in top left panel) and the relative LV geometry (wall volume/cavity volume ratio) are used to compute time-resolved fiber stress (top right panel and red curve in top left panel). The Arts model can also be used to compute average time-resolved fiber strain and strain rate (bottom left and middle panels). The bottom right panel shows the mid-systolic shift of the pressure—stress relation (*gray arrow*) demonstrating a reduction in fiber stress in mid-systole despite rising pressure. In the top left panel, pressure is represented by the blue line, whereas myocardial wall fiber stress is represented by the red line. In other panels, early systole (first third), mid-systole (middle third), and late systole (last third) are represented by the blue continuous line, the *red dotted line*, and the black continuous line, respectively.
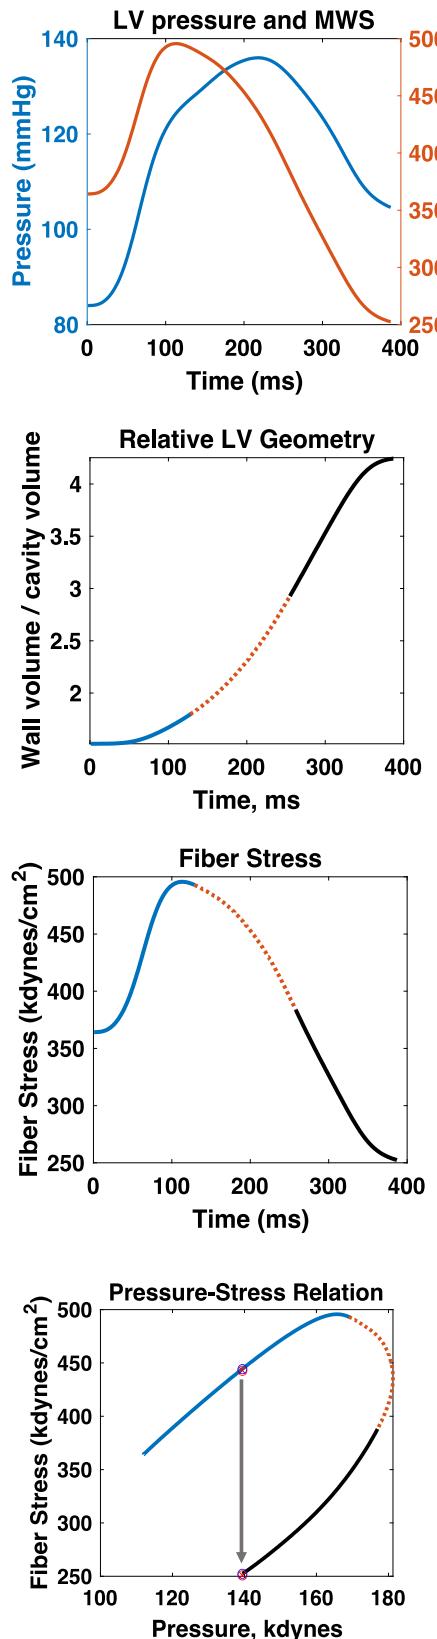


can modulate the influence of wave reflections on late systolic myocardial load. As mentioned above, normally, a marked mid-systolic shift in the pressure—stress relation occurs as a result of LV contraction (Figs. 16.1, 16.3 and 16.5). This shift effectively protects LV cardiomyocytes against excessive wall stress in late systole, a period of increased vulnerability to the ill effects of load. Abnormalities such as reduced early phase ejection, a lower LV ejection fraction, and concentric hypertrophy/remodeling can impair the mid-systolic shift in the pressure—MWS relation, making the LV more susceptible to the effects of wave reflections on the myocardium.[1,12]

Arterial wave reflection

As discussed in detail elsewhere in this book (Chapters 1, 3, 11), wave reflections occur at multiple sites of impedance mismatch, such as points of branching or change in wall diameter or material properties along the arterial tree. Innumerable reflections merge into a discrete reflected wave, which travels back to the heart.[16-18] The time of arrival of the reflected wave to the proximal aorta is strongly dependent on the pulse wave velocity (PWV) of conduit vessels, particularly the aorta, which transmits forward and backward traveling waves from and toward the

FIGURE 16.4 **Example of non-invasive estimation of LV pressure assessments of LV ventricular−arterial coupling in the pressure−volume plane in the presence of aortic stenosis using arterial tonometry and Doppler echocardiography.** Panel A illustrates how the aortic transvalvular gradient measured with continuous wave Doppler can be readily added to the aortic pressure waveform to compute the time-resolved LV intracavitary pressure. Panel B shows the LV pressure volume loop constructed with synchronized pressure and volume measurements, along with an estimation of the LV end-systolic elastance slope using a single beat method (see Chapter 15). The additional pressure above end-systolic pressure from aortic stenosis, wave reflections and other hemodynamic phenomena are not accounted for by the ratio of effective arterial elastance to LV end-systolic elastance (E_A/ E_{ES}). The latter ratio only uses end-systolic pressure and assumes a square shaped pressure−volume loop for assessments of energetic efficiency (see Chapter 15). A more direct assessment of stroke work and potential energy (and thus energetic efficiency) can be made using time resolved pressure and volume and the areas of stroke work and potential energy (shown in blue and gray). In addition, time-resolved pressure and volume allow for straightforward computations of time-resolved fiber stress (Fig. 16.5).

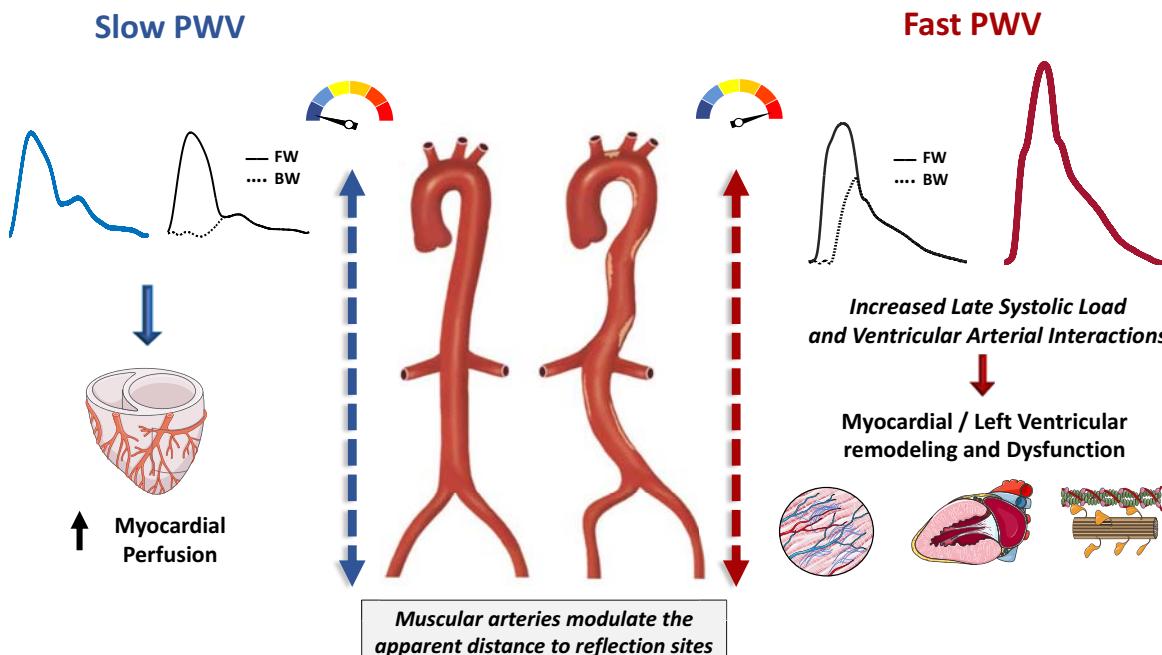
FIGURE 16.5   Assessment of time-resolved ejection-phase myocardial wall fiber stress (MWS) in a patient with aortic valvular stenosis.

LV, respectively.[14,18−20] Stiffer aortas exhibit greater PWV and conduct forward and backward traveling waves at greater velocities and therefore promote an earlier arrival of wave reflections to the LV.[16,18,21,22] As a consequence of the aortic stiffening that occurs with aging and various disease states, the hemodynamic effects of wave reflections shift from diastole to systole (Fig. 16.6), with prominent effects during mid-to-late systole in older adults,[18,21] particularly in women[16,17,21,24−27] and in patients with heart failure and preserved ejection fraction (HFpEF).[28−30] The shift of wave reflection arrival from diastole to systole favors a loss of coronary perfusion pressure on one hand, and increased mid-to-late systolic load on the other. When premature, wave reflections increase aortic pressure and reduce forward flow, therefore increasing the LV pressure while impeding the outflow of blood from the LV in mid-to-late systole. Since this outflow reduces LV cavity size and thus the ratio of cavity to wall volume, premature wave reflections increase mid-to-late systolic MWS by impacting the relationship between LV pressure and LV geometry during this phase of ejection. Therefore, wave reflections can have a substantial impact on the LV loading sequence (increasing mid/late relative to early systolic load).

Wave reflections are typically quantified via wave separation analysis, using the ratio of forward to backward wave amplitude. This approach is discussed in detail in other chapters of this textbook. Pronounced and/or premature wave reflections can have important deleterious effects on the myocardium (Fig. 16.7) as discussed in subsequent sections of this chapter. Importantly, wave reflections may be susceptible to modification by pharmacologic interventions, which could have important implications for the prevention and treatment of HF (as discussed in more detail in Chapters 36 and 51).

LV loading sequence and its role in LV hypertrophy

For any given level of systolic (peak) blood pressure, prominent mid-to-late systolic loading has been shown to

---


Using an aortic pressure waveform (arterial tonometry) and the transvalvular pressure gradient derived from Doppler echocardiography (Fig. 16.4), the LV pressure waveform (top panel) is computed. The LV outflow waveform can also be used to compute time-resolved LV wall volume, and thus relative LV geometry (second panel). The third panel shows the time-resolved ejection-phase fiber stress. The bottom panel shows the mid-systolic shift of the pressure−stress relation (*gray arrow*) demonstrating a reduction in fiber stress in mid-systole despite rising pressure. In the top left panel, pressure is represented by the blue line, whereas myocardial wall fiber stress is represented by the red line. In other panels, early systole (first third), mid-systole (middle third), and late systole (last third) are represented by the *blue continuous line*, the red dotted line, and the *black continuous line*, respectively.

TABLE 16.1 Key events during early, mid, and late systole relevant for understanding the impact of the LV systolic loading sequence on the myocardium.

Early ejection (∼First third of ejection)	Mid-systole (∼2nd third of ejection)	Late systole (∼Last third of ejection)
• Prior to ejection, the myocardium develops force without significant shortening. The initiation of ejection allows the myocardium to shorten as it ejects blood. The point at which the valve opens is dependent on diastolic blood pressure (which in turn varies directly with mean arterial pressure and inversely with pulse pressure). • As the aortic valve opens, the myocardium transitions from isometric contraction to the early ejection-phase, during which peak myocardial wall stress develops (typically ∼70–100 ms after aortic valve opening in humans), followed by the onset of myocardial relaxation. • Prior to the onset of myocardial relaxation, active cross-bridge formation occurs. During this phase, myocytes can partially adapt to increased load by increasing the number of interacting cross-bridges (cooperative activity). • Fiber shortening during this period results in: (1) Initiation of length-dependent deactivation ("shortening-deactivation") of cardiomyocytes; (2) Dynamic changes in LV geometry that favor a subsequent reduction in myocardial wall stress relative to LV pressure. • Pulsatile arterial load in early ejection is governed by aortic root characteristic impedance (Zc). The net load from wave reflections during this phase is small.	• Sustained LV ejection determines a progressive shift in the pressure–stress relation, such that myocardial wall stress progressively decreases for any given LV cavity pressure. • This shift is quite pronounced in normal circumstances but can be reduced in the presence of LV hypertrophy and/or reduced myocardial contractility. • Shortening-deactivation reduces the force of contraction and wall stress decreases. Despite this, increasing pressure can occur, given the shifting pressure–stress relation mentioned above. • This is a period of particularly increased vulnerability to load, because: (1) it follows the onset of relaxation (and cross-bridges can no longer adapt to load); (2) It precedes the full development of the shift in the pressure–stress relation (which "protects" cardiomyocytes from excessive wall stress). • If present (i.e., due to their premature arrival back at the LV), wave reflections exert significant hemodynamic load on the cardiomyocytes during this period.	• Under normal conditions: (1) The shift in the pressure–stress relationship has fully developed; (2) Myocardial wall stress/force development and the velocity of fiber shortening continue to decrease; (3) The end of the action potential promotes full relaxation. • Wave reflections exert significant hydraulic load on the LV, but if a pronounced shift in the pressure–stress relation occurred earlier in systole, LV wall stress is low (cardiomyocytes are "protected" from wave reflections). • However, when earlier systolic phenomena are abnormal (i.e., impaired early phase ejection from decreased contractility or increased load, impaired mid-systolic shift in the pressure–stress relation due to LV concentric hypertrophy/remodeling or decreased contractility), cardiomyocytes continue to be vulnerable to the effects of wave reflections. Moreover, in the absence of a pronounced shift in the pressure–stress relation in mid-systole, persistently increased force development may be necessary to sustain LV pressure and promote continued ejection. • A sustained contraction pattern may be present (as a result of deficient shortening-deactivation), tending to preserve the overall EF on one hand, but impairing myocardial and LV relaxation on the other.

Modified from reference Chirinos JA. Deep phenotyping of systemic arterial hemodynamics in hfpef (part 2): clinical and therapeutic considerations. **J Cardiovasc Transl Res**. 2017; 10:261–274.

FIGURE 16.6   Cardiac consequences of arterial stiffening and premature wave reflection. Earlier arrival of wave reflections favor a loss of coronary perfusion pressure on one hand, and increased mid-to-late systolic load on the other, due to a shift of wave reflection arrival from diastole to systole. In populations with stiff aortas, muscular artery function may become a key determinant of the apparent distance to reflection sites and thus the effects of wave reflections on the central aorta, for any given PWV. *BW*, backward wave; *FW*, forward wave; *PWV*, pulse wave velocity. *Reproduced from Chirinos JA, Segers P, Hughes T, Townsend R. Large-artery stiffness in health and disease: Jacc state-of-the-art review.* ***J Am Coll Cardiol****. 2019; 74:1237—1263.*

exert deleterious effects on LV structure and function in animal models and has been associated with LV hypertrophy in humans.[18,31,32] Kobayashi et al.[31] used a Wistar rat model and performed constriction of either the ascending aorta or suprarenal abdominal aorta. Constriction of the ascending aorta increased LV load in early systole (which mimics an increased proximal aortic characteristic impedance), whereas constriction of the descending aorta caused prominent mid-to-late systolic loading from a large reflected wave that originated at the distal aortic constriction site.[31] In this study, despite identical peak LV pressure levels in both groups, rats that underwent descending aortic banding (and were thus exposed to greater mid-to-late systolic load) demonstrated much greater LV hypertrophy than those undergoing ascending aortic banding (which were exposed to increased early systolic load).[31].

These findings are supported by observational human data. Hashimoto et al.[33] assessed changes in wave reflection magnitude occurring during antihypertensive therapy and observed that the reduction in wave reflections predicted regression of LV mass independently of blood pressure reduction. The association between reflected wave magnitude reduction and LV mass reduction was also independent of age, sex, and use of renin-angiotensin system inhibitors, and was particularly strong in patients with LV hypertrophy at baseline. Of note, despite the fact that standard antihypertensive therapy reduced wave reflections

on average, the change was highly variable, with reflection magnitude actually increasing in some subjects. In agreement with Hashimoto's findings, a relationship between reflection magnitude (approximated from measured pressure and an assumed physiologic flow waveform) and LV mass has been reported in large community-based studies that included normotensive and hypertensive individuals.[25,34] Similarly, Quail et al. recently demonstrated that in patients with repaired aortic coarctation, reflection magnitude assessed from the ascending aortic distension waveform (a surrogate of the aortic pressure waveform) and measured aortic flow (using phase-contrast MRI) was independently associated with LV hypertrophy.[35] When interpreted in the context of available animal data, available human studies support a role for wave reflections and late systolic load in the development of LV hypertrophy, independent of absolute blood pressure levels.

LV loading sequence and its role in LV fibrosis

Available studies also suggest a role for wave reflections and mid-to-late systolic load on LV fibrosis. In the previously mentioned study by Hashimoto et al.,[33] the banding intervention that increased wave reflections, resulting in mid-to-late systolic LV loading also caused more LV subendocardial fibrosis, compared to the intervention that increased load in early systole. A study assessed the role of

FIGURE 16.7 Effect of late systolic load from arterial wave reflections on the myocardium. Increases in mid-to-late systolic load from prominent and/or premature wave reflections can lead to left ventricular concentric remodeling or hypertrophy, myocardial fibrosis, T-tubule dysfunction, contractile dysfunction, and slow relaxation. At the pump level, this may result in systolic and diastolic dysfunction, and consequent left atrial remodeling and dysfunction.

wave reflections on diffuse LV fibrosis (measured by MRI T1 mapping sequences) among patients with severe aortic stenosis undergoing aortic valve replacement. In this study, patients with symptomatic severe aortic stenosis scheduled to undergo surgical aortic valve replacement underwent measurements of aortic root characteristic impedance, wave reflection parameters (reflection magnitude, reflected wave transit time), and myocardial extracellular mass (a validated surrogate of diffuse myocardial fibrosis) using cardiac magnetic resonance imaging (MRI) and arterial tonometry. Patients with higher extracellular mass exhibited greater reflection magnitude and lower aortic root characteristic impedance, the latter being likely a consequence of aortic dilation. Interestingly, in this study, reflection magnitude was a significant predictor of a smaller improvement in the quality of life (Kansas City Cardiomyopathy Questionnaire score) assessed six months after aortic valve replacement. This study demonstrated that arterial wave reflections are associated with interstitial fibrosis and a worse clinical response to surgical aortic valve replacement, suggesting that the loading sequence is important regardless of the presence of overt pressure overload from aortic stenosis.

Effect of mid-to-late systolic load on LV diastolic dysfunction

Multiple animal studies have demonstrated the deleterious effect of mid-to-late systolic load on LV relaxation.[32,36−41] An early study by Hori et al. was performed using a canine model to impose increased afterload by either: (a) clamping

the ascending aorta to induce early systolic load; (b) clamping the descending aorta to induce mid-to-late systolic load; (c) intermittently clamping the ascending aorta in late systole. The authors demonstrated that, for a given increase in peak systolic LV pressure, clamps that resulted in mid-to-late systolic loading prolonged *tau* (the gold standard index of diastolic relaxation) much more than early loading. In a subsequent study, Gillebert et al.[32] studied the effect of the timing of systolic load on LV relaxation in dogs, by inflating balloons in the ascending aorta at different times during ejection (inducing either early systolic load or mid-to-late systolic load). This study elegantly demonstrated that, for a given increase in peak systolic LV pressure, mid-to-late systolic loading prolonged *tau* much more than early systolic inflation, further demonstrating a cause-effect relationship between mid-to-late systolic load and diastolic dysfunction.[32] These results are consistent with several other animal studies[37,40,42,43] Interestingly, one study[44] did not find slowing of relaxation when load was applied selectively in very late systole (∼20−50 ms before aortic valve closure), whereas load applied in mid-systole (∼80−110 ms before aortic valve closure) significantly slowed relaxation. These results suggest that the effects of wave reflections are not necessarily deleterious in very late systole, unless the bulk of their effect "advances" into mid-systole (as occurs in the setting of markedly increased aortic PWV and premature wave reflections). This is consistent with our understanding of the importance of mid-systole as a critical time during which LV contraction progressively shifts the pressure−

stress relation and "protects" cardiomyocytes from the deleterious effects of wave reflection during late ejection[1,2,8,45] (Table 16.1 and Fig. 16.2).

In support of the large body of animal experimental findings demonstrating a cause-effect relationship between mid-to-late systolic load and impaired LV relaxation, several human studies demonstrate that indices of wave reflections and/or mid-to-late systolic MWS are independently associated with diastolic dysfunction,[9,28,41,42,45−52] LA remodeling,[48,53,54] decreased longitudinal systolic function (despite preserved EF),[9,55] and elevated brain natriuretic peptide levels.[41,51,56,57]

Myocardial loading sequence and atrial dysfunction

LA dysfunction has been associated with an increased risk of cardiovascular morbidity and mortality in population-based and hypertensive cohorts.[58,59] LA function is also important to regulate and promote LV filling during diastole, contributing to cardiac output adaptations to changes in loading conditions, inotropic stimulation, and heart rate. We assessed the relationship between the myocardial loading sequence (early vs. late MWS) and LA dysfunction in 260 adults with hypertension referred for a cardiac MRI study.[6] LA function was assessed from classic phasic LA volumes as well as measurements of LA myocardial deformation (strain) using tissue-tracking algorithms applied to cine-MRI SSFP images. Time-resolved central pressure and time-resolved LV geometry were measured with carotid tonometry and cardiac MRI, respectively, for computation of time-resolved ejection-phase MWS. The MWS time-integral (area under the MWS curve) in the first half of ejection (early systole) and the second half of ejection (late systole) were computed. In this study, an LV myocardial loading sequence characterized by prominent late systolic MWS (relative to early systolic MWS) was independently associated with impaired reservoir, conduit, and booster pump LA function. Interestingly, in models that adjusted for late systolic load, early systolic load was associated with better LA function, indicating that it is not only the absolute load but also the myocardial loading sequence that determines LA dysfunction in hypertension. In the context of available experimental data, these findings further support the deleterious effects of late systolic LV loading on systolic−diastolic coupling.

Late systolic load and heart failure risk

Consistent with the effects of wave reflections on LV remodeling, fibrosis and dysfunction, wave reflection magnitude[12,60] and late systolic hypertension[61] have been shown to be strong independent predictors of incident HF in the Multi-Ethnic Study of Atherosclerosis (MESA), as discussed in more detail in Chapter 36.

Cellular processes in the myocardium

The cellular processes that mediate the deleterious effects of wave reflections on the myocardium are poorly understood. The effect of mid-to-late systolic load on diastolic relaxation and chronic LV remodeling are likely due to intrinsic differences in cellular processes at different phases of systole, as summarized in Table 16.1. During early ejection, active development of fiber cross-bridges occurs in the electrically activated myocardium and peak MWS occurs,[1] which is followed by a transition from contraction to relaxation. The transition from contraction to relaxation occurs very early during ejection in dogs (∼34% after the initiation of mechanical systole and ∼16% into the duration of ejection).[62] In humans, the time to peak MWS, which reflects the time of peak force development (and after which force first starts to decline), has been proposed as a marker of the time to the onset of relaxation.[50] This normally occurs ∼70−100 msec into ejection.[1,8,9]

The immediate effects of afterload on diastolic relaxation have been explained on the basis of the differential effect of early versus mid-to-late systolic load on the number of interacting cross-bridges. Loading during active cross-bridge formation in early systole increases the number of interacting cross-bridges (cooperative activity), a physiological mechanism that favors matching of the number of cross-bridges with systolic load.[32,63] However, when increased load occurs after the onset of myocardial relaxation, the number of interacting cross-bridges can no longer adapt. Under these circumstances, a mismatch between the number of cross-bridges and load may occur, increasing the stress imposed on individual cross-bridges and decreasing cross-bridge cycling.

However, a more complex interplay between cross-bridge recruitment, cooperative activity, cross-bridge inactivation, and cross-bridge cycling rate are likely at play.[45,50,62,63] Recently, the course of ejection in early systole (which depends at least partially on myocardial contractility) has been shown to correlate with the subsequent course of MWS.[50] As mentioned earlier in this chapter, under normal conditions, brisk force development and fiber shortening occur in early systole, resulting in LV ejection and a dynamic reconfiguration of LV geometry that results in a mid-systolic reduction in MWS relative to LV pressure,[1] thus protecting the cardiomyocytes against excessive load in mid-to-late systole (a period of increased vulnerability). The phenomenon of shortening-deactivation (which is associated with reduced calcium sensitivity of the contractile apparatus), decreases force development after early systolic rapid shortening, and increases the relaxation rate of muscle.[45,50] This represents a perfect "match" to this normal physiology, because sustained myocardial force development in mid-to-late systole is unnecessary to preserve fiber shortening and LV ejection against the load imposed by wave reflections. However, in the presence of

contractile abnormalities that compromise early ejection, the mid-systolic dynamic geometric reconfiguration of the LV that favors a reduced MWS relative to pressure is impaired. In these conditions, shortening-deactivation may not operate fully, such that force development continues or increases in mid-to-late systole, tending to preserve the overall EF on one hand, but impairing relaxation on the other.[45,50] Disorganization and disruption of transverse (T-) tubules, which are important for the spatial alignment between L-type calcium channels and the sarcoplasmic reticulum, has also been suggested.[12] Disrupted T-tubules lead to inefficient calcium cycling, myocardial dysfunction, and calcium overload in cardiomyocytes due to deficient calcium reuptake.[12,64] These abnormalities are deleterious in their own right, but may also conspire with impaired shortening-deactivation to sustain contraction and prolong relaxation.

The differential effect of time-varying myocardial afterload on cellular and molecular processes taking place in early versus mid-to-late ejection should be a focus of further research. In particular, the molecular mediators of the long-term effects of mid-to-late systolic load on maladaptive remodeling, and the pharmacologic effects of common drugs that may affect the time course of myocardial contraction require further study. In addition, the role of comorbidities is not well understood and requires further research. Long-standing hypertension, and comorbidities such as coronary artery disease, obesity, and chronic kidney disease, may affect the normal contraction pattern that normally protects myocytes from the effects of wave reflection.[1,12]

Conclusions

Substantial evidence from animal and human studies strongly suggest that a systolic loading sequence characterized by late systolic load can cause maladaptive LV remodeling, fibrosis, diastolic dysfunction and failure, thus representing a highly clinically relevant cardiovascular phenotype. The myocardial loading sequence is not assessed through conventional cardiac imaging methods and is not captured in the pressure−volume plane. However, assessments of time-resolved MWS and arterial wave reflections can be accomplished via noninvasive methods, which should be utilized more broadly. The adverse effects of late systolic load on the myocardium provides an opportunity for therapeutic interventions designed to ameliorate these effects, which could in turn reduce the risk of maladaptive LV remodeling, fibrosis dysfunction and failure. This can, in principle, be accomplished independently of effects on microvascular resistance or mean arterial pressure, as discussed in Chapters 36 and 49−51.

Assessment of ventricular arterial interactions via arterial pressure-flow relations in humans

Gary F. Mitchell

Cardiovascular Engineering, Inc., Norwood, MA, United States

Overview of arterial pressure-flow relations

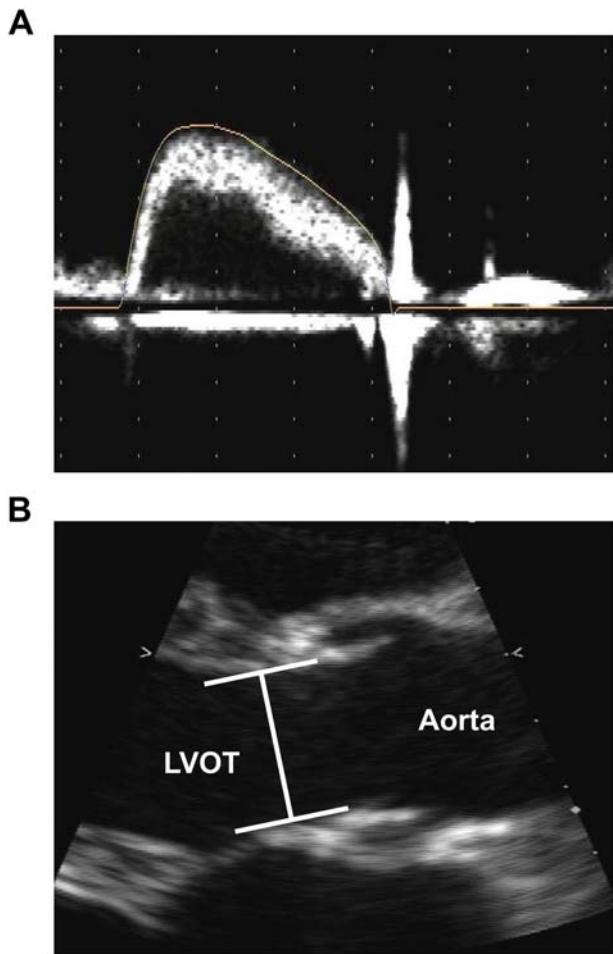
The heart and arterial system represents a flow distribution system that has an ultimate goal of supplying required mean blood flow to the organs. Because the heart is a pulsatile pump, delivery of mean flow is necessarily accompanied by a variable amount of pulsatile overhead. The arterial system is designed to optimize delivery of mean flow with minimal pulsatile overhead. In order to minimize pulsatile overhead, the system design includes a highly compliant aorta coupled to the left ventricle (LV) and followed by a branching network of muscular arteries that arise from the aorta and supply the regional vasculature of various organs. Mean flow (Q_0) in that network interacts with peripheral resistance (Z_0) to produce mean arterial pressure (MAP), where $Z_0 = MAP/Q_0$. During early systole, the LV is exposed to MAP and the load imposed by the proximal aorta, which has a characteristic impedance (Z_c) that is a small fraction of peripheral resistance (Z_0). Z_c is analogous to Z_0, but represents the pressure-flow relations for the pulsatile component only of pressure and flow and can be approximated as $Z_c = dP/dQ$, where dP is the peak time-derivative of pressure and dQ is the peak time-derivative of volumetric flow in early systole. Z_c is normally a small fraction (5%−10%) of Z_0. As a result, whereas peak aortic flow is approximately fivefold higher than mean flow, pulse pressure (PP) (40 mm Hg) is a fraction of MAP (90 mm Hg) in a young healthy person.

In addition to the foregoing forward traveling waves, there are reflected waves in the arterial system that are attributable to impedance mismatch at branch points and other segments of differing physical properties. With advancing age, the aorta stiffens, resulting in an increase in Z_c and the amplitude of forward traveling pressure waves (P_f) produced by a given forward flow wave (Q_f). In addition, pulse wave velocity (PWV), which is the velocity at which these waves travel along the aorta, increases, meaning that reflected waves return to the proximal aorta sooner, resulting in progressive overlap between forward and backward pressure (P_f, P_b) and flow (Q_f, Q_b) waves during systole. These factors combine to increase PP and pulsatile overhead on the LV, resulting in LV remodeling and hypertrophy and leading to wide PP hypertension, which may be isolated systolic or mixed systolic and diastolic hypertension, depending on whether MAP is also increased (mixed hypertension). The resulting increase in pressure pulsatility and pulsatile load also has adverse implications for the periphery, where it triggers remodeling and loss of small vessels, resulting in blunted reactivity and an increase in resting Z_0. The increase in Z_0 can drive up MAP, which will passively stiffen the aorta, resulting in a potential vicious cycle. The loss of reactivity can have adverse effects on perfusion of target organs, especially in autoregulated high-flow organs like the brain and kidneys.[1−3] Similarly, diminished reactivity in muscular beds may limit vasodilatory reserve during exercise, which contributes to diminished exercise tolerance and hypertensive response to exercise.[4]

Noninvasive assessment of aortic pressure-flow relations

When pressure-flow relations in the arterial system were first assessed in the mid-1900s, invasive pressure and flow measurements were required.[5,6] Subsequent work demonstrated the possibility to acquire impedance measurements noninvasively by using carotid artery tonometry and

Doppler flow measurements in the LV outflow tract (LVOT).[7−9] The latter technique allowed investigators to perform large-scale, epidemiologic studies of pulsatile hemodynamics that have greatly expanded our understanding of aortic structure and function and ventricular-vascular interaction.[10−13]

Assessment of aortic input impedance requires measurement of time-resolved proximal aortic pressure and flow waveforms. Pressure can be obtained by performing carotid artery tonometry. The carotid artery waveform is not identical to the central aortic waveform because it is located downstream from the aortic inlet, meaning that there will be modestly more overlap between forward and reflected waves. In addition, there are branch points along the path from aorta to carotid, which will have additional modest effects on the shape of the waveform. However, invasive studies have shown that a properly calibrated carotid tonometry waveforms generally provides an adequate surrogate for central aortic pressure.[14]


Proper calibration of the carotid pressure waveform is also required. Because of differences in relative timing of forward and reflected waves at various locations in the arterial system, systolic blood pressure (SBP) differs between sites. Therefore, brachial cuff blood pressure cannot be used to calibrate a carotid pressure waveform.[15−18] However, MAP and diastolic blood pressure (DBP) are reasonably consistent along the large arteries in the arterial tree, assuming there are no flow-limiting stenoses between the measurement sites. Therefore, brachial artery MAP and DBP can be used to calibrate the carotid pressure waveform. Note that brachial MAP should be based on a brachial waveform that has been calibrated to cuff SBP and DBP and then integrated to assess MAP. Some have used a formula to compute MAP based on a largely erroneous assumed shape factor of 33%, meaning that MAP is equal to DBP plus one-third of PP. However, the foregoing shape factor is highly variable, with values that are related to arterial stiffness, among other things. In addition, some have advocated for using a radial pressure waveform to derive an estimated central pressure waveform by using a generalized transfer function.[19] The foregoing radial waveform is often calibrated by using cuff SBP and DBP. The latter approach ignores pressure amplification between brachial and radial arteries and thereby markedly underestimates central PP.[16] In addition, the transfer function approach is dependent on the assumption that the transformation of a central pressure waveform into a peripheral pressure waveform is consistent across age, sex, and various risk factor exposures, which is known not to be the case based on the marked variability in higher frequencies of the specific transfer functions between participants, which influence some important morphologic details of the pressure waveform.[20,21] While the transfer function approach may result in an estimate of central pressure that correlates with invasive measures, the features of the reconstructed waveform are not suitable for detailed waveform analysis as too much high frequency content is lost as a result of the filtering that is required.[22]

Central aortic flow can be assessed either by Doppler ultrasound or by phase contrast magnetic resonance imaging (pcMRI). Most large-scale studies have utilized Doppler ultrasound because of lower cost, greater convenience, and better ability to minimize time delay between assessment of tonometry pressure and flow, which can readily be done simultaneously or a few seconds apart with Doppler ultrasound, whereas pcMRI flows are generally separated from pressure measurements by 20 min or more due to logistical difficulties in acquiring tonometry waveforms on a participant who is in the bore of the MR machine.

When using Doppler ultrasound to measure proximal aortic flow, it is important to measure flow velocity and cross-sectional area in the LVOT, where it is relatively straightforward to acquire a stable signal, using pulsed Doppler from an apical five-chamber view, and identify the relevant cross-sectional area required to convert flow velocity to volumetric flow (Fig. 17.1). Assuming continuity of flow, LVOT flow will be equal to proximal aortic flow. Attempts to measure flow directly in the proximal aorta, per se, rather than the LVOT, are confounded by acceleration of flow due to the vena contracta effect, which will result in marked overestimation of volumetric flow if paired with the aortic cross-sectional area at the location of the sample volume. In addition, a high-quality measurement of the proximal aortic diameter is not always technically feasible. Methodologic and technical considerations regarding arterial pressure and flow measurements are discussed in detail in Chapter 2.

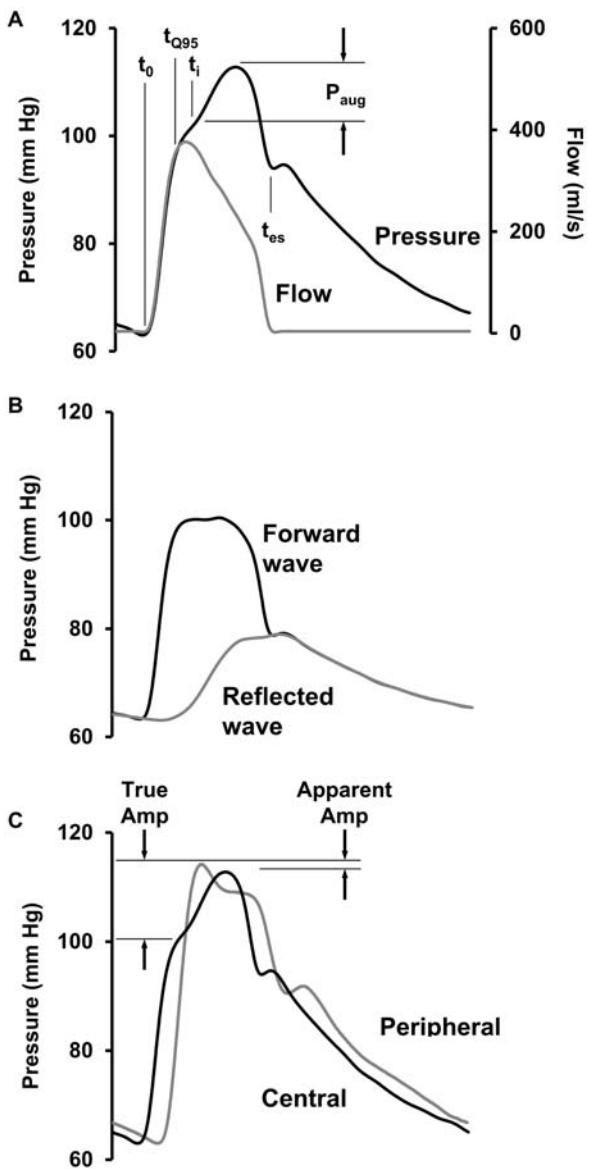
Once properly calibrated central aortic pressure and flow waveforms are obtained, pressure-flow analyses can be performed. Analytic methods for the assessment of pressure-flow relations are discussed in detail in Chapter 3, but some key aspects are discussed below. When evaluating pressure-flow relations in the arterial system, one cannot use simple circuit theory because there are finite propagation delays and reflections that alter the shape of the traveling waveforms. One approach that has been used is frequency domain analysis. Propagation delays and reflected waves render arterial load frequency dependent because the implications of a given delay in reflected wave timing varies directly with wavelength and therefore frequency. Frequency domain analysis decomposes the pressure and flow waveforms into a series of sine and cosine waves by using a Fourier transform. Calculation of the first 15 or so harmonics of physiologic waveforms will provide most of the waveform variance and is acceptable. Impedance at each harmonic (Z_i) is then calculated by taking the ratio of pressure (P_i) and flow (Q_i) at harmonics 0 to $\sim$15,


FIGURE 17.1 Measurement of flow rate in the left ventricular outflow tract (LVOT). When performing pressure-flow analysis in the proximal aorta, flow into the aorta is assessed as flow out of the ventricle through the LVOT. LVOT is easily measured by using pulsed Doppler (A) from a standard apical five-chamber view of the heart. If possible, it is preferable to measure Doppler audio and perform signal averaging of the spectral analysis in order to avoid bias due to single beat selection. The sample volume should be placed just proximal to the leaflet attachment point, high enough in the LVOT to be consistent with the measured LVOT diameter (B) but not so high that one begins to capture flow acceleration because of the vena contracta effect.

where harmonic 0 is the mean term and the first harmonic is equivalent to the heart rate, which is normally around 1 Hz in humans (at a heart rate of 60 beats/min). Z_c can be estimated by averaging the higher harmonics of Z_i across a band of frequencies where the effects of wave reflection cancel and provide an estimate of pulsatile pressure-flow relations in the absence of reflections. While frequency domain techniques are important in some settings and can be readily applied to digitized pressure and flow waveforms with contemporary software platforms, the approach is inaccessible or unintuitive to most clinicians and researchers.

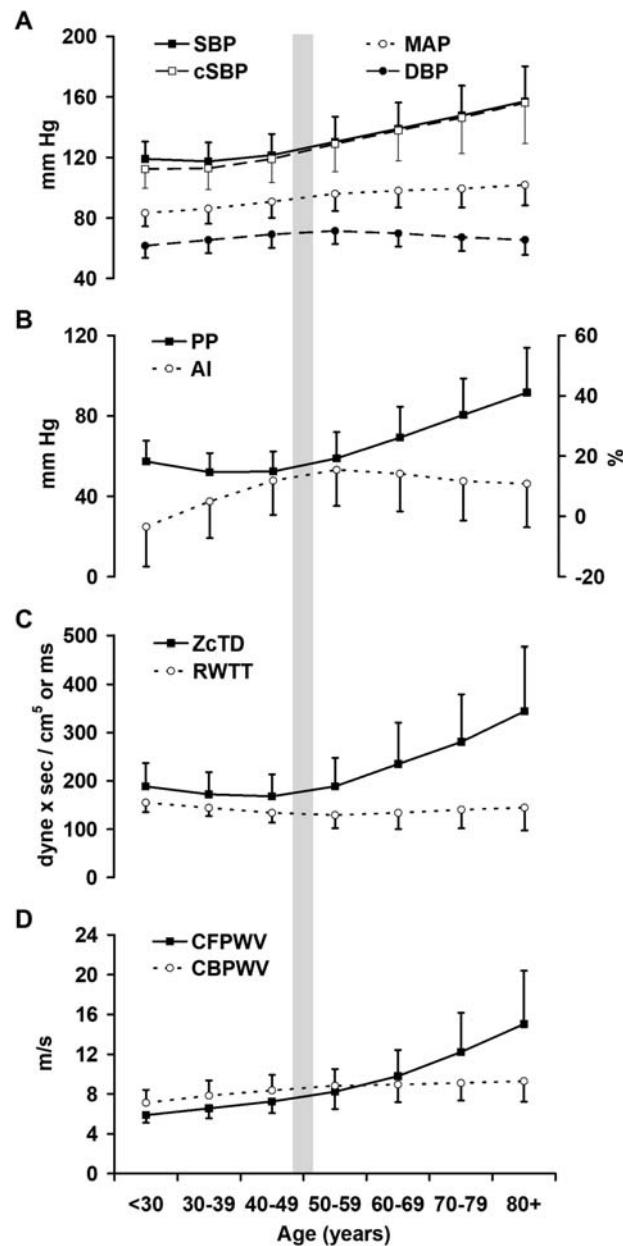
Time domain analysis of aortic pressure-flow relations represents an easily understood alternative to the traditional frequency domain approach and has emerged as a frequently used approach.[12,13,23] Time domain assessment of Z_c is based on evaluation of pressure-flow relations in early systole, prior to arrival of the dominant P_b wave. One approach that has been used for proximal aortic pressure and flow involves finding the time point at which flow reaches 95% (Q95) of maximum flow (Fig. 17.1C). The early change in pressure (dPZ$_c$) attributable to interaction of early systolic flow and Z_c during this same time window is then assessed and time domain Z_c (Z_cTD) is computed as Z_cTD = dPZ$_c$/Q95. Peripheral resistance, Z_0, is computed as noted above. Wave separation is performed (Fig. 17.2) by taking the average of the measured pressure waveform (P_m) and the flow waveform scaled by Z_c (Q*Z_c). This average waveform represents the net forward traveling wave (P_f) in the proximal aorta. The point-by-point difference between P_m and P_f represents the net reflected or backward traveling wave, P_b. The foregoing calculations can be performed in any large artery bed where local pressure and flow can be assessed, such as the common carotid arteries, where pressure is assessed by using tonometry and flow is assessed by using Doppler or pcMRI. When using pcMRI, however, it is important to ensure that the scan sequence employs adequate spatial and temporal resolution.

An alternative method for computing Z_c that does not require pressure measurement is based on the water hammer equation, $Z_c = PWV * \rho/\pi r^2$, where PWV is local pulse wave velocity, ρ is the density of blood, which is generally assumed constant at 1.06 g/cm^3, and r is the lumen radius of the vessel. Local PWV can be measured by MRI. For example, one can assess PWV in the aortic arch by using a pcMRI slice positioned at approximately the level of the right main pulmonary artery. However, there are two important caveats to consider when performing these measurements. First, the transit distance is relatively short and therefore the transit time will be proportionally short, particularly in older participants with a stiff aorta. Therefore, care must be taken to ensure that the temporal resolution of the sequence is as high as possible, e.g., 100 phases/cardiac cycle. Second, it is important to note that all methods for measuring Z_c are sensitive to wave reflections. If there are very early reflected waves that encroach on the Q95 window, they will augment pressure and reduce flow, leading to overestimation of Z_c. The same is true for PWV-based measurements. If PWV is assessed by using two pressure waveforms, the error will be overestimation as wave reflection steepens the upstroke of the distal pressure waveform and appears to accelerate the wave velocity. The opposite error is seen, however, when PWV is assessed by measuring transit time from two flow waveforms because

FIGURE 17.2 Pressure waveform analysis and wave separation analysis. The central (carotid) pressure waveform (A) can be analyzed to determine the time lag between the pressure foot (t_0) and the inflection point (t_i) corresponding to the roundtrip reflected wave transit time (RWTT). The rise in pressure after t_i represents late systolic pressure augmentation (P_{aug}) due to the reflected wave, which increases central pulse pressure (PP) and late systolic load on the left ventricle. The timing of end-systole (t_{es}) relative to t_0 represents the systolic ejection period. Flow (Q) is rescaled by characteristic impedance ($Q*Z_c$) and aligned with the pressure foot. The average of these two waveforms represents the forward wave (B) and the difference between the forward wave and measured pressure represents the backward (reflected) wave. There are two types of pressure amplification that are seen in the arterial system. True amplification represent amplification of the first pressure peak as the forward traveling wave encounter regions of impedance mismatch. Apparent amplification represents the overall difference in PP between central (carotid) and peripheral (brachial or radial) sites. An increase in central pressure augmentation has no effect on true amplification but reduces apparent amplification nearly to zero by midlife, meaning that differences in central and peripheral PP abate as augmentation increases.

distal reflection blunts the upstroke of the distal flow waveform and appears to delay the waveform and reduce wave velocity. Therefore, when comparing aortic Z_c assessed by using pressure-flow analysis versus Z_c assessed by pcMRI using the water hammer equation, it is important to note that the former values will be substantially greater than the latter. In contrast, when comparing Z_c based on pressure-flow analysis using Doppler as compared to pcMRI to measure flow, the values for Z_c should be comparable.

One important corollary of the water hammer equation is that it underscores the differing relations of PWV and Z_c with vessel diameter. Relations of PWV with basic material properties of the artery are expressed in the Moens—Korteweg equation: $PWV = \sqrt{(Eh/2\rho r)}$, where E is Young's modulus, h is wall thickness, and r is lumen radius. Thus, PWV has square root sensitivities to wall stiffness (Eh) (direct) and lumen radius (inverse). Substituting the Moens—Korteweg equation into the water hammer equation: $Z_c = \sqrt{(Eh/2\rho r)} * \rho/\pi r^2$, one can show that $Z_c = \sqrt{(Eh/2\rho r)} *\rho/\pi r^2 = \sqrt{(Eh\rho/2\pi^2 r^5)}$. Thus, Z_c has the same direct relation with the square root of wall stiffness (Eh), but the inverse relation with lumen radius is now raised to a power of $5/2 = 2.5$ rather than a simple square root (power = 0.5).[24] Thus, PWV and Z_c will change concordantly if the vessel wall stiffness changes. However, if lumen radius changes, the effect on Z_c will be $5\times$ greater than the effect on PWV. For example, a 10% increase in lumen radius will produce a 5% reduction in PWV but a 25% reduction in Z_c.

When considering remodeling of the aorta during growth and development or in response to weight gain or other factors that increase blood flow, it is important to note that the mass of elastic fibers in the aorta is relatively fixed.[25,26] Elastic fiber assembly results from the complex and carefully orchestrated expression of a number of components in addition to elastin. Elastic fibers in the aorta and elsewhere in the body (lungs, skin) are formed early in life, beginning during fetal development and ending at around the equivalent of the toddler stage in most mammals, when the gene program for creating elastic fibers is permanently silenced.[27] As a result, the pool of elastic fibers created during this critical period of development must last an entire lifetime. Given that the mass of elastic fibers is fixed, when the aorta remodels to a larger diameter, for example, during post-toddler growth, the pool of elastic fibers is effectively thinned. In addition, the fibers are placed under greater load because of the increase in lumen area, which will increase wall stress (σ) according to the Laplace equation: $\sigma = Pr/h$. Increased stress on elastic fibers will transfer some of the load to stiffer elements in the wall, such as collagen, resulting in an increase in effective wall stiffness (E). As a result, PWV, which is relatively


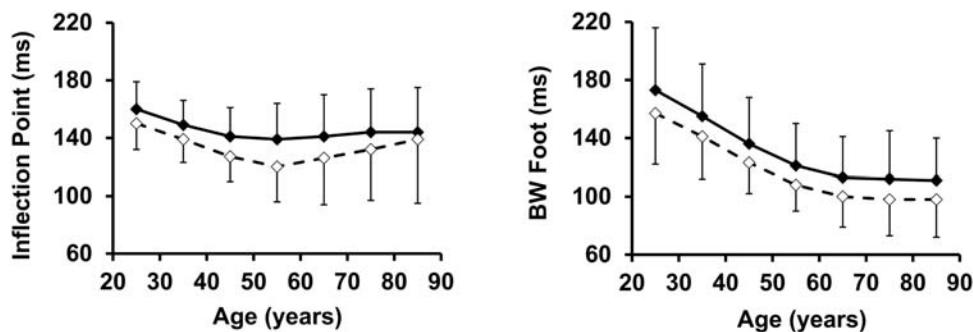
insensitive to lumen radius, may increase whereas Z_c generally will fall unless the increase in Eh is markedly (5×) greater than the increase in lumen radius. Thus, remodeling of the aorta in response to changes in blood flow or other factors can have markedly differing effects on PWV and Z_c.

Age relations of pressure-flow variables across the lifespan

Numerous large cross-sectional studies have examined the complex age relations of various measures of aortic stiffness and aortic pressure-flow relations.[12,13,28] Most studies have revealed markedly differing age relations of various stiffness measures before and after midlife (Fig. 17.3). The standard appearance of blood pressure-age relations in Westerners is presented in Fig. 17.3A,B. PP falls modestly between young adulthood and midlife, whereas MAP increases moderately. After midlife, PP increases rapidly whereas MAP increases modestly. As a result, SBP is relatively flat in young adults but increases rapidly after midlife, whereas DBP increases moderately before midlife and falls moderately thereafter, with the combination resulting in the aforementioned marked increase in PP.

Aortic wall stiffness, assessed as carotid-femoral pulse wave velocity (CFPWV), increases throughout life although the rate of increase accelerates at midlife (Fig. 17.3D). For example, in Framingham Heart Study (FHS) participants, CFPWV increased at a modest rate of 0.52 ± 0.04 m/s per decade of age prior to 50 years and a markedly (4×) higher rate of 2.05 ± 0.03 m/s per decade thereafter. In contrast, Z_c fell modestly prior to 50 years of age, at a rate of -8.4 ± 1.3 dyne*s/cm^5 per decade, and rose markedly thereafter at a rate of 51.1 ± 1.1 dyne*s/cm^5 per decade. The pattern of discordant change in CFPWV (increasing) and Z_c (decreasing) prior to midlife is consistent with remodeling of the aorta to a larger diameter.[12,13,29] Furthermore, the observation that Z_c increases rapidly after midlife, particularly in women, is consistent with the hypothesis that aortic remodeling to a larger diameter is no longer able to compensate for, and may even be contributing to, increasing aortic wall stiffness.

The hemodynamic basis for an increase in PP with advancing age is often debated. An early hypothesis posited that degradation of elastic elements in the aorta led to dilation of the aorta and transferred load to stiffer collagen fibers, resulting in an increase in PWV. The increase in PWV led to premature arrival of P_b during systole rather than diastole, resulting in augmentation of the proximal pressure wave. This late systolic augmentation, which is often assessed by computing the augmentation index (AI), was thought to be the basis for the increase in PP and SBP.[30] However, the foregoing hypothesis is not consistent with empirical observations. While it is true that CFPWV and AI increase prior to midlife that increase in AI occurs in the setting of a fall in PP (Fig. 17.3B). After midlife, AI falls at a time when PP increases dramatically, suggesting

FIGURE 17.3 Age relations of key hemodynamic variables across the full lifespan in the Framingham Heart Study second and third generation cohorts. Systolic blood pressure (SBP) is relatively flat through midlife and increases markedly thereafter (A). Mean arterial pressure (MAP) and diastolic blood pressure (DBP) increase modestly prior to midlife, after which MAP increases modestly and DBP falls. Because of constant SBP and rising DBP, pulse pressure (PP) falls prior to midlife and increases markedly thereafter. Augmentation index (AI) increases markedly prior to midlife, when PP is falling, and falls modestly after midlife, when PP increases markedly, indicating that early wave reflection and increased pressure augmentation are not the reason for rising pulse pressure after midlife. In contrast, characteristic impedance of the aorta (Z_c) parallels the change in pulse pressure across the full lifespan, indicating that changes in PP are attributable to changes in Z_c and forward wave amplitude. Central aortic wall stiffness, assessed by carotid-femoral pulse wave velocity (CFPWV), increases moderately prior to midlife and markedly thereafter (D). In contrast, muscular artery wall stiffness, assessed as carotid-brachial pulse wave velocity (CBPWV) remains relatively constant across the lifespan. Since muscular artery lumen diameter tends to increase with age, peripheral impedance will fall as central impedance (Z_c) increases, resulting in impedance matching between aorta and muscular arteries, reduced global wave reflection and increased transmission of damaging pulsatility into the periphery.


that early P_b and higher AI are not the basis for increasing PP after midlife. In FHS participants, an overwhelming proportion of variance in central and peripheral PP is attributable to variance in P_f, with modest amounts attributable to relative wave reflection (P_b/P_f) and timing of the reflected wave. Furthermore, several studies have shown that higher PP is associated with smaller rather than larger aortic diameter.[24,31,32] For example, in the AGES-Reykjavik study of older adults, markedly higher PP in women was attributable to smaller aortic diameter in women in models that adjusted for body size and other measures of wall stiffness.[11] Furthermore, in a subsequent study that examined aortic structure and function in detail by using MRI, PP was shown to be related directly to aortic wall stiffness and thickness and inversely to aortic lumen area.[33]

The basis for stable or falling AI after midlife despite an accelerated increase in CFPWV has also generated considerable concern and confusion in the literature. One might think that a progressive increase in CFPWV would be associated with proportionally earlier arrival of P_b and greater AI after midlife. However, if one looks at reflected wave arrival time, assessed as either the timing of the inflection point in the central pressure waveform or as the timing of the P_b foot following wave separation, it is evident that an early fall in the roundtrip time prior to midlife gives way to a plateau after midlife (Fig. 17.4). Since CFPWV is increasing and roundtrip time is unchanged after midlife, the distance to the effective aggregate reflection site seems to increase after midlife.[10] Furthermore, the global reflection factor (P_b/P_f) falls modestly with age after midlife.[12] The combination of a modest increase in roundtrip time and a modest decrease in global reflection factor accounts for the fall in AI.

The basis for the fall in global reflection and AI has been attributed by some investigators to impedance matching in the arterial system.[10] In young, healthy adults, aortic stiffness (CFPWV) is markedly lower than peripheral artery stiffness (CBPWV). In addition, the aorta is much larger than the first-generation muscular arteries that arise

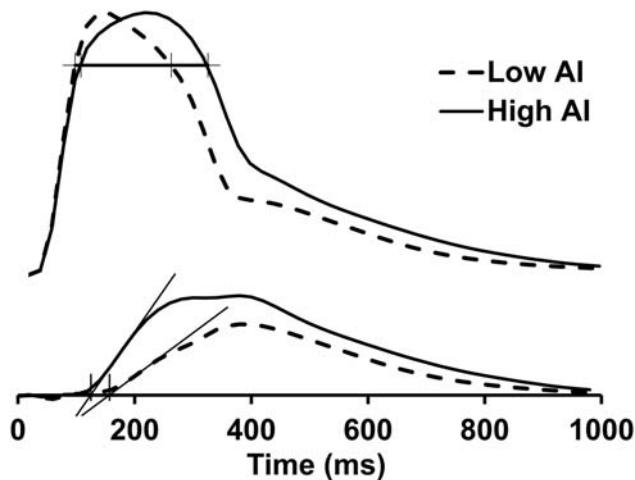
from the aorta and supply various regional vascular beds. Smaller diameter and higher stiffness combine to produce markedly higher Z_c in the muscular arteries as compared to the aorta. This steep impedance gradient, due to impedance mismatch between aorta and first-generation muscular arteries, creates wave reflection that limits transmission of pulsatile power into the muscular arteries. With advancing age, the normally compliant aorta stiffens while the normally stiff muscular arteries dilate and possibly become less stiff,[34] leading to impedance matching between aorta and first-generation branch vessels. The progressive increase in CFPWV and unchanged CBPWV results in a crossing of those values at midlife, coinciding with the timing of the transition from rising to flat or falling AI, falling global reflection factor and rising RWTT despite increasing CFPWV (Fig. 17.3). The most straightforward interpretation of this pattern of changes is that impedance mismatch between aorta and first-generation muscular arteries has diminished, leading to a reduction in wave reflection.[10,12] Furthermore, if proximal wave reflection at the origin of first-generation arteries decreases, wave reflection from more distal sites in the vasculature will become more prominent, resulting in an increase in the average distance to reflecting sites and an increase in effective reflection distance computed from RWTT and CFPWV.[10] However, it has also been pointed out that (for reasons described above), impedance matching is highly dependent on vessel size (rather than just PWV), such that PWV matching does not necessarily imply impedance matching, and vice versa. Indeed, impedance matching tends to occur even at younger ages due to well-matched area ratios of parent and daughter vessels; therefore, in general, the magnitude of wave reflection at individual bifurcations (including first order aortic bifurcations) is relatively small. More complex phenomena are likely at play, which will require further detailed study across the lifespan in health and disease. Theoretical and practical considerations regarding the determinants of wave reflections in the arterial tree are discussed in detail in Chapter 11.


FIGURE 17.4 Comparison of reflected wave transit time assessed by the timing of the inflection point on the carotid pressure waveform (A) or by the timing of the backward wave (BW) foot following wave separation analysis (B). The fall in BW foot time is more pronounced than inflection point time, but nevertheless approaches an asymptote at midlife that is well above zero. As a result, the distance to the "effective" reflecting site increases markedly as pulse wave velocity increases.

One might question why the early increase in CFPWV, prior to midlife, is associated with a reduction in RWTT and a marked increase in AI. During this age range, aortic Z_c is falling whereas peripheral artery wall stiffness, assessed as CBPWV, increases modestly (Fig. 17.3). Thus, it is reasonable to assume that the aorta-peripheral impedance gradient increases with age through midlife. The greater impedance mismatch will increase the amplitude of individual reflected waves occurring at the origins of various branch arteries arising from the aorta. Furthermore, shortening of the transit time will tend to synchronize timing of wave reflection from these distributed reflecting sites, steepening the slope of the rising edge of the aggregate reflected wave and adding to apparent augmentation of the central pressure waveform (Fig. 17.5). In light of potential adverse effects on the heart and brain of central pressure augmentation, additional research is needed to elucidate factors that contribute to constructive and destructive interference between reflected waves arising from various regions in the arterial system.[35]

Aortic pressure-flow measures and the heart

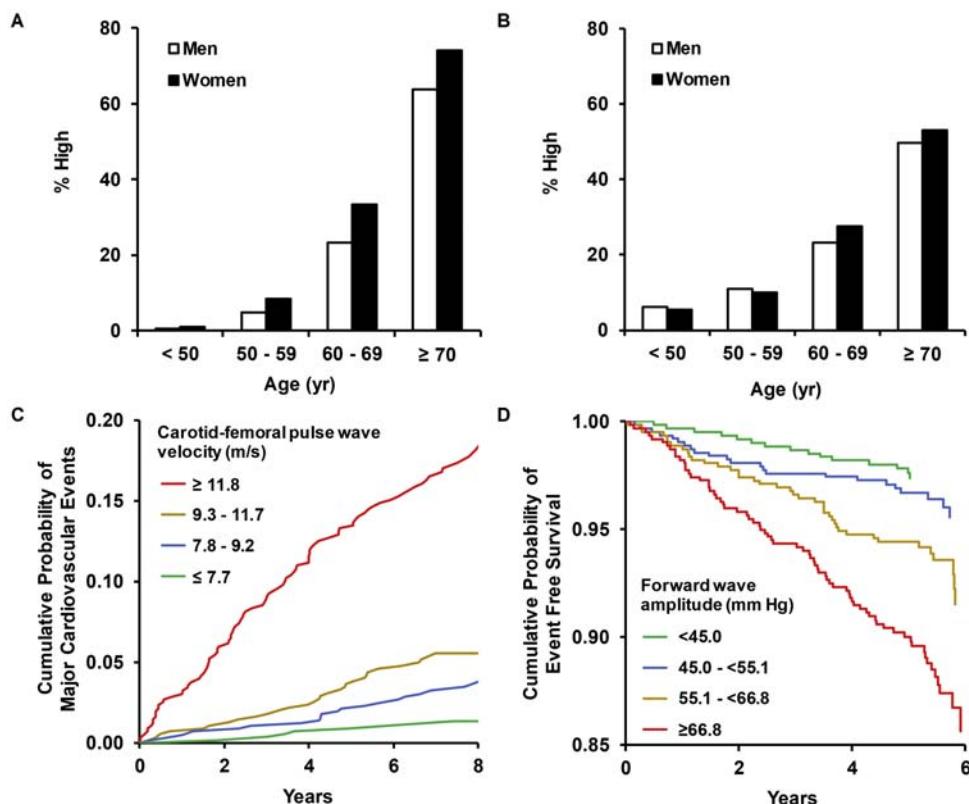
The normal arterial system is designed to isolate the heart, which is a pulsatile pump, from the high impedance peripheral resistance. This isolation is achieved by interposing

FIGURE 17.5 Comparison of ensemble averaged forward (solid line) and backward (dashed line) waveforms for individuals with lowest quartile as compared to highest quartile values for augmentation index (AI). Higher augmentation index is associated with a wider forward wave peak and earlier arrival of a backward wave that has a steeper rising edge. Overlap of the rising edges of the forward and backward waves in the high AI group results in marked augmentation of the measured pressure waveform. In contrast, overlap of the falling edge of the forward wave with the blunted and delayed rising edge of the backward wave results in minimal or negative augmentation of the measured pressure waveform. Vertical lines represent the timing of the foot of the backward wave.

the normally compliant aorta, with a low Z_c and PWV, between the heart and the network of conduit and resistance vessels. Low Z_c ensures low P_f amplitude in response to a given forward flow wave. Low PWV is associated with later return of a reflected P_b wave that has a blunted upstroke, leading to limited or negative pressure augmentation, meaning the late systolic pressure peak does not determine central systolic pressure. As the aorta stiffens, diffuse reflected waves return to the central aorta sooner and are more synchronized, resulting in a steeper P_b upstroke and greater late systolic pressure augmentation, which increases load on the LV and reduces stroke volume. However, it is important to note that a normal LV is protected from the effects of late systolic pressure augmentation because late systolic LV geometry (small chamber volume, high relative wall thickness) favors the heart, leading to low end-systolic wall stress even if AI is high.[36] Consistent with this protected late systolic geometry, in the FHS, higher AI was not associated with LV mass or wall thickness in models that adjusted for standard demographics and CVD risk factors, including MAP.[37] Similarly, P_b amplitude was not associated with LV mass or wall thickness in models that adjusted for forward wave amplitude, indicating that relative wave reflection was not related to LV mass. In contrast, higher P_f, which is closely related to aortic Z_c, was associated with higher LV mass and wall thickness. P_f peaks early in systole, when LV geometry is unfavorable (near diastolic volume, low wall thickness), resulting in an early peak in wall stress that is directly proportional to P_f amplitude and Z_c. Higher AI was associated with lower fractional shortening and higher LV filling pressures, assessed as mitral inflow early velocity divided by mitral annulus tissue Doppler early velocity, E/e', suggesting that an AI-related reduction in stroke volume was associated with a compensatory increase in filling pressure.[37] This is also consistent with the effect of wave reflection and late systolic loading on diastolic relaxation demonstrated in animal models[38] and supported by previous observations in the Asklepios study.[39] Such effects may explain the association between AI and incident AF in the FHS cohort.[40] For a more detailed discussion regarding the impact of the loading sequence on the LV, the reader is referred to Chapter 16.

Pressure-flow measures and cardiovascular disease events

Various aortic stiffness and pressure-flow measures have been related to incident hypertension and CVD events.[41−44] The relation between hypertension and aortic stiffness is often debated. Early studies suggested that arterial stiffness was a consequence of longstanding hypertension that increased stress and strain on the arterial wall and accelerated the aging process, leading to irreversible aortic

damage and stiffening. However, more recent studies have examined blood pressure and stiffness measures at two points in time and demonstrated that abnormal aortic stiffness precedes the development of hypertension.[43] In contrast, in FHS participants, once baseline stiffness was considered, blood pressure did not predict progressive stiffening of the aorta. Thus, aortic stiffness is now viewed as a cause rather than a consequence of hypertension, which remains the leading cause of premature death and disability in the world.


Higher aortic wall stiffness, as assessed by CFPWV, the current reference standard measure of stiffness, is associated with greater risk for a major CVD event and reclassifies risk in individuals at intermediate risk.[44,45] The relative risk associated with higher CFPWV is particularly high in younger individuals,[45] suggesting that CFPWV may represent an ideal risk screening measure at an age when aortic damage can still be mitigated or reversed with lifestyle modification and other interventions. Greater PP, P_f amplitude and higher aortic Z_c are also associated with higher CVD risk in models that adjust for standard risk factors, including CFPWV (Fig. 17.6).[41] In contrast, relative wave reflection, as assessed by AI or the global reflection factor (P_b/P_f), is not associated with higher risk. Aortic stiffness and excessive pressure pulsatility can damage small vessels, leading to dropout and impaired reactivity.[46] The latter damage to small vessels has been shown to partially mediate relations between aortic stiffness and CVD events.[42] Thus, stiffness of specifically the aorta has emerged as a novel CVD risk factor that requires consideration in risk prediction and management.

A number of studies have attempted to demonstrate that central systolic or PP provides incremental risk prediction over peripheral PP. However, several recent studies have shown that in middle-aged and older adults, central and peripheral systolic and PP are very highly correlated ($R \geq 0.9$).[16] In light of the overwhelmingly strong relation between the variables, it will be difficult to demonstrate that one provides incremental risk prediction over the other when both are considered in a single risk model.[17,37] However, as noted earlier, directly assessed central waveform features, such as AI derived by using carotid tonometry, have been related to reduced LV fractional shortening, elevated LV filling pressure, as assessed by the mitral E/e' ratio, and incident atrial fibrillation, suggesting that greater late systolic loading of the LV by a premature reflected wave may have important functional implications.[37,40]

A few studies have derived surrogate pressure-flow measures from pressure waveforms only by using a Windkessel model of the arterial system. By optimizing a normalized flow into a three-element Windkessel model, it

FIGURE 17.6 Prevalence of high values for carotid-femoral pulse wave velocity (A) and the primary (P1) peak of central pressure, a surrogate for forward wave amplitude (B) in the Framingham Offspring cohort. Kaplan—Meier plot of cumulative probability of a major cardiovascular disease event for groups defined by quartiles of carotid-femoral pulse wave velocity (C). Kaplan—Meier plot of cumulative probability of event free survival for groups defined according to quartiles of true forward wave amplitude assessed by using waveform separation analysis (D). For both measures of aortic stiffness, prevalence increases markedly with age and is associated with very high relative risk, indicating that disease burden attributable to aortic stiffness will increase dramatically over the next two decades as the population ages.

is possible to estimate a Windkessel or reservoir pressure as well as an excess pressure. The shape of the Windkessel pressure is closely related to the reflected pressure wave derived by using wave separation analysis on pressure and flow waveforms, although the amplitude is doubled.[47] The associated excess pressure is a surrogate for central aortic flow scaled by aortic Z_c, i.e., $Q*Z_c$. In theory, the combination of $Q*Z_c$ and half of the Windkessel pressure would represent P_f derived from pressure-flow analysis and the other half of the Windkessel pressure would represent P_b. Studies have variably shown that amplitudes of the excess pressure or Windkessel pressure are or are not related to incident CVD events.[48−50]

The foregoing Windkessel model has a few limitations that require additional work to determine whether the values have clear physiologic relevance. For example, a standard Windkessel model has a monoexponential pressure decay during diastole, when inflow is zero and outflow occurs with a time constant equal to the product of peripheral resistance and total arterial compliance. However, the decay of pressure is asymptotic on a terminal pressure (P_{inf}) that is unknown but thought to be related to critical closing pressure, which is the nonzero pressure at which flow through the vascular bed stops because the resistance vessels have occluded. Since the value for P_{inf} is unknown, it is optimized based on the shape of the pressure waveform in diastole. The problem that emerges is that optimized values for P_{inf}, which nearly equal to DBP in many cases, are much higher than physiologic values for critical closing pressure, which should be 20 mm Hg or less.[48] The reason for the model converging on such a high value for P_{inf} is quite straightforward. A monoexponential decay appears relatively linear at values for P that are moderately removed from the asymptote. So, if diastolic pressure is 80 mm Hg and the true asymptotic pressure is 20 mm Hg, the fitted diastolic pressure will appear linear and will not fit the true, concave diastolic pressure adequately. By increasing P_{inf}, the model can add concavity to modeled diastolic pressure decay, resulting in a close fit with observed pressure.[48] However, we know that an estimated P_{inf} that is nearly equal to DBP is unrealistic.

An alternative interpretation of the foregoing P_{inf} dilemma is that the diastolic time constant is not actually constant. If peripheral resistance (R_p) and total arterial compliance (C) are not constant, the time constant of pressure decay (R_p*C) will not be constant. We know that both R_p and C are sensitive to distending pressure, with both values (C and R_p) increasing as pressure falls in the physiologic range encountered during diastole. As a result, the diastolic time "constant" will continuously increase during diastole and the diastolic pressure decay will therefore appear more concave than predicted from a linear Windkessel model, resulting in excellent fitted pressures even when P_{inf} is fixed at a low physiologic value. A recent study that accounted for potential nonlinear relations of R_p or C with distending pressure confirmed that excellent waveform fits were possible and demonstrated relations of Windkessel measures with events.[48] In contrast, measures derived from the standard linear Windkessel model were not related to events. Thus, while a pressure-only approach has considerable appeal for straightforward point-of-care evaluation, it may be important to consider nonlinearities when performing pressure-only analysis of central aortic pressure-flow relations using a Windkessel approach.

Summary

Investigations of arterial stiffness and aortic pressure-flow relations have advanced our knowledge considerably over the past two decades. Studies have elucidated the remarkable ability of a normal, highly compliant aorta to limit simultaneously the pulsatile load on the heart as well as the small vessels. They have also demonstrated that aortic stiffening begins early in adulthood and can be associated with considerable excess risk well before the onset of a marked increase in PP and SBP that occurs after midlife, leading to the current epidemic of wide PP hypertension. Future research will define optimal approaches to detect and correct abnormal trajectories of arterial stiffness and pressure pulsatility and reduce the growing burden of disease that would otherwise be attributable to adverse effects of excessive arterial stiffness.

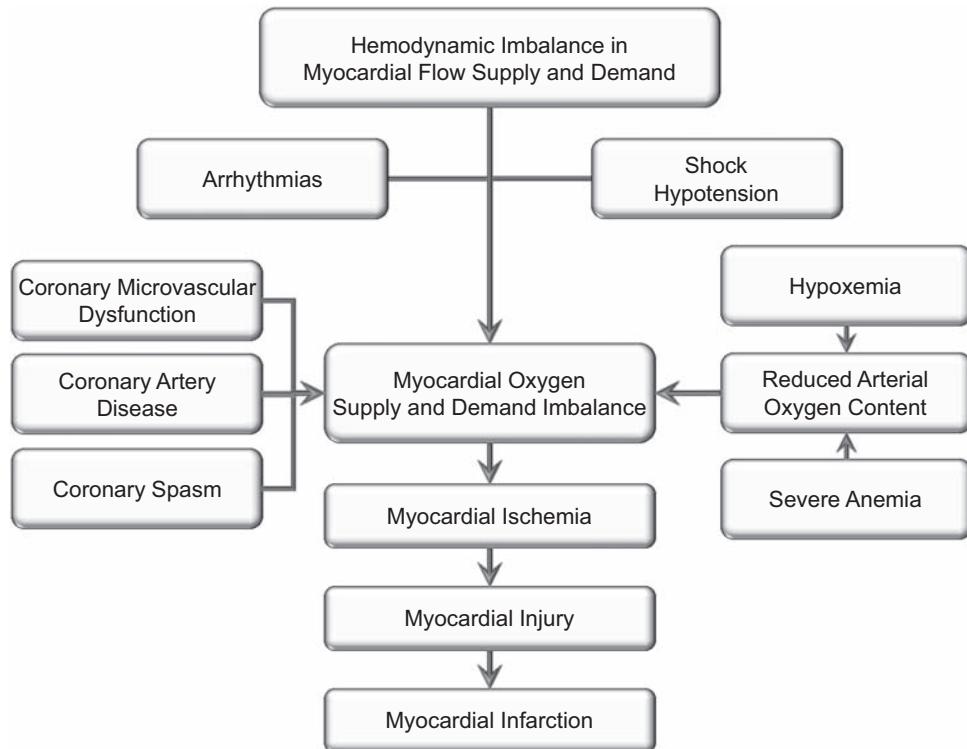
Chapter 18

Hemodynamic determinants of myocardial oxygen demand and supply

Lucia Salvi[1] and Paolo Salvi[2]

[1]Medicina II Cardiovascolare, AUSL-IRCCS di Reggio Emilia, Italy; [2]Istituto Auxologico Italiano, IRCCS, Cardiology Unit, Milan, Italy

Myocardial ischemia results from an imbalance between oxygen supply and demand. The ischemic myocardial damage or acute myocardial infarction (MI) related to atherosclerotic plaque rupture, ulceration, or erosion with resulting intraluminal thrombus in coronary arteries is certainly the best known and most studied type of cardiac ischemic event (Type 1 MI).[1] However, often ischemic myocardial damage or acute MI does not correspond to a significant hemodynamic obstruction of the coronary arteries, and can be caused by a functional imbalance between myocardial oxygen supply and demand (Type 2 MI).[1,2] The latter type of myocardial ischemic damage occurs due to numerous and very different etiopathogenetic mechanisms (Fig. 18.1), such as a fall in arterial oxygen content (severe anemia or hypoxemia), an insufficient blood flow to the myocardium in relation to the myocardial oxygen needs, arrhythmias, hypotension, coronary artery spasm, coronary microvascular dysfunction, or spontaneous coronary artery dissection.[3−5] All these above conditions can also lead to myocardial ischemic cell injury—detected as an increase in circulating biomarkers of myocardial damage—without however resulting in cardiomyocyte necrosis: these cases are referred to as myocardial injury, rather than MI.[1] Type 2 MI and myocardial injury are rather frequently seen in clinical practice and both are related to a poor outcome. Both are due to the same pathogenetic mechanism: the presence of a mismatch between myocardial oxygen supply and its consumption.

The heart is a muscular organ similar to a volumetric pump, as it develops its action through the alternative filling and emptying of a closed volume. During the cardiac cycle, a lower amount of energy is used to ensure the ventricular pump function; most of the energy consumption develops tension in the myocardial fibers and keeps them in this state, in addition to the occurrence of the reactions of the basal metabolism and the excitation-contraction processes.[6] The medium total myocardial oxygen consumption (MVO$_2$) under basal conditions is 250 mL/min, and may rise up to 3−4 L/min during physical activity. The greater the energy demands of the myocardium, the greater the blood flow must be, vice versa, the discrepancy between the two factors may lead to MI or myocardial damage.


In this chapter, we discuss the determinants of myocardial supply, demand and the balance between the two. The reader is referred to Chapter 39 for a discussion of the role of arterial stiffness and pulsatile hemodynamics in coronary artery disease.

Myocardial O$_2$ demand

The heart muscle needs oxygen for two reasons: an external, volumetric work, that is the mechanical activity that allows the pumping of an adequate amount of blood into the aorta, and an internal work, given both by the set of metabolic processes required for muscle metabolism and by the energy needed to develop the tension of the cardiomyocytes. About 75% of myocardial energy is used in processes to ensure the myocardial muscle contraction.[7,8] This mostly reflects ATP splitting associated with cross-bridge splitting during the isovolumic contraction and ejection phases of the cardiac cycle. A smaller amount of ATP is also consumed for calcium confiscation at the end of each contraction. The largest part (approximately 50%) of the MVO$_2$, occurs during the isovolumic contraction phase of the cardiac cycle, which has high energy demand.[9]

The amount of energy, and therefore oxygen, needed to perform both functions depends on:

— left ventricular afterload,
— systolic wall stress,
— heart rate,

FIGURE 18.1 Factors responsible for myocardial ischemia.

- contractility,
- depolarization,
- shortening against load (Fenn effect),
- supporting the state of activity,
- maintenance of cell viability in basal conditions.

Among these, heart rate, systolic pressure (or more specifically, myocardial wall stress which depends on both left ventricular pressure and instantaneous geometry), and left ventricular contractility are the major determinants of myocardial oxygen consumption. If any of these determinants doubled, coronary flow would need to increase by approximately 50%.[10] We next analyze these factors in detail.

Left ventricular afterload

Work (W), in physics, is the product of the component of the force (F) in the direction of the displacement and the magnitude of the displacement (d) caused by the force (W = F × d). The energy used to perform cardiac work is evaluated by measuring the consumption of O_2. In rest condition, an average O_2 consumption of 0.08–0.10 mL/g/min can be considered: in practice, a heart weighing 300 g consumes $\sim$24–30 mL O_2/min, only for volumetric work. Since pressure (P) is defined as a force acting on a surface (A), work is defined as the product of the volume of fluid (V) and the pressure required to move the fluid

$$Work = F \times d = P \times A \times d = P \times V$$

Therefore, ventricular stroke work can be estimated as the product of mean intraventricular systolic pressure during ejection and stroke volume (SV). In a normal heart, mean intraventricular systolic pressure can be approximated by the mean aortic systolic pressure (MAP). Thus:

$$Left\ Ventricular\ Stroke\ Work = MAP \times SV$$

Stroke work is thus best represented by the ventricular pressure-volume diagrams, where stroke work is the area within the pressure-volume loop. This area represents the external ventricular work to eject blood into the aorta. The mean arterial pressure therefore represents one of the major elements on which cardiac work depends, so much so that arterial pressure is taken as a useful surrogate of left ventricular afterload in clinical practice.[11] However, the pulsatile aspect of afterload, and the pressure distribution in systole versus diastole (both of which impact MAP) also has an important effect on afterload, particularly in situations of aortic stiffening with high pulse pressure. Myocardial afterload is also highly related to the stress on myocardial cells. The afterload on individual muscle fibers can be expressed as ventricular wall stress.

Systolic wall stress

Myocardial wall stress is another major critical determinant of MVO_2, so much so that if the tension of the myocardial wall doubles, MVO_2 doubles. The wall stress is the intensity of the force on the muscular wall which, extended

by the volume it contains, would tend to shorten the ventricular circumferences. Being determined by the volume from which the ventricle is extended in end-diastole, wall stress is an expression of preload. It is proportional to the state of deformation to which the parietal myocardium is subjected, therefore it depends on endoventricular pressure, radius of the circumference, and thickness of the wall itself.[12] From a mathematical point of view, the relationship between these components is described by the Laplace law:[9–14]

Contractility

Together with preload and afterload, contractility constitutes the third determinant of cardiac output. The ability to develop muscular tension depends on the efficiency of the sarcomere, originating from the number of actin-myosin interactions present simultaneously and the speed with which the interactions occur.

As in the other striated muscles, these processes are mainly regulated by calcium (Ca^{++}): at the passage of

$$\text{Myocardial Wall Stress} = \frac{\text{Left Ventricular Cavity Pressure}}{\frac{1}{3}\ln\left(1 + \frac{\text{Ventricular Wall Volume}}{\text{Ventricular Cavity Volume}}\right)}$$

From this formula, it can be deduced that the moment of maximum wall stress in the cardiac cycle is the protosystole (i.e., early systole): in fact, at that point of the cardiac cycle, there are the largest endocavitary dimensions, and the smallest wall thickness (as discussed in more detail in Chapter 16).[15] From the above formula, we can derive another concept: the origin of concentric hypertrophy in the presence of chronic overload. If the wall stress per unit of myocardial mass is reduced with increasing wall thickness, the consumption of oxygen per unit of myocardial mass is also reduced. However, this is only an apparently compensatory mechanism. Actually, if the consumption of oxygen per unit of myocardial mass decreases, on the other hand, there is an increase in the global mass, therefore—due to the mechanisms discussed in the next paragraphs—an increase in global O_2 consumption results.

Heart rate

The factors previously described provide their contribution in determining the myocardial oxygen need for each cardiac contraction. It is therefore intuitive that the greater the number of contractions the heart performs per minute, the greater the energy required. Moreover, heart rate is inversely proportional to the diastolic time, which, as we will see below, is the interval in which subendocardial perfusion occurs. Therefore, paradoxically, the increase in heart rate, even though it requires a higher MVO_2 per minute, is inevitably associated with a lower oxygen supply to the heart muscles. In athletes and individuals trained to perform sustained aerobic activity, the heart develops different mechanisms to support the increased demand without such a marked increase in heart rate, such as increasing cardiac contractility.

the action potential that depolarizes the cell, there is an impressive entry of Ca^{++}, which constitutes up to 10%–50% of the intracytoplasmic pool; to this quantity is added the Ca^{++} released by the sarcoplasmic reticulum mediated by concentration-sensitive Ca^{++} channels (ryanodine receptors, RyR2). This "calcium wave" gives rise to an endergonic reaction: the chemical energy, supplied by ATP, is converted into mechanical energy, activating the actin-myosin lever system. A repetitive interaction of the transverse bridges with the actin filaments is required to achieve appreciable shortening during contraction. Then, each transverse bridge must attach, rotate, detach, and then reattach at a more distant point of the thin filament. The contractile cycle therefore requires at least four stages, each of which is accompanied by the hydrolysis of one or more ATP molecules, a reaction that requires the consumption of oxygen to take place. Relaxation also requires ATP hydrolysis, in the dissociation of actin-myosin bridges.

From all these elements, it can be understood how much the oxygen consumption necessary for the hydrolysis of ATP that allows the muscle contraction itself to function is not a negligible energy expenditure in sustaining the heart pump. Luckily for us, the heart muscle is a machine with a good performance, in fact no more than 30%–50% of this energy is dissipated as heat. Importantly, the relative amount of O_2 consumed during the cardiac cycle that is not transformed into mechanical activity is highly variable between individuals, which has important implications for our understanding of the limitations of the left ventricular pressure-volume area as an indicator of myocardial O_2 consumption when comparisons are made between individuals (as discussed in more detail in Chapter 15).

Depolarization

The action potential wave triggers the entry of Ca^{++} into the cell, but also the propagation of the action potential itself requires a certain energy requirement, and therefore oxygen consumption. In fact, the passage of the depolarization wave occurs upon activation of the voltage-dependent counter-concentration channels that pump Ca^{++} out of the myocyte. It has been studied that in a cardiac cycle the amount of oxygen necessary for the depolarization of the whole heart is approximately 0.5% of the MVO_2 consumed by a healthy heart.[16]

Shortening against load (Fenn effect)

When a muscle contracts isometrically, it produces a certain amount of heat, which increases if the contraction occurs against a load: this effect is called the Fenn effect.[17] Cardiac mechanics is an example of a contraction against load, consisting of the blood volume that must be pumped into the aorta. During shortening, the force exerted and the energy it consumes are greater when there is a greater load; the muscles will therefore have to mobilize a greater amount of energy, or a greater MVO_2. More heat than expected in vitro is actually produced in vivo at the end of a contraction against load. This heat is called "recovery heat" and is due to the metabolic processes that regenerate the compounds used for contraction, which essentially depend on oxidation reactions.

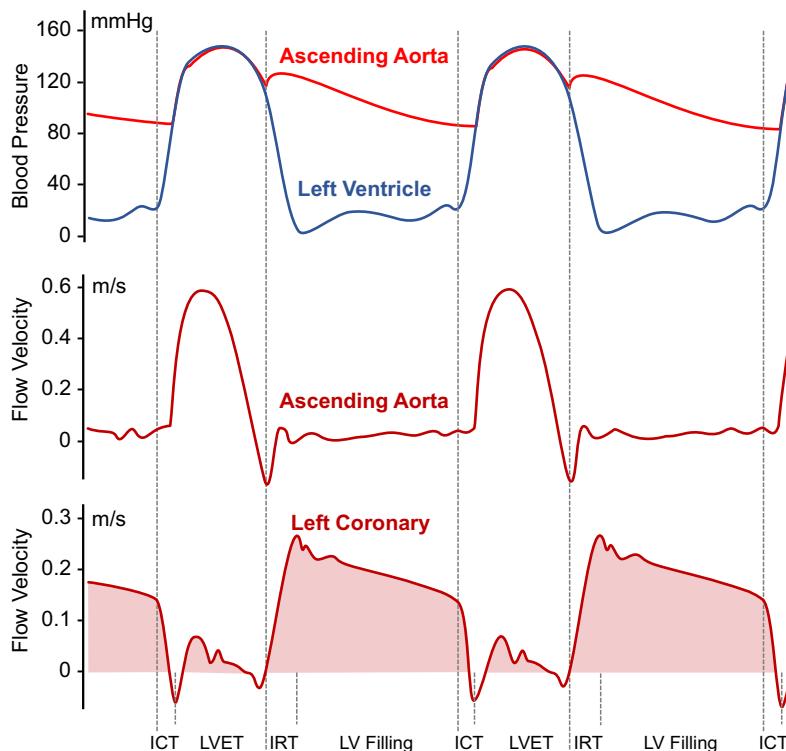
Supporting the state of activity

The energy we discussed in the previous paragraphs can only be released from the sites where muscle tension is generated. In other words, it is necessary that a certain number of ATP-dependent reactions occur that allow the persistence of a minimum number of bridges between thick and thin filaments for the contractile elements to exert a certain constant tension.

Maintenance of cell viability in basal conditions

As in all animal tissues, chemical reactions continuously occur in the myocardium, which serve to maintain cellular integrity. Among these there is, for example, cellular respiration, which is associated with a certain production of heat, defined as resting heat, or internal work. This oxygen consumption cannot be reduced: the efficiency of internal work is the first element on which the well-being of the entire organ depends. MVO_2 represents 5%−8% of resting metabolism, equivalent to about 10 mL of oxygen per 100 g of ventricular mass.

Myocardial O_2 supply

In general, tissue perfusion is kept constant to ensure a quick and efficient transport of oxygen, nutrients, and waste material between the intravascular and extravascular space. However, tissue perfusion in the myocardium is not constant and depends on the cardiac phase and the thickness of tissue considered. Coronary flow occurs mostly during ventricular diastole (Fig. 18.2), as during ventricular systole, it is severely diminished by vessel compression from the myocardial contraction and other factors discussed below.


In undamaged coronary artery condition, the blood supply to the myocardium mainly depends on four factors:

- the coronary diastolic blood pressure, which in the absence of coronary artery disease is equal to the diastolic pressure in the ascending aorta,
- the intra-vessel pressure gradient present in diastole between the coronary ostium and their terminal branches at the subendocardial level,
- the left ventricular intracavitary pressure,
- the duration of diastole.

At the beginning of the isovolumic systole, there is a sudden and rapid rise of the ventricular pressure curve, and, at the same time, an instantaneous interruption of the coronary flow, as the semilunar valves are still closed. This systolic flow stop is due to the sum of two extravascular compressive forces: (a) the pressure caused by the contraction of myocardial muscle on the intracardiac vessels and (b) the intraventricular pressure transmitted to the myocardial wall. This compressive pressure is maximum at the subendocardial layers, reaching values close to zero at the subepicardium.

As such, blood flow to subendocardial layers is virtually absent in systole, even though subepicardial layers remain perfused. Subendocardial perfusion therefore occurs mostly, if not completely, during diastole. It is therefore easy to understand the crucial role of two factors in maintaining the viability of the subendocardium and an efficient contractile function of left ventricle: (i) the duration of the diastolic phase and (ii) the perfusion (aortic) pressure in diastole. Diastolic time is close related to heart rate,[18] so, in conditions of hemodynamic instability, a rapid increase in heart rate can cause a dramatic fall in myocardial perfusion.

For a given heart rate, subendocardial perfusion largely depends on the coronary diastolic pressure. In absence of coronary hemodynamically significant stenosis, the diastolic pressure in coronary arteries is equal to diastolic pressure in the ascending aorta. At the level of the subendocardial layers, perfusion is however opposed by the intracavitary pressure of the left ventricle. Therefore, subendocardial

FIGURE 18.2 Relationships between left ventricular pressure and aortic pressure (upper panel), aortic blood flow velocity (medium panel) and left coronary flow velocity related. The close relationship between coronary flow and the area between the aortic and ventricular pressure curve in diastole is evident. *ICT*, isovolumic contraction time; *IRT*, isovolumic relaxation time; *LV*, left ventricular; *LVET*, left ventricular ejection time.

coronary flow depends on the pressure gradient in diastole between the coronary artery intravascular pressure and left ventricular diastolic pressure.

The wave intensity analysis (WIA) seems to be a promising tool in clarifying the dynamics in coronary blood flow and to characterize the interaction between myocardium and coronary blood flow at each point within the cardiac cycle. The wave intensity is defined as the product of the change in pressure (dP) times the change in flow velocity (dU), at a particular point in the cardiac cycle, during a defined time interval (dt); i.e., $WI = (dP/dt) \times (dU/dt)$. WIA is a time-domain analysis. On the basis of recordings of coronary arterial pressure and velocity, WIA correlates pressure and flow in the aorta and in the coronary artery instant by instant, through the analysis of direction, intensity and type of waves present in a given point of the coronary circulation,[19] estimating the role of forward and backward waves at every time during the cardiac cycle.[20]

WIA helps to better understand the different flow waveform between the ascending aorta and coronary arteries, as evident in Fig. 18.2. The coronary flow velocity waveform has a particular and original feature. Left ventricular systolic contraction greatly increases coronary resistance to antegrade flow, thereby preventing a significant increase in coronary flow velocity during systole and inducing backward compression waves. During early

diastole, the re-expansion of the intramyocardial blood vessels, which are compressed by ventricular contraction during systole, generates a backward decompression wave sucking blood into the coronary artery from the distal vessel, causing an accelerative force on blood flow, coinciding with the fall in intracoronary pressure.[21]

Bender et al.,[22] studying variations of coronary blood flow during exercise in large-sized animals, supported the diastolic nature of coronary flow and showed two moments of retrograde flow. The first of these is present at rest and is named early retrograde coronary blood flow, as it is located at the isovolumic systole; at this point in the cardiac cycle, the inversion of flow increases with cardiac contractility and coronary blood volume and decreases as the aortic pressure (coronary perfusion pressure) rises. The second moment, named late retrograde coronary blood flow, appears during moderate exercise (walking at 5 km/h) and is concomitant with the widening of the anterograde aortic decompression wave. Both the early and the late retrograde coronary blood flow increase with the intensity of physical exercise.

Diastolic pressure decay

In addition to the value of the telediastolic (i.e., late diastolic) pressure, a fundamental determinant of the subendocardial flow is the decay of blood pressure during diastole[23]: the speed and the mode by which the pressure

decreases during the diastolic phase of cardiac cycle. The gradual reduction of blood pressure during diastole may be described using an exponential decay curve, by the equation:

$$P(t) = P_0 e^{-\lambda t},$$

where P_0 is the diastole starting pressure, t is the interval from the beginning of the diastole, and λ is the exponential decay constant. The shape of this hypothetical decay is related with aortic characteristics.

Arterial stiffening affects the decay in blood pressure during diastole in at least two ways. Reducing the Windkessel effect results in a rapid reduction in diastolic blood pressure, so in a rapid diastolic decay.[24] On the other hand, the early arrival of backward (reflected) waves to the ascending aorta during the systolic phase leads to a further rapid decay of blood pressure in diastole. A rapid diastolic pressure decay is associated with lower values of mean diastolic blood pressure. Since subendocardial oxygen supply depends on the area below the diastolic phase of arterial pulse waveform in ascending aorta, a rapid decay of blood pressure in diastole is associated with lower subendocardial oxygen supply.[25]

Coronary blood flow regulation

The ATP consumption to provide energy to the myocardium is reconstituted by oxidative phosphorylation from different energy substrates, especially fatty acids. The myocardium possesses a high aerobic metabolism, demonstrable by the large number of mitochondria present in the tissue. Actually, it is not able to use anaerobic glycolysis, except for short periods of time, and therefore the myocardial metabolism depends on an adequate and continuous supply of O_2. In the myocardium, the extraction of O_2 is, under basal conditions, about $8-10$ mL/min/100 g of tissue, which corresponds to $\sim 75\%$ of the amount contained in the arterial blood. Since extraction is particularly high, increases in myocardial O_2 consumption must be met mainly by an increase in coronary flow.

Different mechanisms affect the regulation of blood flow to the myocardium, depending on the increased or reduced energy needs. We now mention the most relevant elements among these:

Coronary self-regulation

First, the coronary circulation is able to respond to rapid and abrupt hemodynamic changes in the cardiovascular system while maintaining organ perfusion at constant levels, despite changes in thrust pressure present in the ascending aorta: this flow stabilization capability is called self-regulation.[26] Perfusion in normal myocardium can be kept relatively constant over a wide range of mean pressure values in the aorta, ranging from about 130 to 40 mmHg. Exceeding the lower or upper limit of this range, the flow respectively decreases or increases very quickly, exposing tissues to a considerable risk of ischemia, even at rest.[27]

In the case of chronic hypertension and left ventricular hypertrophy, the pressure range in which it is present effective self-regulation is strongly reduced, especially at the subendocardium. In the second case, the limitation is also due to the reduction of the capillary density, which reduces the absolute maximum increase in blood supply for each gram of heart tissue in the setting of increased oxygen demand.[10]

Endothelial vasoactive mediators

The endothelium is one of the main elements regulating the supply of oxygen to the heart tissue. It performs this function by producing both powerful vasodilators (EDRF, NO, and EDHF) and vasoconstrictors (ET-1). Under physiological conditions, the endothelium produces vasodilators when the metabolic demands are elevated, such as during physical exercise, cold, tachycardia, and mental stress. An altered vasomotor response characterized by a lack of increase or even a decrease due to paradoxical vasoconstriction occurs with endothelial dysfunction. Endothelial dysfunction is very common in subjects with increased cardiovascular risk, such as systemic arterial hypertension. In fact, endothelium-dependent vasodilation is particularly important in the smaller vessels, that is, in the resistance vessels: these, although normally not directly affected by atherosclerotic processes, are strongly compromised in endothelial dysfunction.[10] A number of studies suggest that endothelial dysfunction and acute microcirculatory dysfunction may play a central role in Takotsubo syndrome.[28]

Metabolic regulation

The products of the cardiac aerobic metabolism released by the myocardium are other indicators of the muscle's need for oxygen. Adenosine is the main myocardial signal: its accumulation indicates a lack of substrates for mitochondrial oxidative phosphorylation; therefore, it is a signal of the need to increase the oxygen supply, and indeed exhibits potent vasodilatatory activity. Other vasoactive factors with similar action released by the myocardium are nitrogen monoxide, prostaglandins, and potassium ions.

Arterial oxygen content

Myocardial oxygen supply depends not only on coronary blood flow but also on the arterial oxygen content.[29,30] Even in the presence of satisfactory subendocardial flow, a reduction in the amount of oxygen in the blood due to

severe anemia or hypoxemia can compromise the oxygen supply to the subendocardium. When considering the myocardial oxygen supply, it is therefore always necessary to consider the two components: the flow supply and the oxygen supply.

The arterial oxygen content (CaO_2) is the total amount of oxygen in 1 dL of blood. Considering that each g/dL hemoglobin (Hb) can carry 1.34 mL of O_2 and 0.0031 mL of O_2 are dissolved in 1 dL of blood for every 1 mmHg of arterial O_2 tension (pO_2), CaO_2 can be estimated by:

The resulting alterations in the viscoelastic properties of the arterial system cause a stiffening in the arterial wall and a distensibility reduction in the aorta and large arteries. Under these conditions, the amount of SV stored by the aorta during the systolic ejection time decreases, even drastically whereas most of the blood ejected at each systole is "pushed" directly toward the periphery of the vascular system. However, hemodynamic phenomena in the arterial tree are more complicated, since they include the effects of wave travel through the arterial wall at a finite wave

$$CaO_2(mL\ O_2\ /\ dL) = (O_2\ carried\ by\ Hb) + (O_2\ in\ solution) = 1.34\ Hb \times O_2 saturation + 0.003\ pO_2$$

Aortic stiffness

In the previous paragraph we described the hemodynamic cardiac components that play a direct role in determining the O_2 supply and demand ratio at myocardial muscle. Now it is necessary to consider another key determinant in the process: the aorta. Aortic function and cardiac-aortic coupling in fact profoundly influence the subendocardial MVO_2 balance, both in healthy subjects and with cardiovascular pathologies.

Watanabe et al.[31] described clear signs of regional myocardial dysfunction and a reduction in coronary flow reserve following a mechanical increase in aortic stiffness. These researchers reduced aortic distensibility in dogs by banding the thoracic aorta with adjustable plastic rings and studied the changes in coronary flow. Even in the absence of coronary stenosis, decreased aortic compliance was shown to be associated with inadequate subendocardial oxygenation, which could be further impaired in the presence of coronary stenosis.[32] Indeed, as discussed throughout this textbook, the aorta and large arteries play a major role in the regulation of blood pressure and peripheral blood flow (Fig. 18.3). It is well known that large arteries not only have a passive function in relation to the transfer of oxygenated blood from the heart to the periphery but also exert an important buffering function, as they are able to "cushion" left ventricular SV due to their viscoelastic properties. Aorta and large arteries have the task of damping the pulsatile output of the left ventricle and switch the intermittent systolic ejection into continuous blood flow at the capillary level. This be intuitively explained with the "Windkessel phenomenon": after ejection of SV and closure of the aortic valves, a great quantity of blood remains "stored" in the aorta and large arteries; the potential energy stored in the walls of the aorta in systole then turns into kinetic energy in diastole, pushing the stored blood into the bloodstream: the aorta behaves like a sort of "diastolic pump" after the aortic valve closure.

velocity, as well as wave reflections throughout the arterial tree.

In general, increased aortic stiffness has three consequences that impact coronary supply/demand:

- increase in systolic blood pressure,
- decrease in diastolic blood pressure,
- increase in pulse wave velocity.

Increase in systolic blood pressure

Increase aortic stiffness leads to increased pulsatile load and an increase in systolic blood pressure (when left ventricular function is normal). If systolic load is elevated, the left ventricle must contract more energetically to maintain adequate SV, which can only be generated at a higher systolic pressure. Thus, an increase in systolic blood pressure related to an increase in left ventricular afterload is intimately linked to a rise in cardiac work and consequently to an increase in MVO_2. The development of left ventricular hypertrophy and progression toward the resulting left ventricular failure predispose to an increase in left ventricular diastolic pressure and to a prolongation in isovolumic contraction time, further reducing the diastolic subendocardial pressure gradient and perfusion time: this lead to a reduction in subendocardial oxygen supply.

Decrease in diastolic blood pressure

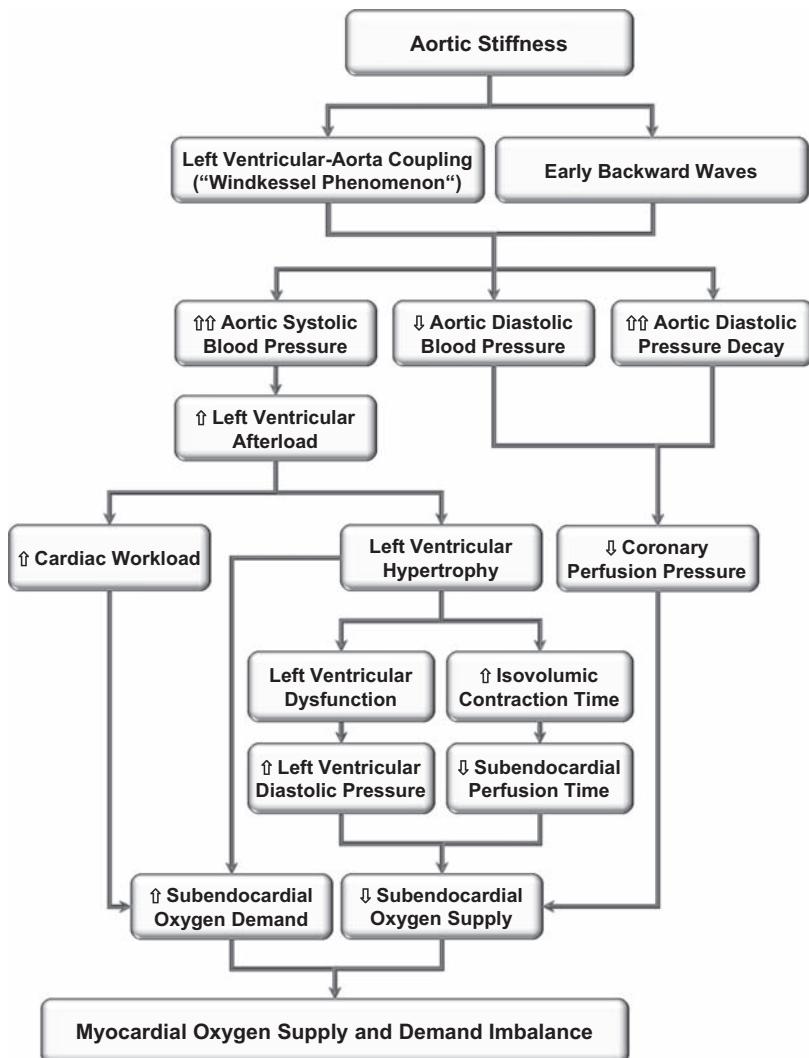
A reduced diastolic pressure in the ascending aorta may lead to a reduction in subendocardial diastolic blood flow.[33] In the absence of coronary hemodynamically significant coronary stenosis, the diastolic pressure in coronary arteries is equal to diastolic pressure in the ascending aorta. In fact, subendocardial coronary flow does not depend only on diastolic time but also on aortic diastolic pressure and on the pressure gradient in diastole between coronary arteries intravascular pressure and left ventricular pressure.


FIGURE 18.3   From arterial stiffening to myocardial ischemia.

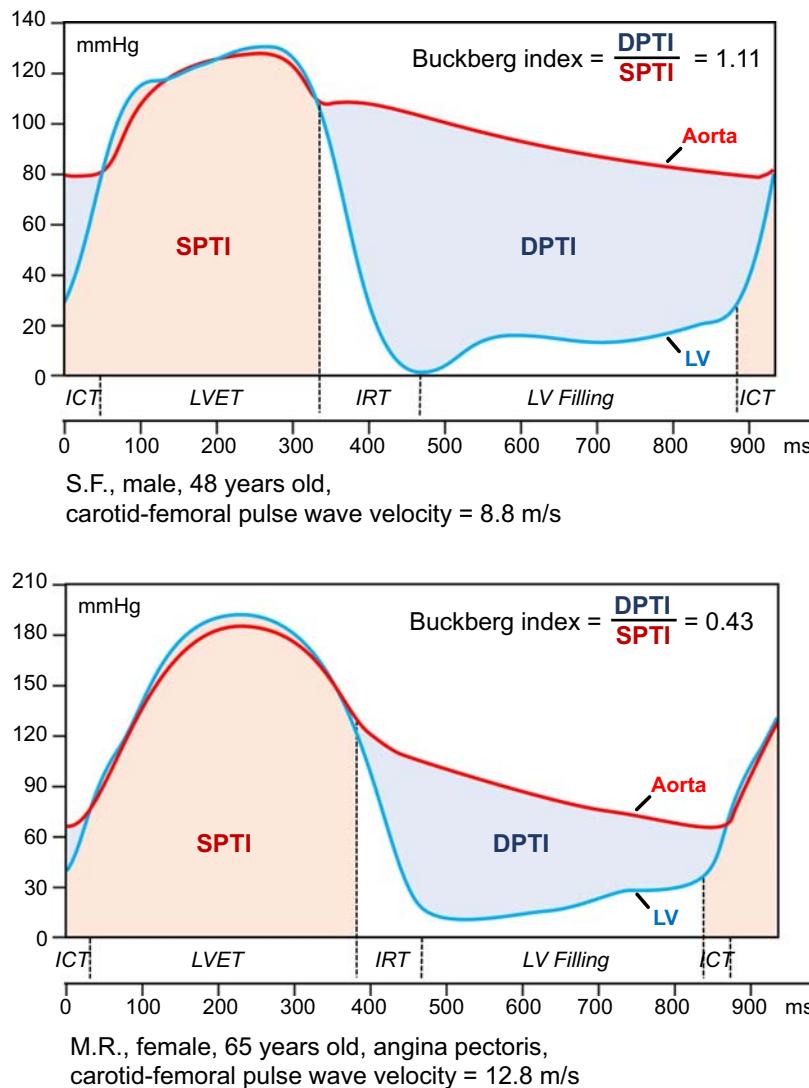
Increase in pulse wave velocity


The pressure and flow at the ascending aorta are the result of two main components: a forward and a backward (reflected) component, given numerous reflection sites present at the periphery of the tree arterial tree. In the presence of high aortic stiffness, there is an earlier superimposition of the two waves, in early-to-mid systole, producing a further increase in systolic blood pressure and pulse pressure values.

The myocardial oxygen supply: demand index

Currently, for the diagnosis of myocardial ischemia, we have specific and sensitive biomarkers available and diagnostic investigations are more and more accurate. While the diagnostic imaging ensures an accurate identification of obstructive coronary artery disease, oxygen arterial content is clearly quantifiable and arrhythmias can be easily recorded, we have few tools available readily assess hemodynamic imbalances between myocardial oxygen supply and demand.

At the beginning of the 70 s, G.D. Buckberg and J.I.E. Hoffman introduced a useful index to assess cardiac ischemic risk that reflects the relationship between subendocardial oxygen supply and demand, also known as the Buckberg index or SEVR (subendocardial viability ratio). This index was defined by analyzing left ventricular and aortic pressure curves during invasive studies on large animals and humans. In truth, already in the late 1950s, S.J. Sarnoff and E. Braunwald focused their studies on oxygen consumption of canine heart, highlighting how the product of the aortic mean pressure during the systolic phase and the duration of systole (TTI, the tension time index) represents a reliable index of total tension developed by the

FIGURE 18.4 Systolic pressure-time index (SPTI, salmon area) and diastolic pressure-time index (DPTI, light blue area) in adult with preserved viscoelastic properties of the aorta (upper panel), and in old hypertensive patient with increased aortic stiffness (lower panel). Left ventricular (LV) pressure (blue line) and aortic arterial pressure (red line) were recorded by invasive catheterization. Buckberg index was calculated as DPTI and SPTI ratio. *ICT*, isovolumic contraction time; *IRT*, isovolumic relaxation time; *LVET*, left ventricular ejection time.

myocardium per beat. The area beneath the systolic portion of the aortic pressure curve was then used as an index of the actual myocardial fiber tension, showing a close correlation with myocardial O_2 utilization.[34,35] Buckberg and Hoffman, taking advantage of these previous studies, tried to formulate an index capable of helping the clinician in the diagnosis of subendocardial ischemia in the absence of anatomical obstruction of the coronary arteries, resulting from a discrepancy between metabolic needs and available blood supply.

Whereas the analysis of the systolic phase of the ventricular pressure curve provides an indication on the myocardial oxygen requirement, the analysis of the diastolic phase provides indications on the oxygen supply to the myocardium (Fig. 18.4).

As stated above, the area below the ventricle pressure curve during the whole systolic phase, from the onset of ventricular systole to the dicrotic notch, is closely related to myocardial oxygen demand.[29] This area is known as systolic pressure-time index (SPTI, analogous to the Sarnoff's TTI) and includes both isovolumic contraction time and left ventricular ejection time.[29] SPTI mainly depends on left ventricular ejection time, ejection pressure, and myocardial contractility. If we multiply SPTI by the heart rate, we obtain a surrogate of the left ventricular oxygen requirement per minute.

The area between aortic and ventricular pressure curve during the diastolic phase DPTI (SPTI) is closely related to the blood supply to the subendocardium. DPTI mainly depends on the coronary arterial diastolic pressure,[36] the

pressure gradient in diastole between coronary arteries and left ventricular pressure, and the duration of diastole.[37]

These two areas therefore reflect subendocardial oxygen supply (DPTI) and demand (SPTI), and their ratio is a useful index of supply/demand:

$$\frac{DPTI}{SPTI} = \frac{Supply}{Demand}$$

Buckberg index corrected for cardiac mass

In the presence of myocardial hypertrophy, it is to be noticed a reduction of capillary density, that in an oxygen supply/demand ratio inevitably increases the denominator, resulting in a reduction of the final outcome. In order to improve the estimation of SPTI, recently Hoffmann and Buckberg[38] suggested to multiply SPTI by the relative left ventricular mass index (rel.LVMI) as determined by echocardiography. Thus, Buckberg index can be rewrite as follows:

$$Buckberg\ index = \frac{DPTI}{SPTI \times rel.LVMI}$$

Buckberg index corrected for arterial O_2 content

In the evaluation of the oxygen supply to the sub-endocardium, it has been taken in account the oxygen content of in arterial blood: the blood flow, being equal, the supply of oxygen can be significantly reduced in hypoxic hypoxia conditions as in the case of anemia, hypoxemic respiratory failure, or hypobaric hypoxia. Under these conditions, it is appropriate to correct the Buckberg index multiplying DPTI for arterial O_2 content (CaO_2).[30] Therefore the Buckberg index should be rewritten more correctly as:

$$Buckberg\ index = \frac{DPTI \times CaO_2}{SPTI \times rel.LVMI}$$

Reference values for the Buckberg index

For Buckberg index values less than 0.45, the ratio between subendocardial flow and subepicardial flow, per gram, is reduced in the left ventricle as a signal of insufficient sub-endocardial vascularization.[29,30,39] However, due to the coronary autoregulation, above this value, a linear relationship between Buckberg index and coronary blood flow does not exist. Indeed, for values greater than 0.45, the degree of subendocardial vascularization remains almost constant and the ratio between subendocardial flow and subepicardial flow, per gram, remains within the reference range.

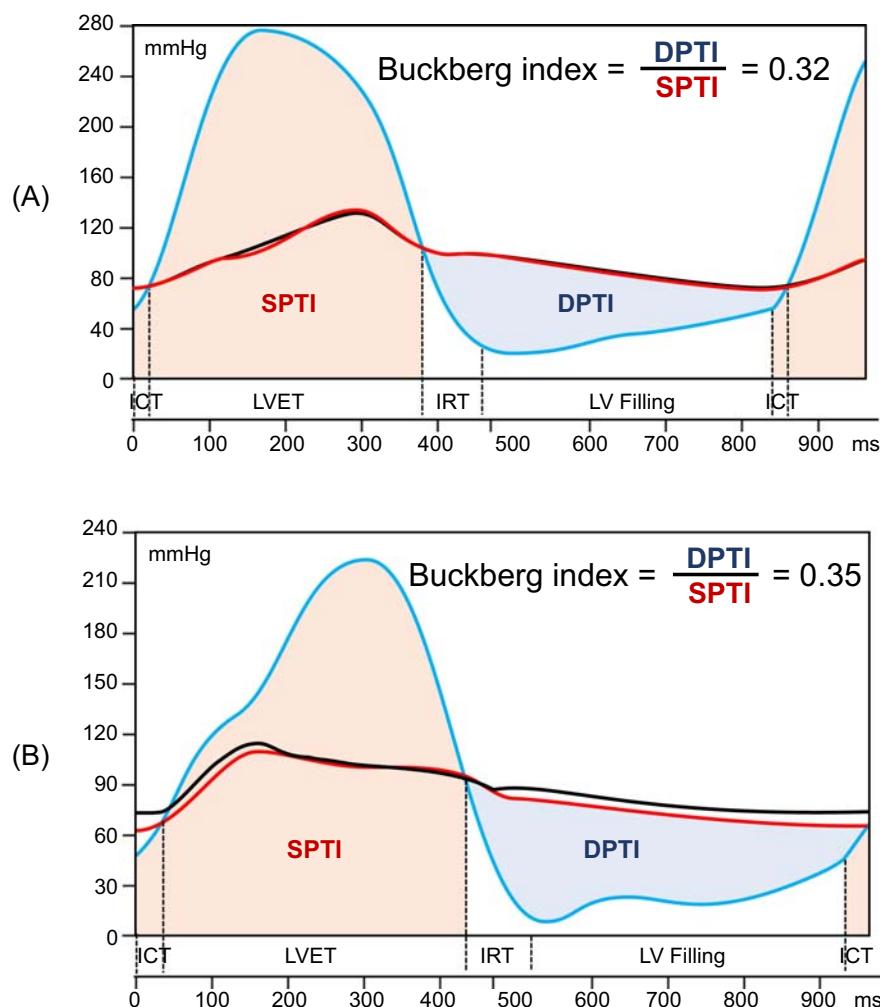
Since oxygen supply to the subendocardium depends not only on coronary blood flow but also on the arterial oxygen content, it is also necessary to consider the critical threshold of Buckberg index in relation to the arterial oxygen content (Buckberg index $\times CaO_2$). According to this formula, the "critical" value for Buckberg index corresponds to 9.0. Buckberg index $\times CaO_2$ values are associated with insufficient oxygen supply to the sub-endocardium, in relation to its needs.

Buckberg index estimated by arterial tonometry

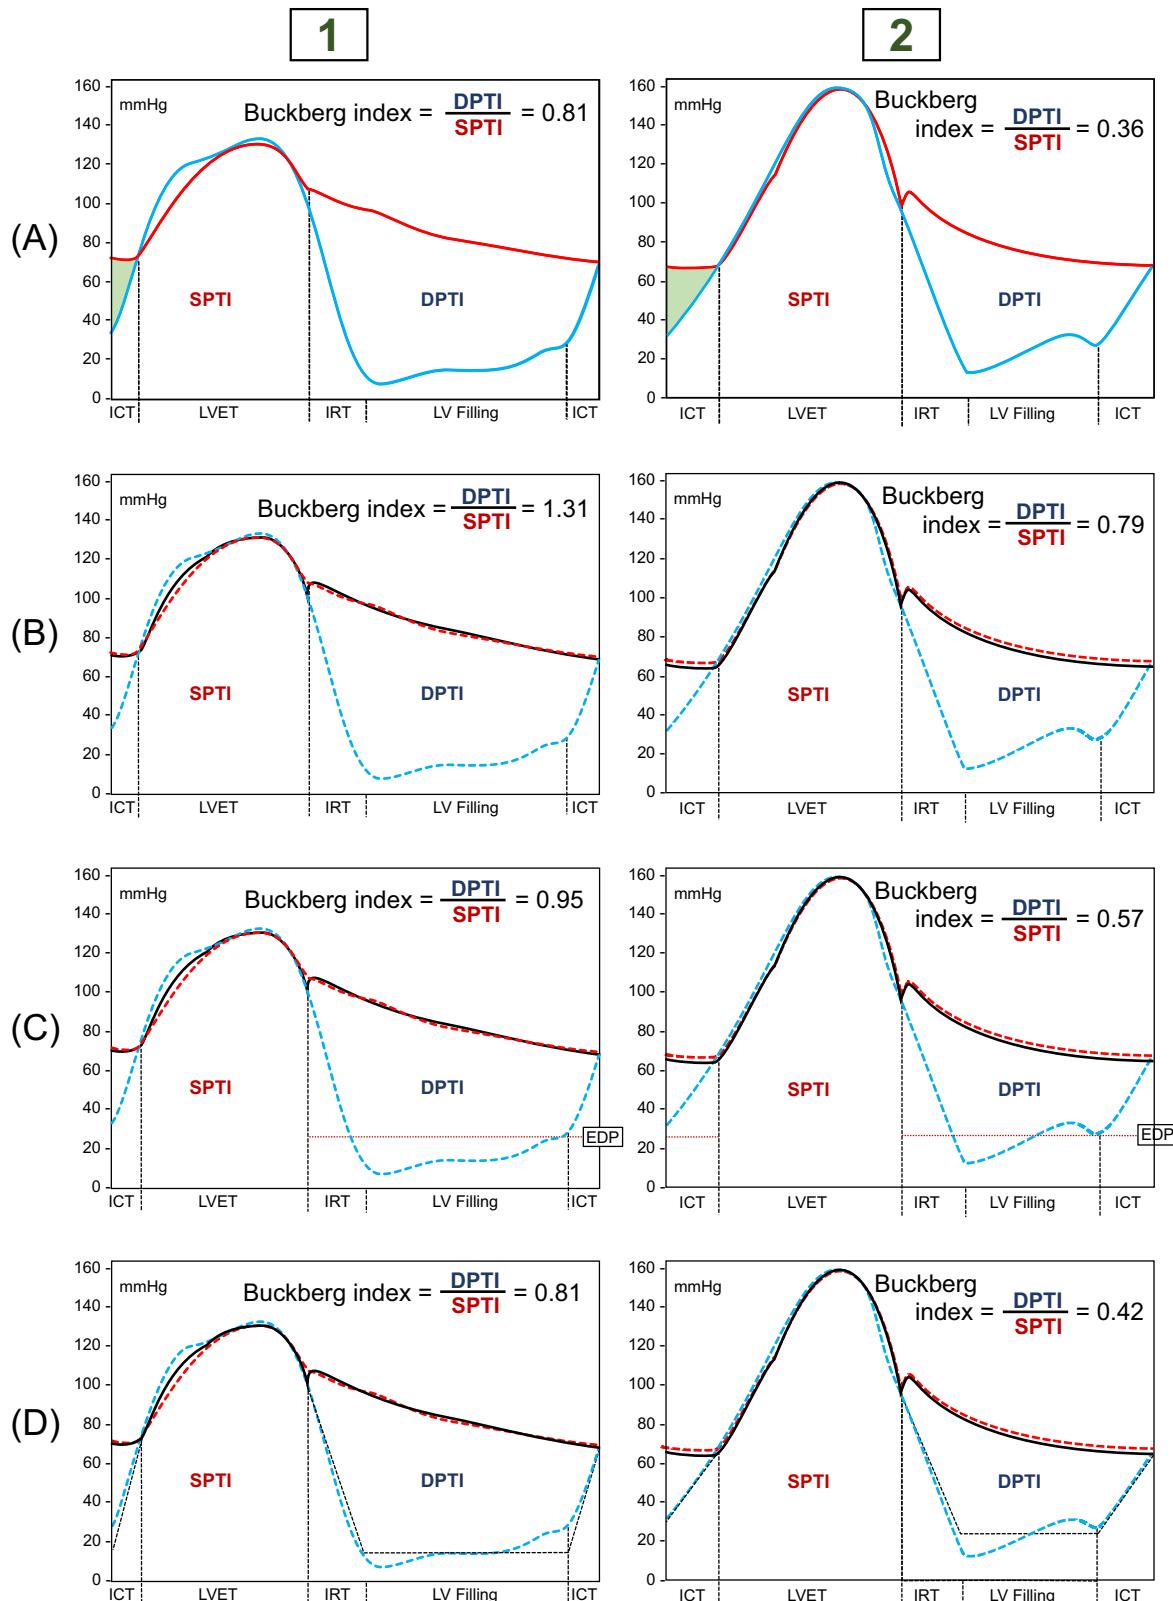
Evaluation of the myocardial oxygen supply and demand ratio, as described by Buckberg and Hoffmann, however, requires invasive catheterization, and this has been the most important limitation to its application in clinical practice. The introduction of transcutaneous arterial tonometry provides a useful approach to noninvasively determine the subendocardial oxygen supply:demand ratio through a simple, fast, well tolerated by the patient, reproducible, and extensively validated procedure.[40–42]

A reliable pressure waveform of the ascending aorta can be directly recorded from the common carotid artery waveform, or estimated from the radial artery waveform, using a transfer function. At present, transcutaneous applanation tonometry is considered the reference method for the noninvasive estimation of central blood pressure and for central pulse wave analysis.[43] All devices available on the market using the method of applanation tonometry provide values of Buckberg's index on the basis of the analysis of the central pulse waveform. DPTI is evaluated by these tonometric system as the area under the diastolic portion of the blood pressure wave and is obtained by multiplying the mean value of blood pressure during the diastolic phase of cardiac cycle by the diastolic time. SPTI is evaluated as the area under the systolic portion of the pressure wave, obtained by multiplying the mean value of blood pressure during the systolic phase of cardiac cycle by the left ventricular ejection time.[44]

In summary:

$$Buckberg\ index\ by\ arterial\ tonometry = \frac{Aortic\ Mean\ Diastolic\ Blood\ Pressure \times Diastolic\ Time}{Aortic\ Mean\ Systolic\ Blood\ Pressure \times Ejection\ Time}$$


The noninvasive estimation of Buckberg index by means of tonometric analysis of the central pressure waveform is unable in the presence of a stenosis to the aortic valve outflow. Fig. 18.5 shows examples of unreliable estimation of Buckberg index in the presence of aortic stenosis and obstructive cardiomyopathy.

Limits in Buckberg index estimation by arterial tonometry


However, the method used by arterial tonometry to assess Buckberg index provides an unreliable estimate of the balance between subendocardial oxygen supply and demand.[39] A recent study, comparing invasive and noninvasive method to assess Buckberg index, showed an average overestimation of tonometric Buckberg index values of 0.44 ± 0.11 (limits of agreement of differences: $0.23-0.65$).[45] A number of factors can cause this discrepancy (Fig. 18.6).

First, the estimation of subendocardial flow supply (DPTI) by the tonometric approach leaves out left ventricular diastolic pressure. The true estimation of diastolic myocardial O_2 supply involves the inclusion of the area between aortic and left ventricular pressure curve during the diastolic phase of the cardiac cycle. Indeed, intraventricular pressure, which is fully transmitted to the

FIGURE 18.5   Unreliable estimation of Buckberg index in the presence of severe aortic stenosis (upper panel) and obstructive cardiomyopathy (lower panel). Left ventricular (LV) pressure (blue line) and aortic arterial pressure (red line) were recorded by invasive catheterization; carotid arterial pressure (black line) was recorded by applanation tonometry. The light blue area shows diastolic pressure-time index (DPTI) and the salmon area shows systolic pressure-time index (SPTI). Buckberg index was calculated as DPTI and SPTI ratio. *ICT*, isovolumic contraction time; *IRT*, isovolumic relaxation time; *LVET*, left ventricular ejection time.

FIGURE 18.6 Representative recordings of diastolic pressure-time index (DPTI, light blue area) and systolic pressure-time index (SPTI, salmon area). Buckberg index was calculated as DPTI and SPTI ratio. Left ventricular pressure (blue line) and aortic arterial pressure (red line) were recorded by invasive catheterization; carotid arterial pressure (black line) was recorded by applanation tonometry. Drawings on the left (1) were recorded on an adult

subendocardial layers, opposes the flow in the sub-endocardial microcirculation during the whole diastole. While in young healthy individuals, the weight of left ventricular diastolic pressure may be negligible due to the low values of intracardiac pressure; on the other hand, in patients with valve disease, diastolic dysfunction or heart failure, characterized by increased left ventricular diastolic pressure, neglecting intraventricular diastolic pressure causes an overestimation of the DPTI, therefore of the Buckberg index values.

Second, the estimation of myocardial oxygen demand (SPTI) requires analyzing the blood pressure curve during the entire systolic phase. This presupposes the analysis of both periods that make up systole: isovolumic contraction time and ventricular ejection time. Conversely, the tono-metric estimation of myocardial oxygen demand takes into account only the left ventricular ejection time, totally ignoring the isovolumic contraction time, with a conse-quent underestimation of SPTI. On the other hand, isovolumic contraction time is considered in DPTI deter-mination, with a consequent overestimation of DPTI. Actually, during isovolumic contraction, time left ventricle develops an important contractile activity, which results in a significant consumption of O_2. It is therefore evidently incorrect to consider this time as a period of oxygen supply to the subendocardium. If in young healthy individuals the weight of ventricular activity during isovolumic contraction time may be negligible due to the low ratio between isovolumic contraction time and ejection time, on the contrary, a misleading evaluation of the isovolumic contraction time induces a significant overestimation of the Buckberg index in the elderly and in patients with heart failure. Indeed, these patients are characterized by high isovolumic contraction time/ejection time ratio.

Third, the tonometric Buckberg index inappropriately includes the isovolumic relaxation time in the assessment of the DPTI. However, blood flow to the subendocardium during this phase of diastole is limited and increases very gradually. The full insertion of the isovolumic relaxation time within the analysis of the oxygen supply to the subendocardium can generate an overestimation of the DPTI, therefore of the Buckberg index.

Fourth, the close dependence of Buckberg index is estimated by tonometry on the diastolic time and ejection time ratio.[46,47] The formula used by tonometers to assess Buckberg index can be rewritten as follows:

$$\text{Buckberg index} = \frac{\text{Aortic Mean Diastolic BP}}{\text{Aortic Mean Systolic BP}} \times \frac{\text{Diastolic Time}}{\text{Ejection Time}}$$

However, the ratio between mean diastolic and mean systolic blood pressure in the aorta presents a limited interindividual variability which makes this parameter insignificant in determining interindividual differences in Buckberg index values.[46] In a large population, our research group found values of this ratio between 0.60 (fifth percentile) and 0.80 (95th percentile). This misleading simplification of the supply and demand ratio therefore implies that tonometry systems provide Buckberg index values between 60% and 80% of the diastolic time/ejection time ratio, i.e., Buckberg index = diastolic time/ejection time × (0.60 ÷ 0.80). These data may erroneously lead to the conclusion that the evaluation of the tonometric Buckberg index can reasonably be replaced by the simple measurement of the diastolic time/ejection time ratio.[29] Actually, interin-dividual variability in hemodynamics induces marked variations in the mean pressure during both the systolic and diastolic phases of the cardiac cycle and the relationship between myocardial oxygen supply and demand is strongly affected by these different blood pressure levels.

Buckberg index estimated by arterial tonometry and echocardiography

Evaluation of the myocardial oxygen supply and demand ratio by means of tonometry associated with echocardiog-raphy can theoretically be useful in overcoming the limits in the estimation of Buckberg index by means of arterial tonometry alone. Echocardiography can in fact offer useful information on ventricular diastolic pressure, providing the value of the end-diastolic pressure. However, the values of the ventricular end-diastolic pressure do not correspond to the values of the ventricular mean diastolic pressure,[45] and the overestimation of Buckberg index values by tonometry is only partially due to the neglect of the role of

---

male (Do.St.), 62 years old. Aortic pulse wave velocity = 10.4 m/s. Drawings on the right (2) were recorded on an adult female (Ma.EL.), 80 years old. Aortic pulse wave velocity = 25.0 m/s. First line (A): invasive Buckberg index assessment. DPTI represents the area between the aortic and left ventricular pressure curves in diastole; SPTI represents the area under the systolic left ventricular pressure curve, including left ventricular isovolumic contraction time. Second line (B): "traditional" tonometric Buckberg index: DPTI is the area below the carotid pressure curve during diastole, including also the left ventricular isovolumic contraction and relaxation times; SPTI is the area below the carotid pressure curve during systole, excluding the left ventricular isovolumic contraction time. Third line (C): Buckberg index estimated by applanation tonometry associated with echocardiography. DPTI is the area below the carotid pressure curve during diastole to which the area corresponding to the left ventricular end-diastolic pressure (EDP, evaluated by echocardiography) is subtracted. Fourth line (D): modified tonometric Buckberg index[45]: DPTI is estimated from the area below the diastolic phase of the carotid pulse pressure curve, after subtracting the ventricular diastolic pressure area, isovolumic contraction, and isovolumic relaxation times; SPTI is estimated from the area below the systolic phase of the carotid pulse pressure curve, to which the area related to the isovolumic contraction time is added. *ICT*, isovolumic contraction time; *IRT*, isovolumic relaxation time; *LVET*, left ventricular ejection time.

ventricular mean diastolic pressure. Other factors, such as isovolumic contraction and relaxation times, play an important role in this discrepancy between real and tonometric Buckberg index values.

New perspectives in Buckberg index estimated by arterial tonometry

Arterial tonometry can provide reliable Buckberg index values only when all the main factors determining myocardial oxygen supply and demands are taken into consideration, including left ventricular diastolic pressure, isovolumic contraction, and relaxation times.

Recently, an original and reliable method to estimate systolic time intervals with arterial tonometry has been proposed,[45,48] by combining analysis of the carotid pressure waveform with pulse wave velocity assessment. The measurement of isovolumic contraction time evaluated with this approach showed good agreement with that performed with conventional echocardiography.[48] The possibility of obtaining measurements of the systolic times intervals from the analysis of the carotid pressure waveform has allowed to develop an algorithm for a more reliable estimation of Buckberg index by carotid tonometry.[45]

DPTI is estimated from the area below the diastolic phase of the carotid pulse pressure curve, defined by the integral of the pressure curve in diastole, from which the following areas are subtracted: (i) the area related to the left ventricular diastolic pressure. The estimate of left ventricular mean diastolic pressure is based on parameters deduced by the pulse waveform analysis, on brachial blood pressure values and on anthropometric variables[45]; (ii) the area related to isovolumic contraction time, according to a validated formula[48]; (iii) the area related to isovolumic relaxation time, based on morphological analysis of the central pulse pressure and the degree of vascular stiffness.[45] SPTI is estimated from the area below the systolic phase of the carotid pulse pressure curve, defined by the integral of the pressure curve in systole, to which the area related to isovolumic contraction time is added.

Buckberg index assessed with this approach, based on carotid tonometry, showed good agreement with measurements performed with invasive catheterization,[45] thus setting the scene for a possible wide use in clinical practice. The reliable noninvasive estimation of the subendocardial oxygen supply and demand balance could be a useful parameter to assess the risk of myocardial ischemia, particularly in those forms of myocardial damage that are not justified by overt coronary artery disease.

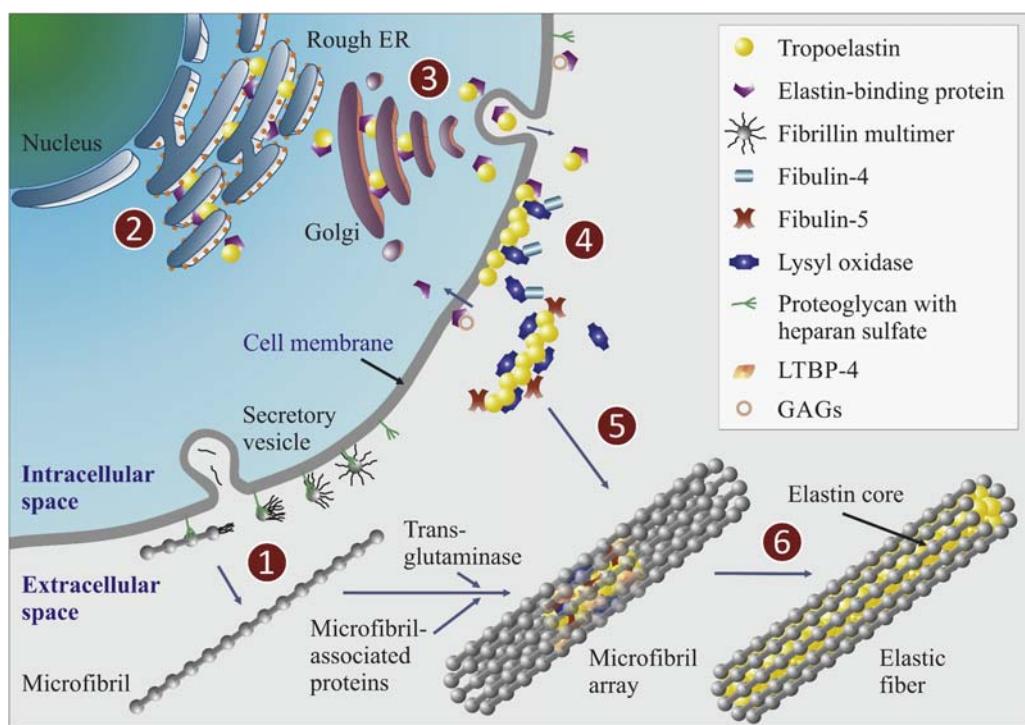
Elastic fibers and elastin

Function and composition

A key step in the evolution of vertebrates was conversion from an open to a high-pressure closed circulatory system. The required mechanical stability and elasticity of the blood vessels were achieved in particular by structural changes of the vessel walls. The extracellular assemblies that account for the necessary elasticity and extensibility are the elastic fibers, which are highly abundant in large and small arteries. Individual fibers have a very low Young's modulus of between 0.3 and 1.5 MPa[1] and can be linearly stretched to ~150% of their original length before they tear.[2] Elastic fibers store the potential energy required to maintain blood flow during diastole thus enabling proper cardiovascular function. They are also essential for the physiological function of many other organs such as skin, tendons, or lungs, which undergo reversible and repetitive deformation. Elastic fibers consist of two morphologically distinguishable components: a mantle of longitudinally aligned fibrillin-based microfibrils and a dense core of cross-linked elastin, which accounts for over 90% of the fiber content.

The microfibrils are 10−12 nm wide filaments, which have a beads-on-a-string appearance.[3] They provide the tissues with long-range elasticity, especially with participation of elastin when it is deposited on a microfibrillar scaffold. Microfibrils are formed mainly from fibrillins, which are ~350 kDa large modular glycoproteins secreted from mesenchymal cells. In humans, there are three fibrillin isoforms of which each comprises 43 Ca^{2+}-binding epidermal growth factor (EGF)-like domains, five EGF-like domains, seven eight-cysteine-containing domains and two so-called hybrid domains.[4] Several other proteins are known to be associated with microfibrils.[3] Among them are the microfibril-associated glycoproteins,[5] elastin microfibril interfaces (EMILINs),[6] a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS), and ADAMTS-like proteins,[7] and latent transforming growth factor-β binding proteins (LTBPs).[8]

The other major component, elastin, is an insoluble biopolymer made up of units of its soluble precursor tropoelastin (TE). TE's primary structure is characterized by alternating hydrophobic and hydrophilic domains, which are encoded by distinct exons, and thus TE's domain structure maps the exon organization of the gene. The hydrophilic domains are involved in covalent cross-linking and contain either Lysyl-Alanine (KA) or Lysyl-Proline (KP) motifs. In the KA domains, Lys residues occur as pairs or triplets separated by two or three Ala residues and sometimes by another residue. The KA motifs are often

299


embedded in stretches of poly-Ala. In KP domains, the lysine residues are separated by at least one proline residue. Human TE consists of up to 34 domains of which 5 are KP and 11 are KA domains.[9] In contrast to other vertebrates, the human gene lacks exons 34 and 35, which have been lost during primate evolution.[10] Elastin's primary transcript undergoes extensive alternative splicing resulting in numerous isoforms. For human TE, 18 isoforms ranging from 49 to 69 kDa have been described. At least seven exons have been reported to be alternatively spliced: 3, 10, 11, 13, 22, 23, and 32.[11] The splicing occurs in phase without affecting the reading frame and hence an exon is either included, extended, shortened or removed. The expression of several of these isoforms in human tissues has been proven in some studies.[12] The functional consequences are still elusive, but it has been suggested that splicing may be tissue-specific or related to developmental changes in cells.[13]

Under healthy conditions, mature elastin is metabolically stable over the species' lifespan. Its half-life in humans has been determined to be greater than 70 years.[14] One of the reasons for this exceptional durability is elastin's high resistance to proteolysis, which is mainly caused by its vastly cross-linked nature and the extremely dense packing of the molecules. In its mature form, elastin is hydrophobic and completely insoluble, but its hydrophobic hydration is required for its elastic properties.[15]

Elastogenesis

The in vivo process that leads to the formation of functional elastic fibers, also known as elastogenesis, is a complex and yet not fully understood process involving numerous proteins. Elastogenesis time course has been studied in animals (mouse, chicken, sheep, and bovine) and starts at midgestation. It reaches its maximum around birth and completes during postnatal development, until adolescence. In the aorta, expression decreases rapidly when the physiological rise in blood pressure stabilizes postnatally.[16,17] Virtually no new functional fibers are assembled in adult tissues with the exception of the uterus, where they are rapidly removed after parturition and the fiber formation starts again with every new pregnancy.[16] The main stages of elastogenesis are shown in Fig. 19.1 and discussed below.

FIGURE 19.1   The elastic fiber assembly: (1) Fibrillin and microfibril-associated proteins are secreted into the extracellular space, multimerize, and form the microfibrillar array. (2) TE is synthesized on the rough endoplasmic reticulum (ER) where it binds to the chaperone EBP. (3) The EBP-TE complex is transported through the Golgi apparatus and secreted to the cell membrane. (4) TE is released from the chaperone and forms globules at the cell surface, while EBP dissociates as result of the interaction with glycosaminoglycans. Fibulin-4 is important for the chain alignment of TE mediating the interplay with lysyl oxidases. The oxidation of Lys residues is followed by various condensation reactions leading to the formation of covalent intra- and intermolecular cross-links. (5) After the cluster of TE molecules reaches a critical size, it is moved from the plasma membrane through the extracellular space. Fibulin-5 is thought to direct the premature elastin to fibrillin microfibrils. (6) The elastin aggregates fuse into larger assemblies with support by LTBP-4 and are subsequently further cross-linked. *EBP*, elastin-binding protein; *ER*, endoplasmic reticulum; *LTBP*, latent TGFβ-binding protein; *TE*, tropoelastin.

Microfibrils deposition

Elastogenesis is initiated with the expression of fibrillins and their assembly into microfibrils, which serve as a scaffold for the subsequent TE deposition. During or after secretion of the fibrillin precursors, they undergo N- and C-terminal cleavages by furin/PACE-like proprotein convertases at the consensus motif RXK/RR resulting in ∼320 kDa mature forms. This process is a prerequisite for the subsequent linear multimerization through the C-terminal domain and their assembly at the cell surface.[18] The fibrillin network can undergo cross-linking, which further stabilizes the three-dimensional bundle structure. The cross-links reported to date are intermolecular disulfide bonds[19] and ε(γ-glutamyl)lysine cross-links that are catalyzed by members of the transglutaminase family.[20]

Synthesis and secretion of tropoelastin

With the known exceptions of teleosts and frogs, a single gene encodes TE in vertebrate species.[21] The human gene (ELN) is located on the long arm of chromosome 7 (7q11.23).[22] The expression of the monomer takes place in elastogenic cells, which include vascular smooth muscle cells or fibroblasts. After the mRNA is exported from the nucleus, translation occurs on the surface of the rough endoplasmic reticulum (ER) where the N-terminal signal peptide is cleaved off. Before TE is transported through the Golgi apparatus to the cell surface, many proline residues are partially hydroxylated by prolyl 4-hydroxylase.[23] TE is transported along the secretory pathways together with a chaperone, the elastin-binding protein (EBP). EBP is a 67 kDa large inactive β-galactosidase splice variant that prevents intracellular degradation and aggregation of TE. When the EBP-TE complex is secreted, it associates with the other subunits of the elastin receptor complex (ERC): the membrane-associated proteins cathepsin A/protective protein (PPCA) and neuraminidase-1 (Neu-1).[24] EBP is thought to interact with glycosaminoglycans, which probably causes conformational changes in EBP and leads to the release of TE from its chaperone.[25] The EBP is recycled back into the intracellular endosomal compartments and associated with newly synthesized TE.[24]

Microassembly

TE subsequently undergoes rapid self-association in an endothermic, entropically driven process of liquid−liquid phase separation referred to as coacervation.[26] During this key process of microassembly, hydrophobic domains of TE, especially the domains 17−27, interact with each other[27] leading to the formation of distinct globular aggregates on the cell membrane.[28] It has been further suggested that interactions of the C-terminal region of TE, especially domain 30, with microfibrillar proteins are required for the assembly of elastic fibers.[29] Another

important sequence comprises the polybasic motif KXXXRKRK located in the C-terminal domain, which is encoded by the across-species highly conserved exon 36. It has been shown that TE lacking this sequence is less efficiently incorporated into mature elastin and shows abnormal cross-linking.[30] Proteoglycans may interact with this domain facilitating the correct alignment of the TE monomers.[31] The alignment of TE and the subsequent cross-linking is further promoted by fibulin-4, which mediates the association between TE and the extracellular Cu^{2+}-dependent amine oxidase, lysyl oxidase (LOX).[32]

Cross-linking and macromolecular assembly

LOX and LOX-like enzymes catalyze the oxidative deamination of the ε-amino group of Lys residues to the highly reactive α-aminoadipic acid-δ-semialdehyde, termed allysine (Lya).[33] Intra- and intermolecular cross-links are then formed spontaneously by nonenzymatic condensation reactions. The aldol condensation of two Lya residues results in the formation of an allysine aldol (AA) cross-link. The Schiff base reaction of a Lya residue with the ε-amino group of another Lys residue, however, yields dehydrolysinonorleucine (Δ-LNL). These reducible bifunctional cross-links further condense with each other, partly with participation of unmodified Lys residues or with other intermediates, to form the trifunctional cross-links dehydromerodesmosine and cyclopentenosine as well as the tetrafunctional cross-links desmosine (DES) and its isomer isodesmosine (IDES).[12] While some cross-links such as Δ-LNL and AA are also found in collagen, DES and IDES are unique to elastin in mammals.[34] In-depth characterizations of the cross-links in bovine[35] and human[12] elastin revealed that mature elastin is composed of an unordered network of TE molecules and that the cross-linking pattern is very complex and heterogeneous.[9]

Over time, the clusters formed at the cell surface grow in size by the addition and cross-linking of newly secreted TE molecules. When enough TE is secreted and accumulated, the formed globules are released from the cell surface and move through the extracellular matrix (ECM). Fibulin-5 and fibulin-4 are able to interact with fibrillin and are thought to play central roles in controlling the deposition of the premature elastin aggregates onto the microfibril scaffold.[32] The globules associate with fibrillin-containing microfibrils and readily coalesce into larger aggregates and eventually form functional fibers. Another contributing protein is LTBP-4, which does not directly interact with TE but with the fibulin-5-fibulin-4-TE complex and is apparently required for the proper linear deposition on the microfibril network.[36] Over time, deposited elastin is further oxidized by LOX and/or condensation reactions take place until elastin has been fully integrated into the microfibrillar scaffold.[37]

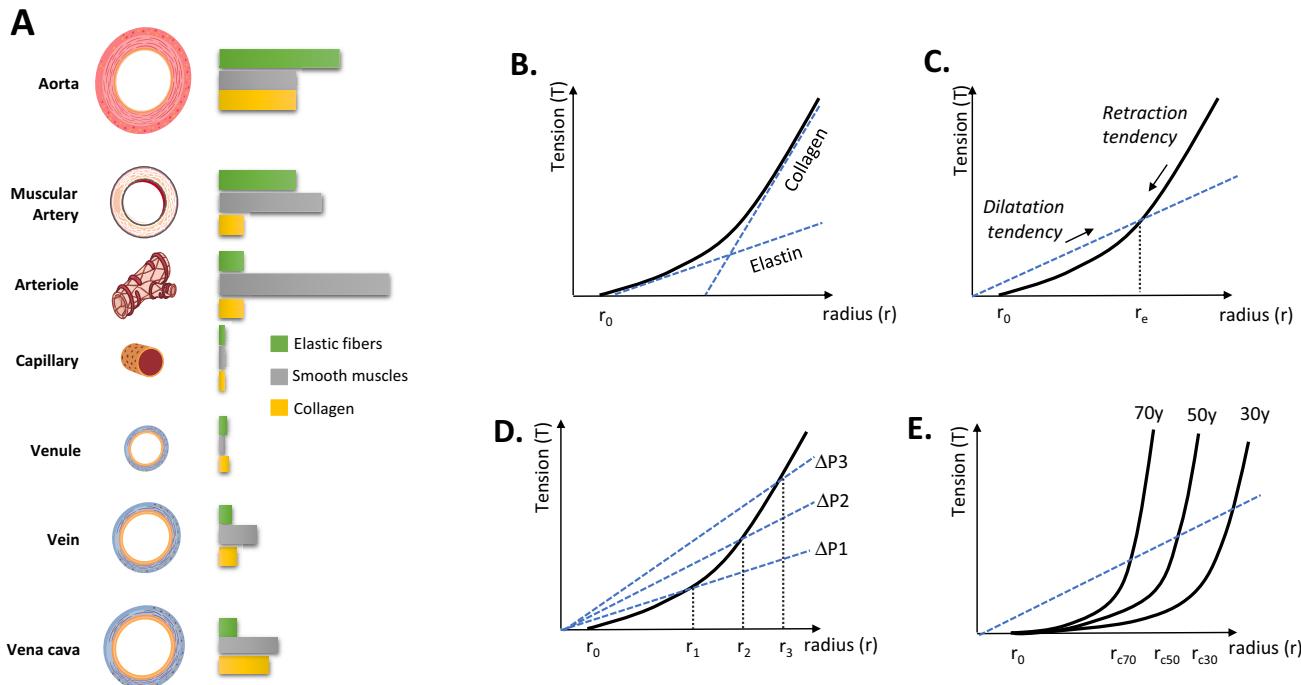
Elastin role in arterial function

Elastin: a major functional vascular wall component of vertebrate's arteries

The closed circulatory system is made up of a set of branching vessels (arteries, veins, and capillaries). The walls of arteries and veins have, to varying degrees, two fundamental properties: the first one is elasticity, due to the presence of constituents of elastic fibers called elastic lamellae. They transform the pulsatile flow imposed by the blood into permanent laminar flow. The second property concerns contractility, due to a smooth musculature whose role is essential in controlling the caliber of the vessel. Unlike arteries and veins, the extremely branched capillary network which constitutes the zone of exchanges between the vascular system and the tissues, presents a thin wall, more permeable, reduced to a single layer of cells, without muscular or elastic elements. The presence of elastin within these different vessels was first depicted at the end of the 19th century, notably through the work of Unna and colleagues using dyes such as orcein or Weigert's dye to allow the individualization of elastin.[38]

Elastin role in normal hemodynamics

Distributed concentrically and interconnected by structures that could be described as "pillars," elastic lamellae ensure the propulsion of blood throughout the arterial tree when the ventricles are in diastole. Indeed, elastic lamellae transform the pulsatile flow leaving the heart into a continuous flow in arteries. As reviewed in detail in Chapters 3 and 10, when blood is ejected from the heart during ventricular contraction and enters the large elastic arteries, their walls stretch under the pressure of the blood. As they stretch, the elastic fibers temporarily store mechanical energy and thus become reservoirs of pressure of the so-called systolic pressure. When the aortic valve is closed during cardiac systole, and in the absence of blood pressure at the exit of the heart, the elastic lamellae resume their initial degree of stretch and convert the stored potential into kinetic energy, thus propelling the blood. This kinetic energy thus allows blood to flow through the microcirculation while the ventricles are in diastolic phase. Therefore, elastic fibers, under heart systolic-diastolic cycle influence, alternate between stretched and relaxed states approximately 3 billion times during human lifetime.

As discussed in detail in Chapter 7, elastin ensures the elasticity of the vessel at the lower range of vessel stretch, while collagen provides rigidity at the higher range of vessel stretch. The capacity of fibers to return to their initial shape after stopping the stretching, is named elasticity (recoil ability).[39–41] Stiffness is the resistance offered by an elastic body to deformation. The stiffness of elastin is 1000 times lower than that of collagen.[42]


The large amount of elastic fibers in the aorta, especially in its proximal part, influences vascular flow. In fact, the rise of blood pressure during systole distends the aortic wall, increasing its volume. This volume is restored at the time of diastole. As a result, aortic output increases and decreases less quickly than ventricular output during cardiac cycles. This phenomenon transforms a discontinuous flow at the exit of the left ventricle into continuous flow at the capillary level (Fig. 19.2). Taking into account the mechanical properties of the arteries, in order to achieve an identical flow rate, the heart of a young subject (with a much more elastic aorta) must perform significantly less work than that of an older person in whom the integrity of the elastic fibers of the aorta is already compromised by stiffness and fragmentation.

Elastin modifications during aging and pathophysiological consequences

Nonenzymatic posttranslational modifications of elastin

Due to its long half-life, elastin is subjected to various chemical reactions which induce a molecular aging responsible for progressive alterations of its structural and functional properties. These chemical reactions, commonly called nonenzymatic posttranslational modifications (NEPTMs), are characterized by the binding of small metabolites to functional groups of proteins, especially amino groups of lysine and arginine residue side chains.[43] Among these reactions, the best known is glycation, corresponding to the reaction of reducing sugars (or their metabolites) to protein amino groups, followed by complex molecular rearrangements resulting in the formation of advanced glycation end-products (AGEs). However, other NEPTMs have been described to contribute to protein molecular aging such as oxidation and carbonylation, which share similar features. As another example, carbamylation, which is a more recently described NEPTM, is triggered by the reactive metabolite cyanate.[44] Cyanate mainly derives from the spontaneous dissociation of urea or from the myeloperoxidase-dependent metabolism of thiocyanate. Its reactive form, isocyanic acid, binds to the ε-amino groups of lysine residues, leading to the formation of homocitrulline, the most characteristic carbamylation-derived product.

Elastin molecular aging is concomitant to organism chronological aging but can also be intensified during chronic diseases such as diabetes mellitus, end-stage renal disease (ESRD), or atherosclerosis. For instance, the investigation of age-related changes of human aortic elastin in healthy subjects showed a significant increase of elastin

FIGURE 19.2 Role of elastin and collagen fibers on the mechanical properties of blood vessels. (A), Distribution of elastin (green bar), collagen (yellow bar), and myocytes (gray bar) within the vascular wall of various types of blood vessels. (B−E), Impact of elastin/collagen proportions in the tension-radius relationship. (B), Tension-radius curve, for an elastic artery, dependent of elastin and collagen components. r0 is the base radius of the artery when there is no transmural pressure gradient. (C), Laplace line (*dashed blue line*; its slope is equal to the transmural pressure gradient) and tension-radius curve (*black solid line*) for an elastic artery. The artery will have a radius such that both relationships (Laplace and tension-radius relations) are verified simultaneously. This ray is called the balance ray (re). (D), When the transmural pressure gradient varies, the slope of the relation $T = \Delta P.r$ changes, inducing a variation of the equilibrium radius. (E), For the same pressure gradient, when the elastic properties of the arteries decrease with age (30, 50, 70 years), the equilibrium radius of the aorta decreases (rc70, rc50, rc30).

glycation rate with age.[45] In patients with ESRD, levels of glycation and carbonylation of aortic elastin are also increased in comparison with control subjects.[46] Finally, skin elastic fibers are carbamylated during aging,[47] suggesting that vascular elastic fibers could also be susceptible to this modification.

The consequences of elastin molecular aging are multiple, ranging from direct impacts on structural and mechanical properties of this matrix protein to inappropriate effects on vascular cells. In vitro experiments have shown that glycation of elastin was responsible for a drastic loss of its elastic and biomechanical functions.[48,49] In the same way, cross-linking AGEs produced by glycation reactions contribute to limitation of the elastic and resilience properties of elastic fibers.[50] In addition, elastin glycation is responsible for an increased deposit of calcium on elastic fibers in ESRD patients.[51] Taken together, these combined effects contribute to the global increase of arterial stiffening and progression of arteriosclerosis.[50] Finally, elastin-bound AGEs may trigger inappropriate cellular effects such as alteration of migration properties of smooth muscle cells or induction of local oxidative stress mediated by the receptor for AGEs.[52]

Mechanical fatigue and enzymatic fracture of elastin

The breakdown of elastin is a multifactorial process, which can lead to stiffening of tissues and strongly affects vascular remodeling. One important cause is the mechanical fatigue of elastin lamellae due to the billions of repetitive cycles of stretching caused by pulsatile changes in blood pressure as well as shear stress within and between the elastic fibers.[53,54] The impairments or even ruptures lead to a decrease of elastic fiber function, and to a transfer of mechanical stress to other extracellular components such as collagen fibers.[55] The failure of elastic fibers is further induced by the action of members of several classes of extracellular proteases. Elastin-cleaving proteases are collectively termed elastases, although this description does not indicate that elastin degradation is the only physiological function of the enzymes. The known elastases belong to three classes of families: serine proteinases with cathepsin G, proteinase-3 and human leukocyte elastase,[56−58] matrix metalloproteinases (MMPs) including MMP-2, -7, -9, -12, and -14[59−61] and the cysteine proteinases cathepsins K, L, S, and V.[62,63] These proteinases

are primarily produced by fibroblasts, mesenchymal cells, platelets, macrophages, and leukocytes. All these enzymes are capable of irreversibly damaging elastin in vivo, either alone or in concert. Despite their different catalytic mechanisms, all elastases have in common that they cleave elastin in a relatively nonspecific manner at various locations of the molecule. Besides this mechanical impairment, elastin degradation leads to the release of bioactive peptides named elastokines and belonging to the matrikines family.[64,65]

Pathophysiological consequences of elastin modifications

Elastin modifications are involved in the development of several vascular wall–related diseases such as atherosclerosis, abdominal aortic aneurysms (AAAs), or hypertension, processes that can be related to arterial stiffness.

It has been shown during atherosclerosis that both the synthesis and degradation of elastic fibers are increased.[66] Degradation of elastic fibers allows infiltration of lipids and immune cells into the aortic wall participating to plaque formation and disruption.[67] The involvement of elastin degradation in atherosclerosis has moreover been confirmed using animal models and especially by cross-breeding mice deficient in MMP (-2, -7, -9, and -12) or in cathepsins (K, L, and S) with atherogenic models (LDLR$^{-/-}$ and ApoE$^{-/-}$).[68] These results clearly demonstrate that degradation of elastic lamellae is a prerequisite for the development of the disease.

AAA is a chronic degenerative vascular disease that accounts for 1.3% of all deaths in men aged 65 to 85 in developed countries.[69] It corresponds to a localized dilation of the abdominal aorta, usually asymptomatic until the often-fatal outcome, exceeding the normal diameter by more than 50%. Aneurysmal degradation is greatly reduced in genetic models of elastolytic enzymes MMP-2 and MMP-9 knockdown.[70] Comparable results were found in mouse models of AAA deficient in cathepsin L (decrease in elastic fibers fragmentation and decrease in proliferation, apoptosis and infiltration of inflammatory cells) confirming that in this vascular disease too, the degradation of the elastic network is crucial for the progression of AAA.[71]

On the hypertension side, the modulation of TGF-β availability by emilin-1, a protein associated with elastic fibers, determines systolic blood pressure in mice and thereby demonstrates a role for elastic fiber integrity and TGF-β signaling in hypertension.[17] It was shown, in a mouse model deficient in elastin (Eln$^{-/-}$),[72] that the arteries appear similar to the control until day E17.5. After that, however, a significant increase in the number of cells obstructing the arterial lumen is observed. At the postnatal stage, the arterial pressure of Eln$^{-/-}$ mice is doubled compared to wild-type mice and the stiffness is significantly

increased. Smooth muscle cells are disorganized and proliferate. The arteries show local dilations and narrowing and the mice die soon after birth. Heterozygous Eln$^{+/-}$ mice feature hypertension, aortic stenosis, and heart dysfunctions. In these mice, vascular stiffness is observed from the seventh day of birth but hypertension does not appear until the 14th day: the change in mechanical properties therefore seems to precede the change in blood pressure. The team of Hirano et al. generated an elegant mouse model expressing human elastin in a bacterial artificial chromosome (BAC-ELN) which they crossed with Eln$^{+/+}$, Eln$^{+/-}$, and Eln$^{-/-}$ mice to produce a spectrum of mice expressing from 30% to 120% of normal elastin level. Data from these mice show that the level of elastin is inversely related to arterial stiffness and blood pressure, clearly showing the pivotal role of elastin in these processes.[72]

Elastin-derived peptides signaling, elastin receptor complex, and pathophysiological consequences

Elastin-derived peptides

Besides its fundamental importance for the mechanics and function of arteries, elastin is also involved in other biological processes through the production of elastin-derived peptides (EDPs) upon its degradation. As mentioned previously, insoluble elastin can undergo mechanical fragmentation or degradation by elastases. The released bioactive EDPs, also called elastokines due to their cytokine-like properties,[64,73] induce a variety of biological activities including cell adhesion, chemotaxis, migration, proliferation, proteinase activation, angiogenesis, and apoptosis.[74] They are involved in vascular diseases progression, and are now considered central modulators of the cardiovascular continuum.[24]

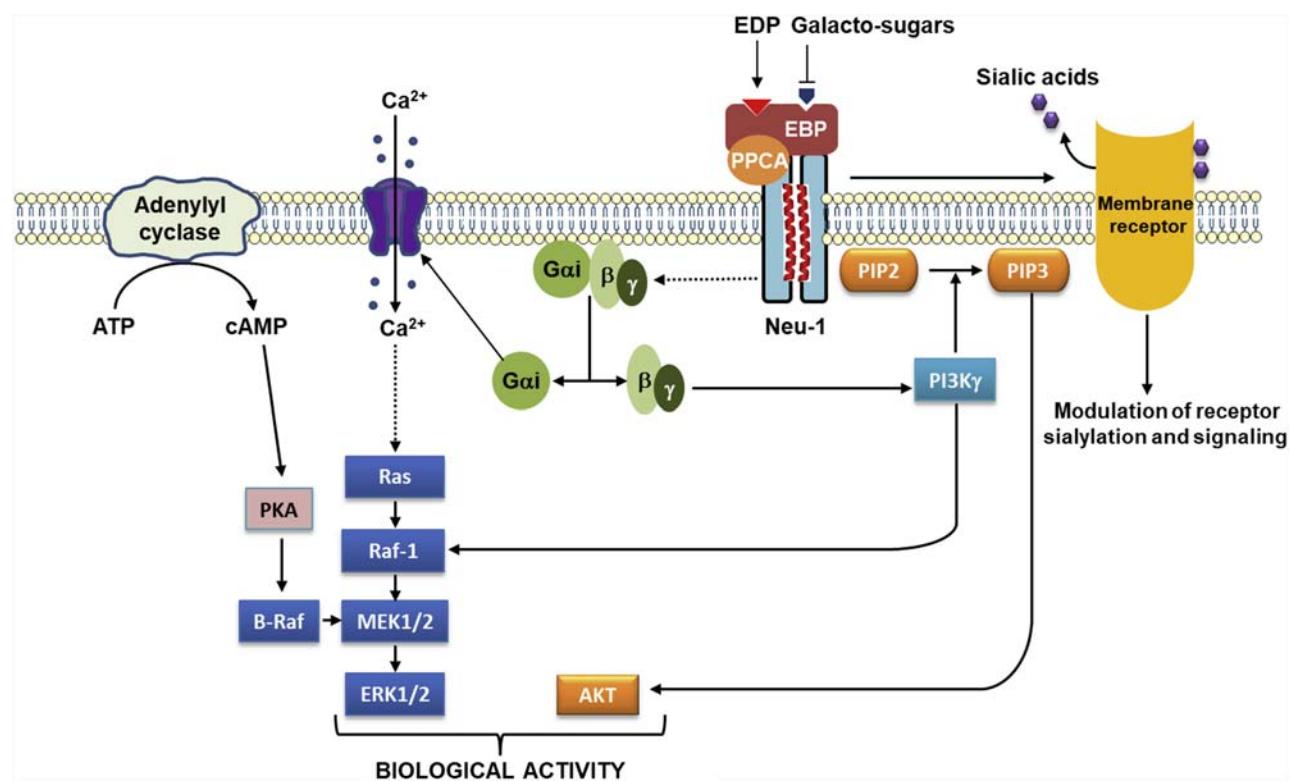
The typical elastokine is the VGVAPG peptide, which is repeated several times within exon 24-encoding sequence.[75] Longer peptides were shown to be also bioactive[76] and recent analysis of fragments generated by the atherosclerosis-related elastases, leukocyte elastase, cathepsin G, and proteinase-3, brought into light new bioactive GxxPG-related peptides: GVYPG, GFGPG, and GVLPG.[57] Moreover, studies using MMP-7, -9, and -12 showed that GxxPG-containing peptides, such as YTTGKLPYGYGPGG, YGARPGVGVGGIP, and PGFGAVPGA, have also biological activities.[61]

Structural studies on VGVAPG using nuclear magnetic resonance and circular dichroism spectroscopies suggested that the peptide exhibited folded conformations in organic solvents.[77] In later studies, it was found that the GxxPG sequence adopts a type VIII β-turn conformation, which is required for binding of elastokines to EBP in order to mediate biological activities.[75] For note, the β-turn is the third most important secondary structure after helices and

β-strands and belongs to the turn structure family, defined as a type of nonregular secondary structure in proteins causing a change in direction of the polypeptide chain. β-turns have been classified according to the values of the dihedral angles φ and ψ of the central residue and type VIII is one subtype of this family.[78] Then, molecular dynamics simulations on VGVAPG, (VGVAPG)$_2$ and (VGVAPG)$_3$ showed that VGVAPG exists in an equilibrium between different conformations including extended polyproline II and folded conformations such as the type VIII β-turn.[79] The repetition of VGVAPG leads to the formation of additional structures very close to a type VIII β-turn, and the authors hypothesized that the repeated VGVAPG sequence in domain 24 may favor elastin−cell interactions as VGVAPG is more likely to bind to EBP if it occurs in the TE sequence multiple times.[73] With respect to other elastokines, it has been described that GxxP sequences, in which X is not Gly, are well able to adopt the type VIII β-turn conformation.[75,80] Pro following a Gly (GPxPG) has been reported to stabilize the type VIII β-turn owing to its unique heterocyclic pyrrolidine ring structure.[80]

There are 17 GxxPG sequences in elastin, which of nine have been shown to display biological activities while eight have not been investigated except for GGVPG, which has been shown to not be chemotactic to monocytes.[81] In addition to GxxPG-based elastokines, further peptides display biological activities, including VPGVG,[82] VGVPG,[81] PGVGVA,[83] and the nonapeptides GLGVGAGVP[76] and AGVPGLGVG.[84]

All known bioactive peptides are derived from the noncross-linked hydrophobic domains, whose building blocks are Gx, Px, GGx, and PGx with x being either G, A, V, L, or I. Domains 17−27, which contain the four biggest hydrophobic domains encrypting various elastokines, have been described to be key regions for coacervation of TE molecules during elastic fiber formation.[27,85] These domains are solvent-exposed and it is, hence, likely that they are cleaved by elastases during ECM turnover, tissue aging and elastic fiber diseases, resulting in the release of elastokines.

Elastin receptor complex−dependent cell signaling


EDPs are able to bind several membrane receptors. So far, the most described is undoubtedly the ERC. The human elastin receptor was originally identified as a 67 kDa peripheral membrane protein called EBP that binds to elastin and laminin fragments.[86] EBP interacts with the 55 kDa (PPCA and the 61 kDa) membrane-bound Neu-1 to form a ternary complex called the ERC.[87] The EBP subunit[88] displays two functional-binding sites comprising (i) the elastin site on which EDPs binding is directly involved in the generation of intracellular signal transmission and (ii) the galactolectin site whose occupation by galactosugars leads to EDPs release and ERC dissociation.[89] EDPs

binding to EBP leads to Neu-1 activation which locally catalyzes the conversion of the GM3 ganglioside into lactosylceramide (LacCer), an essential second messenger of ERC signaling pathways.[90,91] Many intracellular signaling pathways induced by EDPs depending on the cell type have been described: for instance, EDPs induce the activation of multiple tyrosine kinases including MEK1/2 and ERK1/2 through a signal dependent on protein kinase A and phosphoinositide 3-kinase γ (PI3Kγ) in fibroblasts.[92] In endothelial cells, EDPs activate ERK1/2 by a PI3Kγ/Akt/ endothelial nitric oxide synthase/nitric oxide/protein kinase G pathway.[93] Finally, it has been shown in smooth muscle cells that EDP binding on ERC triggers the activation of Gi-proteins, the opening of L-type calcium channels, and then cell proliferation.[94] Neu-1 plays a key role in these signaling pathways and several studies have been conducted to further elucidate its involvement in ERC signaling. In addition to its role in the production of the second messenger LacCer, our group has demonstrated that a distinctive dimerization process is responsible of its catalytic activity. Indeed, two potential dimerization sequences, corresponding to two transmembrane domains (148−168 and 316−333 residues), have been found within human Neu-1. Point mutations in the 316−333 transmembrane domain inhibit significantly dimerization and sialidase activity of Neu-1.[95] Moreover, an increasing number of studies also indicate that Neu-1 plays an important role in modulating the activation of numerous membrane receptors such as the insulin receptor (IR), c-Met, IGFR, PDGFR, or CD36 by desialylation.[96−99] As a whole, these data imply that Neu-1 may be one of the crucial factors of the membrane signalosome from the lipids but also the protein points of view (Fig. 19.3).

Pathophysiological roles of elastin-derived peptides

Elastin remodeling during aging and disease clearly affects vascular events linked to arterial stiffness. It is however important to consider both the protein elastin and EDPs to have a better view of their respective participation. As previously mentioned in this chapter, elastin alteration leads to a loss of function impacting the mechanics and stiffness of arteries.[100] Genetic diseases due to mutations in the elastin gene such as Williams−Beuren syndrome and supravalvular aortic stenosis exhibit clear consequences such as arterial hypertension. Animal models like haploinsufficient murine models (Eln$^{+/-}$) confirmed these observations showing a higher arterial pressure (25−30 mmHg higher than their wild-type counterparts), whereas elastogenesis induction in the same murine model limits arterial hypertension.[100−103]

Besides, it has been shown that EDPs trigger a vasodilatation effect in an isolated organ model.[104] However, due to the uncoupling between the ERC and its intracellular targets during aging, this protective effect is progressively

FIGURE 19.3 Signaling pathways mediated by EDPs through the elastin receptor complex. The binding of EDPs on EBP triggers Neu-1 activation responsible for the induction of signaling pathways. Besides, Neu-1 subunit is able to modulate the sialylation level of other membrane receptors and their signaling. *EBP*, elastin-binding protein; *EDPs*, elastin-derived peptides; *ERK1/2*, extracellular-regulated protein kinases ½; *MEK1/2*, mitogen-activated protein kinase kinases ½; *Neu-1*, neuraminidase-1; *PI3K*, phosphoinositide 3-kinase; *PIP2*, phosphatidylinositol (4,5)-bisphosphate; *PIP3*, phosphatidylinositol (3,4,5)-trisphosphate; *PKA*, protein kinase A; *PPCA*, protective protein/cathepsin A.

lost.[105,106] Moreover, the net production of NO has been shown to drastically decrease during aging. Consequently, despite the positive effect of EDPs on the regulation of the vascular tone, the resulting endothelial dysfunction along with elastin loss of function clearly contribute to vascular stiffness. Nevertheless, the role of EDPs in the regulation of NO production is more complex as EDPs directly participate to the regulation of the vascular tone through their involvement in IR signaling blockade. Indeed, IR which is also present at the surface of endothelial cells, is known as an activator of NO pathway.[107] The blockade of IR signaling by EDPs could thus decrease NO production contributing to vascular dysfunction.

The role of elastin and EDPs in atherosclerosis and its link with arterial stiffness have been also widely studied. The Wagenseil's group evaluated if elastin deficiency and the consequent increase in arterial stiffness could play a role in atherosclerotic plaque formation. Using $Eln^{+/-}$ mice bred with atherosclerosis-prone mice presenting 60% of wild-type elastin levels, they showed that the observed reduced aortic compliance and the associated increased blood pressure were not directly linked to plaque appearance suggesting that other processes are required.[17,108,109] In this way, EDPs are drastically involved in atherosclerosis development as shown using proatherosclerotic $ApoE^{-/-}$ and $LDLR^{-/-}$ mice. The chronic administration of EDPs to such mice leads to an important increase in atherosclerotic plaques through the recruitment of inflammatory cells. Additionally, the use of chimeric $LDLR^{-/-}$ mice devoid of Neu-1 sialidase activity in hematopoietic cells obtained by bone marrow transplant from CathA/Neu-1-deficient mice to irradiated $LDLR^{-/-}$-recipient mice, showed a decrease in atherosclerosis development and in monocyte and lymphocyte infiltration.[110] Moreover, Dale et al. reported that EDPs induced an M1 macrophage polarization that could participate in the disease.[111] Finally, recent data from our group demonstrated that EDPs stimulation of macrophages leads to an increase in oxidized LDL uptake by CD36 involving the Neu-1 subunit of the ERC.[99] It is worthy to note that degraded elastic fibers are not repaired or renewed, but replaced by collagens and proteoglycans. This molecular switching contributes to the stiffening of arteries. In addition, the TE molecules produced by smooth muscle cells and/or macrophages during atherosclerosis development, are not cross-linked into mature and functional elastin, reinforcing the absence of elastic compensation processes.[112,113]

Finally, due to its mineral scaffolding function, elastin can suffer from calcification during atherosclerosis, but also during aging or other pathologies. This has been observed in human carotid arteries obtained by endarterectomy.[114] In human and several animal models, a clear correlation

between elastin degradation and vascular calcification has been demonstrated[115,116] in addition to an osteogenic differentiation of vascular SMCs induced by EDPs which may contribute to vascular calcification and aortic stiffening.[117]

Elastin biology-derived therapeutic options

Targeting elastin synthesis

Elastin production is regulated in a specific temporal and tissue manner and reinduction of functional elastic fibers is of high difficulty. This requires to target the TE production restoration.

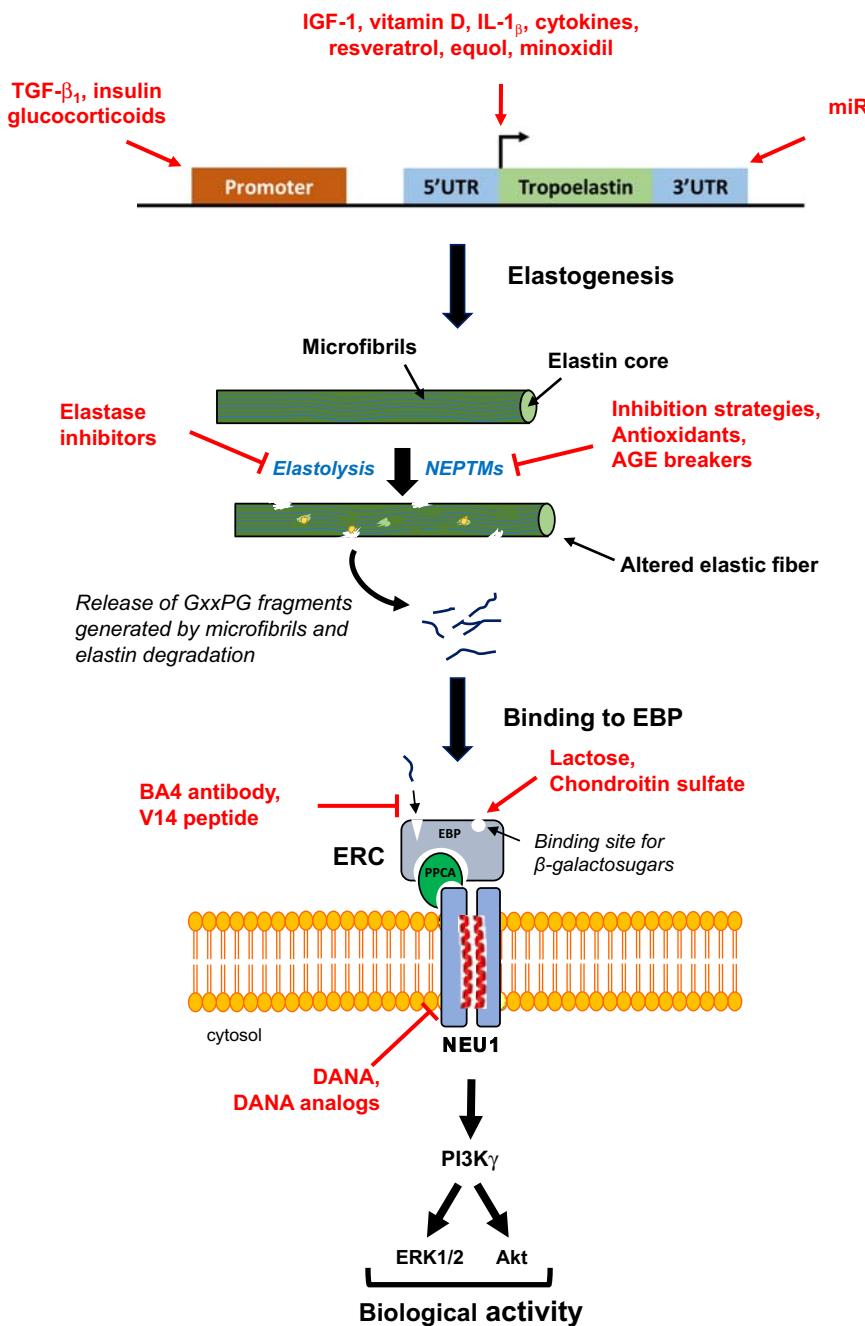
The TE promoter contains response elements to TGF-β1,[17] to insulin[118] and to glucocorticoids.[119] However, the regulation of TE expression is also believed to be under control of the binding of regulatory microRNAs (miRs) in the 3′UTR and the coding sequences of TE mRNA.[120] Indeed, a strong expression of miRs-29 and -15 is thought to be responsible for the posttranscriptional repression of elastin in the adult aorta,[121] causing a degradation of the TE mRNA. Insulin-like growth factor-1, vitamin D, and interleukin-1β also modulate the expression of TE either at the promoter level or through the increase of mRNA stability.[22] The regulation of TE production by cytokines includes pro- and antielastogenic cytokines which control the biosynthesis/degradation of TE by transcriptional and posttranscriptional mechanisms, and depends on how these cytokines influence cell cycle actors.[122] Finally, exogenous molecules, whether medicinal or bioactive dietary compounds, can also influence the level of expression of the TE gene. Indeed, in different models of human skin, it has been shown that resveratrol, 4′-acetoxyresvereatrol as well as equol and R-equol are able to increase the expression level of TE mRNA. This effect is correlated with an augmentation of the corresponding protein expression level.[123] In mice receiving minoxidil, an antihypertensive and peripheral vasodilator for two weeks, the TE gene is induced when the drug is withdrawn. Interestingly, this is associated with functional elastic fibers presence.[103] This induction was also found in 24-month aged mice treated for 10 weeks, suggesting the high potential of this molecule in the induction of elastogenesis.[102]

Targeting proteolysis and nonenzymatic posttranslational modifications

Strategies aiming at limiting elastin proteolysis generally rely on the use of elastase inhibitors. However, many enzymes are able to degrade elastin, ranging from neutrophil elastase to MMPs and cathepsins. Thus, global inhibition is not conceivable because of their role in the regulation of multiple useful tissue functions and the potential side

effects such a strategy could cause.[124] However, several synthetic inhibitors have been tested with often disappointing results. Strategies based on the use of natural inhibitors, such as elafin, could give better results but a chronic administration seems necessary to obtain a significant reduction of elastolysis.[125–127]

The limitation of elastic fiber molecular aging may consist of global therapeutic strategies aiming at limiting NEPTMs at the body level without being elastin-specific. The first approaches are based on the administration of small molecules, which compete with the reactive groups of proteins for the binding of reactive metabolites and thus scavenge these metabolites. Numerous studies have been conducted with aminoguanidine, which has provided good results in vitro and in vivo in rodents, for reducing glycation-mediated complications including arterial stiffening.[128,129] Unfortunately, this molecule failed at the stage of clinical trials due to safety concerns. These trials were limited to its action on diabetic nephropathy,[130] and to our knowledge, there is no report about its potential role in the improvement of arterial stiffening. Similar strategies have been considered for limiting carbamylation reaction. Thus, amino acid solutions were used in patients with ESRD, which significantly reduced the level of protein carbamylation.[131] Since oxidative stress favors glycation and carbonylation reactions, the administration of antioxidants may also be considered an interesting therapeutic strategy.[132]

Other approaches have targeted generated products such as AGEs. For example, molecules called "AGE breakers" have been developed, the most studied being alagebrium (ALT-711).[133,134] This compound has given interesting results (even though no specific data on the reduction of elastin glycation are available), particularly in several conclusive clinical studies on cardiovascular diseases. Despite these encouraging data, this molecule has not yet become a commercially viable drug because of the lack of sufficient financial supports and the difficulty to license as a drug.[135]


The combination of different strategies could be considered, as recently proposed for chronic obstructive pulmonary disease.[136] However, the major problem with these therapeutic approaches is that their effectiveness will only be guaranteed by long-term preventive treatments, which constitutes a barrier for their regular use in clinical practice, especially because of the cost such treatments would represent.

Elastin-derived peptides and elastin receptor complex modulators

Beside the use of elastase inhibitors, modulation of the pathophysiological effects related to EDPs can be achieved by either modulating the interaction between elastokines

and the ERC and/or by blocking ERC-mediated signaling pathways (Fig. 19.4). EDPs binding to the ERC can be hampered by using two strategies: a blocking antibody (BA4 antibody) targeting the GxxPG motifs located in elastin[70,111,137−140] or a 14-mer peptide (V14 peptide) that encompasses the ligand binding domain on the EBP subunit.[98,99,141,142] EBP also contains a binding site for β-galactosugars, and binding of lactose or chondroitin sulfate to EBP has been shown to change the conformation of the protein such that it loses its ability to bind to elastin

FIGURE 19.4 The different elastin-associated therapeutic strategies. This scheme illustrates the different therapeutic options that could be used to either simulate tropoelastin synthesis, decrease proteolysis and nonenzymatic posttranslational modifications of elastin occurring during aging and/or under pathophysiological conditions, or reduce elastin-derived peptides cell signaling. *AGE*, advanced glycation end-products; *DANA*, 2-deoxy-2,3-dehydro-N-acetylneuraminic acid; *EBP*, elastin-binding protein; *ERC*, elastin receptor complex, *ERK*, extracellular-regulated protein kinases; *IGF*, insulin-like growth factor; IL, interleukine; *NEPTMs*, nonenzymatic posttranslational modifications; Neu-1, neuraminidase-1; *PI3K*, phosphoinositide 3-kinase; *PPCA*, protective protein/cathepsin A; *TGF*, transforming growth factor; *UTR*, untranslated region.

and EDPs and can be shed from the cell surface.[86,89,143] Another valuable strategy relies on the blocking of the activation of key signaling proteins involved in ERC signaling pathways, such as Neu-1. Due to the lack of selective Neu-1 inhibitors, the majority of studies reported so far have used the broad-spectrum sialidase inhibitor DANA (2,3- dehydro-2-deoxy-N-acetylneuraminic acid) or inhibitors of bacterial or viral neuraminidases, such as zanamivir or oseltamivir. However, these bacterial or viral inhibitors were shown to have broad or weak activities against human neuraminidases.[144,145] To date, two selective inhibitors of human Neu-1 have been reported, based on modifications of the DANA scaffold: the C9-amido analog (16) and the C5-hexanamido-C9-acetamido analog.[146] As mentioned previously, recent findings from our group have shown that human Neu-1 contains a dimerization interface located within a transmembrane domain that is involved in membrane Neu-1 dimerization and sialidase activity.[95] These data should open new avenues for selective inhibition of this sialidase.

Conclusion

This chapter aimed at summarizing the role of elastin and elastokines in arterial stiffness. Besides its fundamental role in arterial mechanics, when degraded, elastin leads to the production of highly bioactive EDPs, also named elastokines, able to modulate vascular events and now seen as crucial modulators of the cardiovascular continuum. It is consequently clear that the extensive understanding of elastin biology, through its dual mechanics/elastokines role, could lead to the development of an innovative therapy based on matrix biology with an important potential.

Chapter 20

Inflammation and arterial stiffness

Kaisa Maki-Petaja[1] and Ian B. Wilkinson[1,2]

Introduction

Inflammation is a key element in atheroma formation, playing a pivotal role in the initiation, progression, and propagation of the disease.[1] Circulating levels of several cytokines are elevated in subjects with atherosclerosis, and correlate with disease burden. Levels of the acute phase reactant C-reactive protein (CRP) also predict the risk of future cardiovascular events both in subjects with known cardiovascular disease (CVD),[2] and in apparently healthy individuals.[3] Moreover, the incidence of CVD is increased in patients with chronic systemic inflammatory diseases such as rheumatoid arthritis (RA),[4,5] systemic lupus erythematosus (SLE),[6] psoriasis,[7] chronic obstructive pulmonary disease (COPD),[8] and polymyalgia rheumatica (PMR).[9] The mechanism by which inflammation leads to increased CV risk remains unclear and numerous potential mechanisms have been proposed, including acceleration of the atherosclerosis process, destabilization of plaques, direct inflammation of the vasculature, endothelial dysfunction, or premature stiffening of large arteries.

Arterial stiffness is regulated by numerous factors. Traditionally, mean arterial pressure (MAP) and structural changes in the components of arterial wall were thought to be main determinants of arterial stiffness. With aging, the neat arrangement of the elastin fibers within the media is lost, the elastin fibers become thinner and fragmented, the stiffer collagen fibers become the load bearing ones, and arterial calcification occurs.[10] Moreover, a disrupted balance between elastin synthesis and breakdown, the latter mediated by matrix metalloproteinases (MMPs), contributes toward arterial stiffening.[10] Arterial stiffness is also regulated by smooth muscle tone, and endothelium-derived mediators, such as NO and endothelin-1, contribute to the functional regulation of arterial stiffness.[11] More recently, the role of inflammation in large arterial stiffening has been recognized,[12] possibly via changes in the composition of the arterial wall, due to inflammatory cell infiltration or via endothelial dysfunction.[13]

Arterial stiffness and low-grade inflammation

Cross-sectional studies

The largest community-based cross-sectional study investigating the association between inflammatory markers and aortic stiffness by Schnabel et al. demonstrated an association between interleukin-6 (IL-6) and aortic pulse wave velocity (PWV); importantly, this association remained significant after adjusting for traditional CV risk factors.[14] A number of studies in healthy individuals and in patients with isolated systolic hypertension indicated an association between arterial stiffness and serum levels of CRP,[13,15−17] suggesting that inflammation plays a role in the regulation of arterial stiffening. However, these studies do not provide information about the causality between inflammation and CVD. By adapting Koch's "Postulates" and using surrogate markers of CV risk, this could be done by answering the following questions; (1) Does inflammation cause arterial stiffening? (2) Does a reduction in inflammation reduce arterial stiffness?

Prospective studies

There have only been very few prospective studies assessing the association between inflammatory markers and arterial stiffness, and data from these studies are conflicting. Data from the Caerphilly Prospective Study showed that both current CRP and CRP at the beginning of the 20-year follow-up period were strongly associated with aortic PWV.[12] Likewise, The Whitehall study demonstrated that baseline inflammatory markers CRP, IL-6, and IL-1Ra predicted aortic PWV measured at 10-year follow-up visit.[18]

Taking another approach, Schumacher et al. investigated the relationship between three single nucleotide polymorphisms in the CRP gene and aortic PWV and found no relationship between any of the CRP genotypes and aortic stiffness, despite these genotypes having an impact on CRP levels, suggesting that CRP is a simply a marker of vascular damage/inflammation, rather than a causal molecule.[19] Furthermore, a large genome-wide association study by Elliott et al. concluded that the lack of concordance between the effect of CRP genotypes on coronary heart disease risk and its effect on CRP levels argues against a causal association of CRP with coronary heart disease.[20]

Experimental models of inflammation

Another approach to study the role of inflammation in arterial stiffening is to induce inflammation in healthy people, and study changes in arterial properties. In these acute experimental models of inflammation, *Salmonella typhi* vaccination was used to induce acute inflammation and shown to lead to an increase in PWV.[21,22] These studies are hypothesis generating, and they suggest a causal role of inflammation in the pathogenesis of large artery stiffening. However, the limitation of this model is that it is not known whether these acute changes reflect "a real-life" situation. After all, healthy volunteers cannot be made chronically inflamed; therefore, an alternative approach to assess the role of inflammation in arterial stiffening is to study patients with existing inflammatory conditions.

Arterial stiffness in patients with primary vasculitides

Booth et al. conducted a series of studies in patients with antibody-associated systemic vasculitis to establish the role of systemic inflammation on arterial stiffness. These studies demonstrated that patients with active disease had a significantly higher carotid femoral pulse wave velocity (CF-PWV) and augmentation index (AIx) than those in remission or matched healthy control subjects.[23] More recently, Chanouzas et al. demonstrated that T-cell expansion is independently associated with increased arterial stiffness in ANCA-associated vasculitis. They showed that the $CD4^+CD28^{null}$ T-cell percentage was associated with increased systolic blood pressure (rho = 0.305, P = .026), pulse pressure (rho = 0.428, P = .001), and CF-PWV (rho = 0.371, P = .006).[24] A metaanalysis performed by Upala et al. extracted data from four observational studies, resulting in 303 subjects with Behçet's disease. They found that CF-PWV is significantly higher in patients with Behçet's disease compared with controls (MD = 0.74; 95%, CI: 0.28−1.20, P = .002, I(2) = 63%).[25]

Vasculitis is an interesting model of systemic inflammation, but the use of this model also has a limitation; these patients have a direct vascular disease, which complicates the interpretation of the results, such that what is seen in vasculitis patients may not necessarily reflect changes in arterial stiffness seen in other conditions. Therefore, other conditions with chronic, systemic inflammation may provide a better model to study the role of systemic inflammation and the effect of circulating cytokines and acute phase proteins in the process of arterial stiffening.

Arterial stiffness in chronic inflammatory diseases

Chronic, systemic inflammatory diseases represent an ideal model to study effect of inflammation on arterial stiffness, especially as they are associated with increased CV mortality, which cannot be fully explained by the traditional CV risk factors.[5] There are numerous studies in various chronic systemic inflammatory conditions that demonstrate that patients with these conditions exhibit increased arterial stiffness.[13]

Perhaps the largest study to investigate the role of inflammation in aortic stiffening was the study by Dregan.[26] This study tested the hypothesis that arterial stiffness is elevated in inflammatory disorders in comparison to the inflammation-free control group. In total, 171,125 adults from the UK Biobank who did not have CVD and have had arterial stiffness measurements performed were included in the analysis. A total of 5976 (3%) participants diagnosed with inflammatory disorders had data on arterial stiffness. However, it is important to note that the stiffness as not assessed using the gold standard measurement of large artery stiffness, (CF-PWV), but was based on waveform analysis. Participants diagnosed with RA, SLE, Sjogren syndrome, psoriasis, ankylosing spondylitis (AS), systemic vasculitis, or inflammatory bowel disease (IBD) represented the exposed group. Participants free of these diagnoses represent the comparison group. Adjusted linear regression analyses revealed 14% increase in mean arterial stiffness for chronic inflammatory disorders (beta coefficient (β) 1.14, 95% CI 1.05 to 1.24, P = .002) compared with the control group. Moreover, the association appeared to increase with the severity of chronic inflammation, as assessed by leukocytes count and granulocytes count.[26]

Rheumatoid arthritis

Numerous small studies have concluded that patients with RA[27−29] exhibit increased aortic CF-PWV which correlates, independently of blood pressure, age, and gender, with the degree of active inflammation.[27] A recent, large

metaanalysis by Ambrosino et al. evaluated the relationship between RA and arterial stiffness across 25 studies (1472 RA patients, 1583 controls). They demonstrated that RA patients had a significantly higher CF-PWV in comparison to controls with a mean difference (MD 1.32 m/s; 95% CI 0.77, 1.88; $P < .00001$); ankle-brachial-PWV (MD 198.42 cm/s; 95% CI 45.79, 342.76; $P = .01$), AIx (MD 11.50%; 95% CI 5.15, 17.86; $P = .0004$), and AIx@75 (MD 6.99%; 95% CI 4.92, 9.06; $P < .00001$) were also increased in RA patients. Furthermore, this metaanalysis demonstrated that there is an association between the severity of inflammation and stiffness, and that increased arterial stiffening is present even in early-stage disease.[30]

Inflammatory bowel disease

A recent metaanalysis by Zanoli et al. used data from four cohorts in three countries, which included 151 patients with ulcerative colitis, 159 with Crohn's disease, and 227 control patients. The results demonstrated CF-PWV was increased in patients with Crohn's disease (mean difference 0.78 z-score; 95% confidence interval, 0.56−1.00 z-score, $P < .001$) and ulcerative colitis (mean difference 0.75 z-score; 95% confidence interval, 0.52−0.97 z-score, $P < .001$).[31]

In a linear regression model adjusted for prespecified confounders, aortic PWV was associated with disease duration and white blood cell count but not with CRP and erythrocyte sedimentation rate, cardiovascular risk factors, or therapy.

Systemic lupus erythematosus

A metaanalysis of data from 14 studies in SLE patients was performed by Wang et al. They used fixed-effect or random-effect models to estimate the pooled standardized mean difference (SMD) and 95% confidence intervals (CIs) between patients and controls. This study demonstrated that patients with SLE had significantly higher CF-PWV levels than the control group (SMD = 0.56; 95% CI: 0.30−0.82). They also showed that body mass index and disease duration were associated with increased CF-PWV.[32]

Systemic sclerosis

A large metaanalysis was performed comprising a total of 1292 patients with systemic sclerosis (SSc) from 35 individual studies. Arterial stiffness, assessed by both CF-PWV and ankle-augmentation index, was found to be higher in SSc patients in comparison to controls. The SMD for CF-PWV was 0.62 (95% CI: 0.35, 0.88, $P < .001$), whereas the standardized difference for AIx was 0.96 (95%CI: 0.45, 1.47, $P < .001$).[33]

Chronic obstructive pulmonary disease

Despite being primarily a chronic lung condition, patients with COPD exhibit an increased risk of CV events. A large metaanalysis of 32 studies (3198 patients and 13867 controls) reported that COPD patients had significantly higher CF-PWV (SMD: 0.70; 95% CI: 0.52, 0.88; $P < .0001$), AIx normalized to a heart rate (MD: 4.59%; 95% CI: 2.80, 6.38; $P < .0001$). Metaregression analysis revealed that the severity of lung disease (as expressed by FEV_1%predicted) was associated with PWV. In the subgroup analysis, the authors showed that COPD patients with even mild airway obstruction had increased arterial compared with controls subjects, suggesting that subclinical vascular changes occur prematurely and increase with declining lung function.[34]

Human immunodeficiency virus infection

Whether patients with human immunodeficiency virus (HIV) have increased arterial stiffness is contentious. A recent review evaluated 18 observational studies which compared individuals with HIV infection and controls, and found that 55% of studies showed no difference in aortic stiffness between HIV+ and age-matched HIV− control groups. The main reported determinants of aortic stiffness in the reviewed studies were age, blood pressure, smoking, metabolic syndrome, and HIV-related variables, including CD4/CD8 ratio, current T-CD4 count $<200/mm^3$, and nadir T-CD4+ count $<200/mm^3$. These findings suggest that HIV and associated immune dysfunction may be associated with large artery stiffness.[35] The impact of HIV infection on arterial stiffness and hemodynamics will be discussed in detail in Chapter 47.

Antiinflammatory treatment for arterial stiffness

Numerous studies in both healthy individuals and in patients with inflammatory conditions have demonstrated that inflammatory markers are independently associated with arterial stiffening, suggesting that stiffening may be modifiable by antiinflammatory treatments. This part of this chapter aims to explore the studies investigating the effect of antiinflammatory drugs for arterial stiffness reduction.

Only few relatively small studies have investigated the effect of traditional antiinflammatory drugs on arterial stiffness. Pieringer et al. demonstrated a reduction in AIx in patients with PMR following corticosteroid treatment; from $28 \pm 9\%$ to $25 \pm 10\%$, $P = .006$.[36] Schillaci et al. demonstrated in patients with PMR that 4-week treatment with prednisolone reduced aPWV (from 11.8 ± 3 to 10.5 ± 3 m/s, $P = .015$) and AIx (from $34 \pm 7\%$ to $29 \pm 8\%$, $P = .01$). These changes were independent of BP

and heart rate and the change in CF-PWV correlated with change in plasma CRP (r = 0.40, P = .037).[37] The results of these studies are contradicted by a study by Wong et al. who found that antiinflammatory therapy with cyclooxygenase (COX) inhibitors indomethacin and rofecoxib did not improve endothelial function or reduce arterial stiffening.[38] It is important to recognize that some of the conventionally used antiinflammatory drugs may actually increase CV risk. Corticosteroids cause dyslipidemia, hypertension, impaired glucose tolerance, and imbalances in thrombosis and fibrinolysis.[39] Methotrexate use can lead to hyperhomocysteinemia, which is an independent predictor of CV events, although this problem can be overcome by concomitant supplementation of folic acid.[40] Selective COX-2 inhibitors and also nonselective NSAIDs increase mortality and CV events in numerous patient groups due to an imbalance of thromboxane A2 and prostacyclin.[41] However, these drugs may also have an ameliorating effect on the vasculature by the reduction of inflammation and hence oxidative stress.

Due to their high specificity, biological immunomodulatory drugs may represent a better pharmacological tool to investigate the role of inflammation on stiffness. Maki-Petaja et al. demonstrated in 17 RA patients that following 8 weeks of antitumor necrosis factor-α (TNF-α) therapy, CF-PWV was reduced from 9.09 ± 1.77 m/s to 8.63 ± 1.42 m/s (P = .04). Also, aortic inflammation assessed by tissue to background ratio of (18)F-fluorodeoxyglucose uptake within the aortic wall decreased from 2.02 ± 0.22 to 1.90 ± 0.29, which correlated with the reduction of CF-PWV (R = 0.60, P = .01).[28] Similarly, Angel at al. demonstrated in 55 patients inflammatory arthropathies that a 1-year treatment course with anti-TNF-α therapy, but not placebo, led to a reduction of CF-PWV (-0.54 ± 0.79 m/s vs. 0.06 ± 0.61 m/s, respectively; P = .004) and carotid intima-media thickness (cIMT) progression was reduced in the treatment group in comparison to the control group.[42] Tam et al. demonstrated in 40 RA patients that after a 6-month treatment period, there was a significantly greater reduction in CF-PWV in those patients receiving both methotrexate and the anti-TNF-α agent, infliximab compared to those receiving methotrexate only (-0.78 ± 1.13 m/s vs. 0.18 ± 1.59 m/s; P = .04), which was accompanied by significantly greater reduction in CRP and disease activity.[43] This suggested that a greater reduction in inflammation and disease activity may in turn lead to a greater reduction in PWV. Contrary to the encouraging findings seen in RA patients with anti-TNF-α agents, McInnes et al. found in a randomized double blind phase III trial, that interleukin-6 receptor (IL-6R) blocker tocilizumab was not beneficial in reducing CF-PWV in 132 patients with RA.[44] Opposing their

hypothesis, they found that reduction in CF-PWV was greater in the placebo group in comparison to tocilizumab group at 12 weeks posttreatment (adjusted mean difference 0.79 m/s; 95% CI 0.22 to 1.35; P = .007). This could be due to the observed increase in total cholesterol, LDL-cholesterol, and triglyceride levels in tocilizumab recipients. However, they demonstrated that tocilizumab led to a reduction of lipoprotein(a), as well as inflammatory and thrombotic markers. And as such the net effect of cardiovascular benefits and/or risks of tocilizumab remains unclear.

Another recent study explored the effect of IL-12/23 inhibition with ustekinumab in patients with psoriasis. In this study by Ikonomidis et al., 150 psoriasis patients were randomized to receive ustekinumab, anti-TNF-α treatment (etanercept), or cyclosporine, and CF-PWV, as well as a host of left ventricular (LV) function tests and inflammatory markers were assessed at baseline and 4 months posttreatment. Data from all three treatment arms demonstrated an improvement in global longitudinal strain, LV twisting, and coronary flow reserve, as well as reduced inflammatory markers, but the greatest improvements were seen in the ustekinumab group. Interestingly, CF-PWV and central augmentation index were only improved by ustekinumab.[45] This could potentially be explained by the fact that IL-12 signaling plays integral part in the pathogenesis of psoriasis, and hence inhibition of IL-12 would had a greater benefit in the vasculature in this particular patient cohort. Pina et al. conducted a prospective study in 29 patients with moderate to severe psoriasis to determine the effect of anti-TNF-α monoclonal antibody adalimumab on endothelial function and CF-PWV[46]. In contrast to the findings of Ikonomidis et al. demonstrated 6-month treatment with anti-TNF-α agent led to an improvement of endothelial function as measured by flow-mediated dilatation (from $6.19 \pm 2.44\%$ to $7.46 \pm 2.43\%$; P = .008) and reduction of CF-PWV (from 6.28 ± 1.04 m/s to 5.69 ± 1.31 m/s; P = .03).

A follow-up study by Zanoli et al. provided important novel data on the longitudinal changes in CF-PWV by after commencement of antiinflammatory therapy.[47] Longitudinal study changes in CF-PWV were observed for 3.4 ± 0.5 years in IBD subjects receiving mixed antiinflammatory therapies: 14 were treated with salicylates; 11, with steroids and azathioprine; 7, with anti-TNF-alpha and 30 matched healthy controls were also studied. Interestingly, the results showed that CF-PWV increased during follow-up in both control and IBD subjects treated with salicylates, whereas CF-PWV remained unchanged in those treated with steroids and azathioprine or anti-TNF-α therapy. Therefore, the annual increase of CF-PWV was significantly higher in subjects treated with salicylates than in those treated with steroids and azathioprine or anti-TNF-alpha (P = .004 and P = .001,

respectively). These data suggest that a better control of inflammation by the use of more potent antiinflammatory drugs may help to slow down aortic stiffening over time.

Although many studies have shown in numerous different chronic inflammatory conditions that antiinflammatory treatments lead to a reduction of arterial stiffening, this does not necessarily seem to be the case in patients with AS. Capkin et al. showed in a prospective trial of 28 AS patients that despite significant improvement in markers of disease activity and inflammation, anti-TNF-α therapy did not improve CF-PWV after 24 weeks of therapy (7.9 ± 1.3 m/s vs. 7.7 ± 1.3 m/s; $P = .4$).[48] Mathieu et al. came to very similar conclusions by demonstrating that there were no changes in CF-PWV or central augmentation index after 6 or 12 months following anti-TNF-α therapy in 49 patients with AS, despite the treatment leading to a significant reduction of inflammation and disease activity.[49] These somewhat unexpected results could potentially be due to a low baseline CF-PWV in these relatively young subjects; after all, number of studies have shown that the greatest change in CF-PWV is seen in those with highest baseline values.

Only very few studies have investigated the effect of antiinflammatory drugs on arterial stiffness in healthy individuals. Vlachopoulos et al. used *S. typhi* vaccination to induce acute inflammation healthy subjects.[22] Interestingly, they demonstrated that there was no change in CF-PWV following the vaccination in those subjects that were randomized to receive aspirin pretreatment, whereas CF-PWV significantly increased in the placebo group. Using the same model of acute inflammation, Wallace et al. similarly demonstrated that pretreatment with Simvastatin also prevents inflammation-induced aortic stiffening.[21]

Antilipidemic drugs

Numerous studies have reported so-called "pleiotropic effects" of HMG-CoA reductase inhibitors (statins). These include improvements of endothelial function,[54] increased nitric oxide bioavailability,[55,56] antioxidant[57] and antiinflammatory[58] or immunomodulatory effects.[59] Therefore, it comes as no surprise that numerous studies have investigated statins as a means to reduce arterial stiffness.

In the late 1990s, Tomochika et al. first suggested in a small prospective study that arterial stiffness, as measured by Beta stiffness index, can be reduced with a strict cholesterol-lowering therapy with pravastatin, probucol, and diet.[50] A year later, Muramatsu et al. demonstrated in 59 patients with hypercholesterolemia, that those patients who had 15% or more reduction in total cholesterol following pravastatin therapy also had a significant decrease in CF-PWV and total peripheral resistance.[51]

Since these first two studies in the 1990s, numerous groups have studied the effect of different statins in various patient groups. Indeed, statins have now been shown to reduce arterial stiffness in patients' hypercholesterolemia, hypertension, CVD, chronic kidney disease, diabetes, RA, and in obese individuals.[52]

Mechanisms of inflammation-induced arterial stiffening

Although there is plenty of evidence to demonstrate that inflammation has a causal effect on arterial stiffening and that treatment of inflammation leads to reductions in stiffness, the mechanisms behind inflammation-induced stiffness remain incompletely understood. Numerous potential mechanisms have been suggested, some of which are discussed below.

Endothelial dysfunction

Endothelial function can regulate arterial stiffness via changes in smooth muscle tone. Both basal and stimulated nitric oxide (NO) production can regulate muscular artery distensibility. There is also an inverse correlation between endothelial function, as measured by flow-mediated dilatation response, and CF-PWV, which appears independent of potential confounding factors, including age and MAP.[53] Furthermore, local arterial distensibility is reduced by blockade of endogenous NO synthesis with the NO synthase inhibitor NG-monomethyl-L-arginine in the human iliac artery.[11] However, the role of nitric oxide in regulating stiffness of the more elastic thoracic aorta remains controversial. A detailed discussion of endothelial dysfunction and its hemodynamic consequences can be found in Chapter 23.

The association between acute and chronic inflammation and endothelial dysfunction has been demonstrated in numerous studies.[54] However, the mechanisms behind this are incompletely understood. One possibility is that certain cytokines induce expression of inducible nitric oxide synthase (iNOS) leading to a production of reactive oxygen species with subsequent uncoupling of endothelial NOS (eNOS) and reduction in nitric oxide (NO) production.[55] Moreover, the acute phase reactant CRP may also decrease eNOS expression and thus reduce NO bioavailability directly.[56] Production of myeloperoxidase (MPO) is another potential key mediator in inflammation-induced endothelial dysfunction. MPO is released from activated neutrophils during inflammation. MPO can catalytically degrade NO, thus reducing NO bioavailability. Furthermore, MPO has the unique ability to produce hypochlorous acid and subsequently lead to uncoupling of eNOS,[57]

oxidation tetrabiopterin (BH_4),[58] and further superoxide (O_2^-) production. Tetrahydrobiopterin (BH_4), a naturally occurring essential co-factor for eNOS, is thought to play an important role. Recent in vitro studies suggest that activation of iNOS may lead to endothelial dysfunction by depleting the bioavailability of BH_4 from eNOS and subsequently uncouple eNOS, resulting to production of superoxide (O_2^-) rather than NO.[59] When O_2^- reacts with NO in vivo, peroxynitrite is formed, leading to oxidation of BH_4 and a reduction in the allosteric stability of eNOS, further uncoupling of eNOS. Furthermore, increased levels of adhesion molecules may damage endothelial cells and lead to altered endothelial function.[60] Activation of neutrophils by antineutrophil cytoplasm antibodies within the vascular lumen may contribute to endothelial cell injury.[61] Finally, oxidation of LDL promoted by inflammation may lead to direct endothelial cell toxicity[62] and disturbed eNOS function.

Increased synthesis of matrix metalloproteinases

Another mechanism that may contribute to arterial stiffening during inflammation is an accelerated elastin breakdown by matrix MMPs. MMP synthesis is induced by CRP, and the release of MMPs from the leukocytes can degrade elastin within the media. Yasmin et al. demonstrated in mixed cohort of 677 hypertensive and normotensive subjects that MMP-9 levels are independently associated with CF-PWV.[63] In a further study, Yasmin et al. demonstrated that aortic stiffness and elastase activity are influenced by MMP-9 gene polymorphisms, suggesting that the genetic variation in this protein may have a causal role in the process of large artery stiffening.[64] Although elastin degradation may play an important role in arterial stiffness over long periods of time, it is unlike to explain more acute changes or how antiinflammatory therapies are able to reduce stiffness. After all very little, if any, elastin is synthesized beyond the first year of life.[65]

Calcification

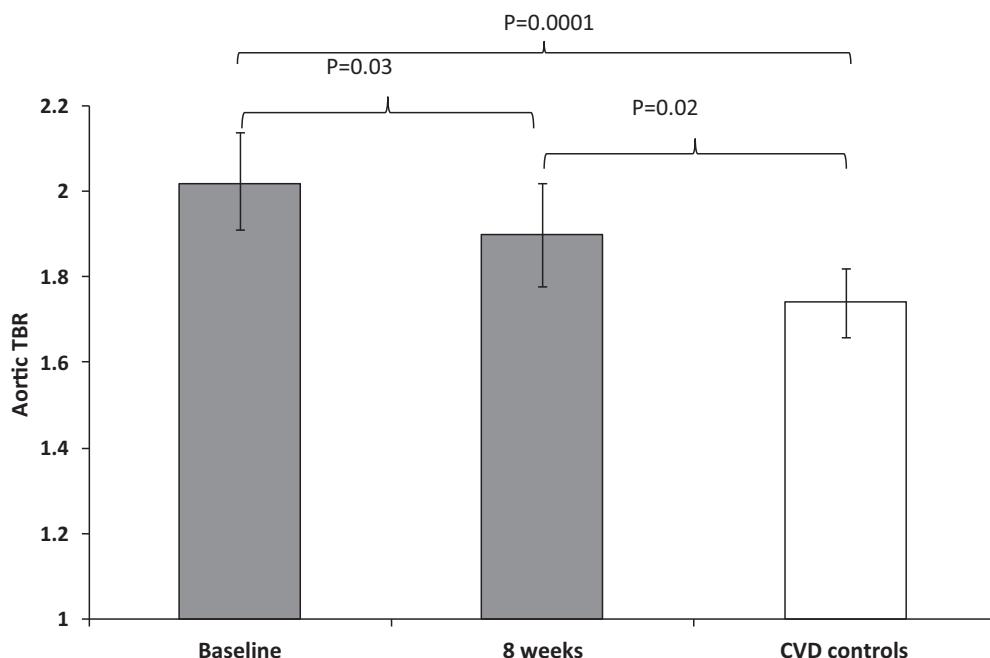
Calcification is another potential mechanism behind inflammation-induced arterial stiffness. Several mediators of inflammation such as oxidation, carbonyl stress, CRP, and cytokines may directly stimulate vascular calcification.[66] This can lead to a phenotypic transformation of vascular smooth muscle cells (VSMCs), which increases bioapatite formation and therefore calcification, as well as a transformation of VSMCs to osteoblast-like cells. Also,

fetuin-A, an endogenous inhibitor of vascular calcification, is downregulated during inflammation, and recently it has been demonstrated that fetuin-A is an independent risk factor for progressive arterial stiffness[67] in patients with chronic kidney disease. A study in children on dialysis, demonstrated that fetuin-A and another physiological inhibitor of calcification (osteoprotegerin) are associated with increased aortic stiffness and calcification.[68] The role of inflammation on arterial stiffening and mechanisms of aortic wall calcification will be further discussed in Chapter 21.

Smooth muscle proliferation and changes in the composition of extracellular matrix

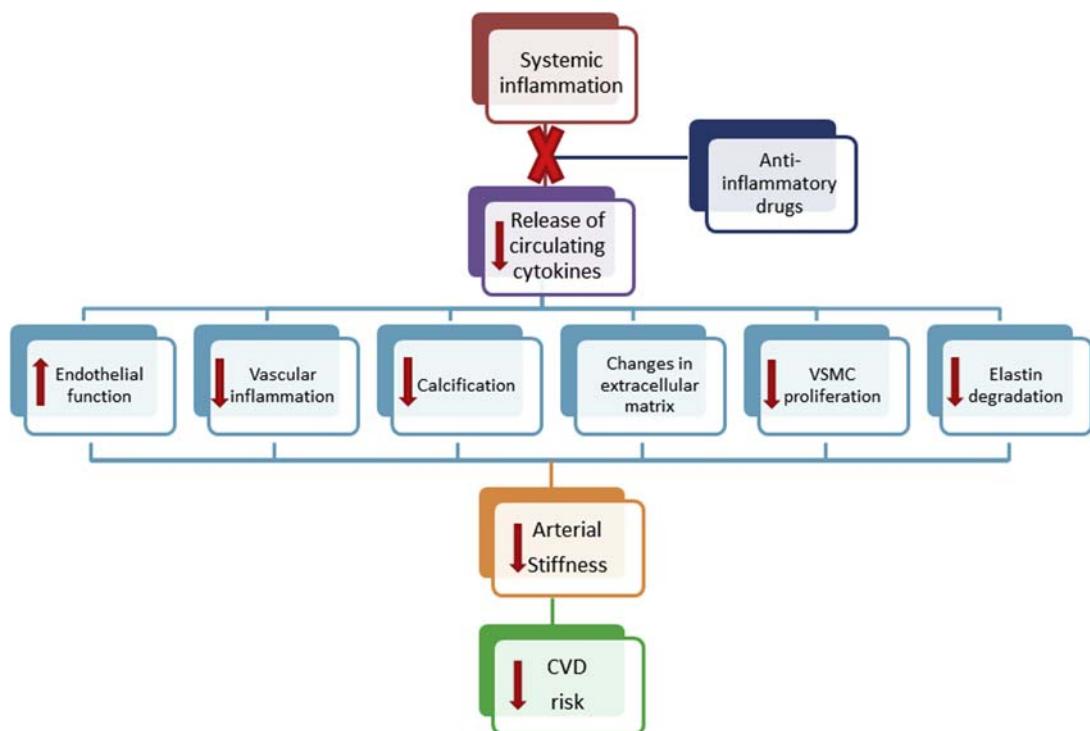
The inflammatory response initiates an accumulation of leukocytes into the vascular endothelium. This can lead to a complex cascade of VSMC activation, migration, and proliferation. The role of vascular smooth muscle dysfunction on arterial stiffness will be discussed in detail in Chapter 22. Activated VSMC can synthesize and secrete biologically active mediators such as endothelin, angiotensin II, cytokines, proteases, collagen, and proteoglycans (PGs) that regulate contraction, relaxation, inflammation, proliferation, apoptosis, and matrix alterations[69] and can therefore subsequently lead to arterial stiffening. Alternatively, inflammation can alter the extracellular matrix (ECM).

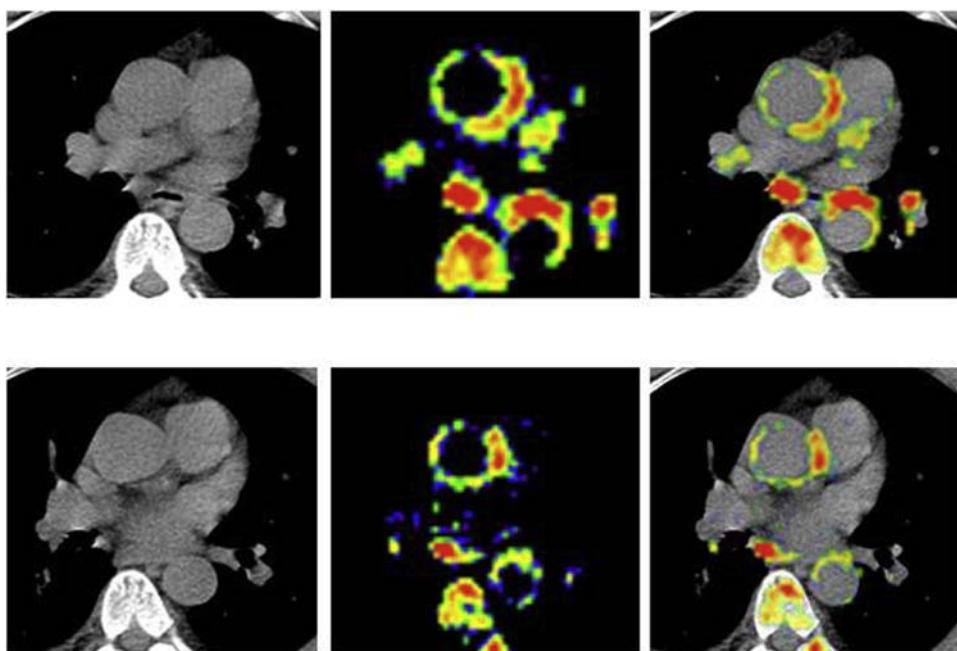
ECM is a complex collection of fibrous proteins and glycoproteins, which are embedded in a hydrated ground substance of PGs, proteins with glycosaminoglycan (GAG) chain attached to them.[70] PGs have numerous specific roles within the vascular ECM, such as hydration, filtration, and regulation of various cellular activities as well as inflammatory processes.[71] During atherosclerosis and inflammation arterial GAGs accumulate within the intima, and inflammatory cytokines have the capacity to alter GAGs both quantitatively and qualitatively.[72] In intermediate and advanced atherosclerotic lesions, GAGs such as decorin, versican, biglycan, and hyaluronan (HA) are upregulated, and alterations in HA metabolism, distribution, and function have been documented in various inflammatory disease states.[73] Tissue enriched with HA tends to trap water and swell, forming a viscous hydrate gel which allows the ECM to resist compression forces,[73] making the wall stiffer. In addition, overproduction of HA in the aorta results in stiffening of the arterial wall by thinning of elastic lamellae in animal models.[74] In vitro findings indicate that upregulation of hydrating GAGs leads to an increased water content of the vessel wall.[75]

Direct vascular inflammation


Aortic stiffness in chronic inflammatory conditions may, at least in RA, be driven by direct vascular inflammation. Although the prevalence of clinical vasculitis in RA is low,[76] the results of an autopsy series[77] and histological studies[78] suggest that subclinical vasculitis in RA is may be relatively common. However, it is rarely recognized in clinical practice due to the difficulty in its noninvasive diagnosis.[79] A recent study in patients with severe RA, but without clinically manifest CVD, demonstrated increased aortic inflammation using 18F-FDG PET/CT imaging, in comparison to subjects with established, stable CVD.[28] Additionally, the study demonstrated a reduction in inflammation along the whole aorta (Fig. 20.1A and B), as well as in its most diseased segment following anti-TNF-α therapy, and that the reduction in aortic inflammation correlates with the reduction in CF-PWV. Interestingly, RA patients exhibited a generalized increase in aortic inflammation, rather than focal uptake, suggesting that RA patients exhibit a subclinical vasculitis, rather than increased atherosclerosis, which could provide a potential mechanism for the increased CVD risk seen in RA.[80]

Conclusion

Large number of studies have suggested that inflammation plays a role in arterial stiffening; however, many of these studies are observational studies in patients with inflammatory conditions, whereas the cause–effect studies and placebo-control trials are not as numerous. There are several potential mechanisms which may explain this association, including endothelial dysfunction with subsequent changes in smooth muscle tone, smooth muscle proliferation and activation, changes in the composition of the ECM, and direct vascular inflammation, but further studies are required to ascertain these mechanisms.




Similarly, the mechanisms by which antiinflammatory therapies lead to a reduction of arterial stiffness are speculative at present (Fig. 20.2). Potentially, treatment with antiinflammatory drugs, leading to reductions in cytokine release, could lead to beneficial changes in the arterial wall composition via improvement of endothelial function, or via reductions of vascular inflammation, and hence, a reduction of the number of inflammatory cells present within the aortic wall. Other potential mechanisms include inhibition of smooth muscle cell proliferation, changes in glycosaminoglycan content of the ECM, reduction of calcification, and inhibition of elastin degrading matrix MMP synthesis. However, studies addressing these possible mechanisms need to be done to ascertain the role of these processes in inflammation-induced arterial stiffening, and large randomized placebo-controlled trials are needed to establish the true effect of antiinflammatory therapies on arterial stiffness, especially in healthy individuals.

Cardiovascular events associated with calcification in the aortic wall and aortic valve

Increased life expectancy over the past several decades has caused a surge in the burden of cardiovascular diseases (CVDs), leading to high mortality, morbidity, and overall healthcare costs.[1] The heart and vasculature undergo numerous alterations during the aging process, primarily as a result of deregulation of molecular longevity pathways, causing impaired vascular structure and function.[2] Age-related CVDs include coronary heart disease, peripheral arterial disease, valvular heart diseases, heart failure, stroke, and vascular dementia.[1,3] In general, the relationship between the average human lifespan and the occurrence of CVDs can be related to two pathologic processes: atherosclerosis (which leads to atherothrombotic events, including myocardial infarction) and large artery stiffening (a general reduction of elasticity in large arteries over time), which causes isolated systolic hypertension and contributes to the development of heart failure, age-related cognitive dysfunction, and chronic renal disease, among others. In children and young adults, CVDs are uncommon due to high tissue durability and elasticity; however, those become weakened with age due to pathologic matrix remodeling, which results in fibrosis and calcification.[4,5] Epidemiological studies have shown extensive age-associated vascular changes that constitute a central etiologic component of CVDs.[5] Among these changes are an individual's immune response, genetic background, comorbidities, environmental exposures, and overall lifestyle.[6–8] These factors can strongly influence the variability and severity of CVD.

Among CVDs, atherosclerosis, aortic wall calcification, and calcific aortic valve disease (CAVD) remain the primary contributors to mortality worldwide, with ectopic mineralization as the central condition.[9] Although these diseases share several risk factors, they cannot be generalized as the same disorder. Only ∼25%−50% of patients with CAVD also present with significant coronary artery disease, suggesting divergent pathological processes.[10] Similarly, large artery stiffening and calcification of the medial layer of the aorta can occur in the absence of atherosclerosis. Aortic wall calcification, CAVD, and large artery stiffening manifest clinically in middle to late adulthood, with increasing severity over time.[11] Similar to many progressive disorders, it has a long subclinical phase, hampering early diagnosis that could reduce future complications.[12]

Advanced calcification in the intimal layer of atherosclerotic plaques has been associated with stable atheroma.[13] However, the link between calcification and plaque rupture, while predicted computationally, is still clinically unproved and an ongoing topic of debate in the field. While macrocalcification can act as a biomechanical stabilizer, microcalcifications have a predisposition of susceptibility to rupture.[14–16] Moreover, calcification reduces aortic wall elasticity.[17] Atherosclerotic plaque rupture can cause subsequent acute events, such as myocardial infarction and stroke.[5] Nonatherosclerotic calcification, common in chronic kidney disease (CKD), affects the medial layer of the ascending aorta and aortic arch; therefore, impacting the efficacy of aortic valve replacement and most treatments of severe aortic stenosis.[18,19]

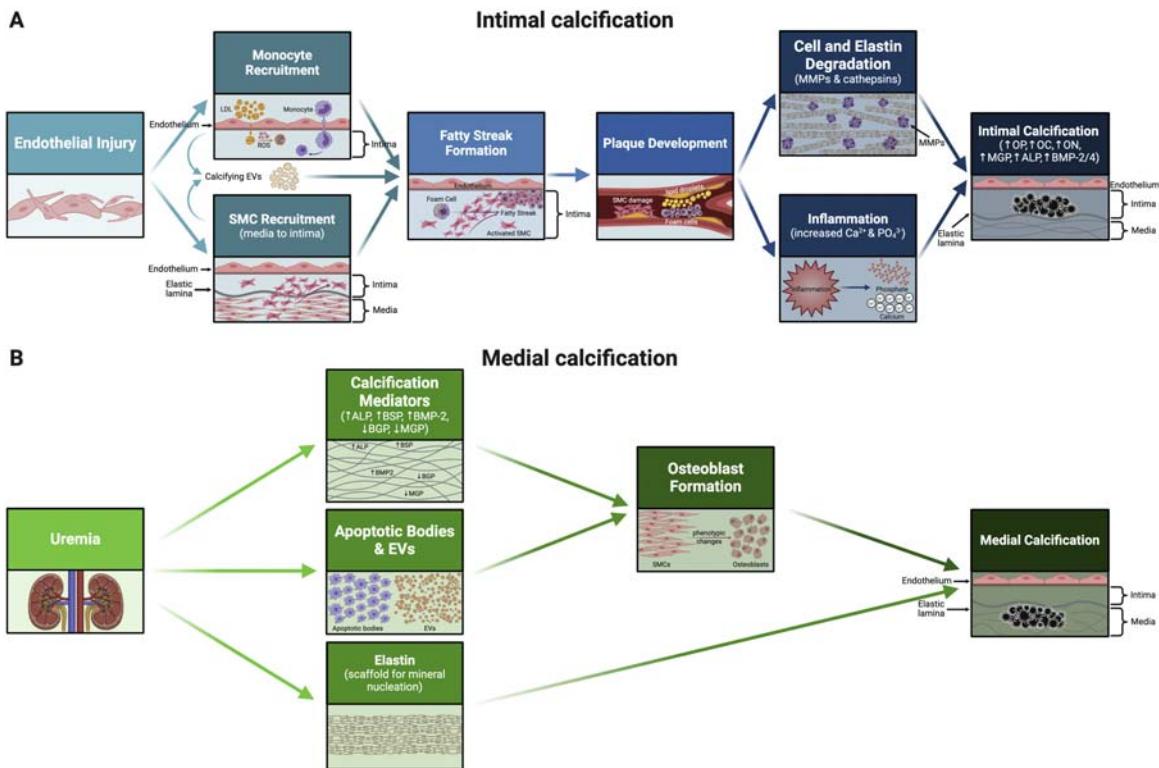
In aortic valves, calcification reduces leaflet compliance and fails to maintain directionality of blood flow from the left ventricle to systemic circulation.[20–22] Additionally, calcium deposits damage the structural integrity of aortic leaflets, therefore, interfering with the biomechanical functionality.[23] As a risk factor, arterial calcification leads to a fourfold increase in cardiovascular events.[2,24] The size and density of calcification reflects disease stage, since it usually progresses from small calcium deposits to large and dense calcific masses.[25,26]

This chapter will outline the pathogenic mechanisms of aortic wall and aortic valve stiffness. In addition, it will go in depth into the role that calcification plays in these mechanisms, as well as the important factors associated with the role of hemodynamic shear stress throughout all stages of disease. Furthermore, the synergistic effects of risk factors in vascular endothelial dysfunction will be delineated.

Calcification is a result of multiple synergistic pathogenic processes

Several interconnected cellular and a cellular processes are involved in the nucleation and crystallization of calcium/phosphate, resulting in the formation of hydroxyapatite within the cardiovascular system.[22] As a multifaceted disorder, many factors play a role in disease manifestation and calcification extent, thus influencing the overall clinical outcome.[27] Initial mechanisms of mineralization often overlap among different types of cardiovascular calcification, especially initial vascular endothelial injury caused by mechanical alterations of blood flow. However, mechanisms of pathogenesis secondary to hemodynamic abnormalities differ depending on the localization of ectopic mineralization. In this section, we will first discuss the pathological mechanisms of aortic wall calcification and CAVD, followed by the role of hemodynamic shear stress as an instigator and propagator of disease.

Atherosclerosis and intimal calcification of the aortic wall

The endothelium is a major regulator of arterial vasculature homeostasis, thereby, playing an important role in the pathobiology of atherosclerosis.[28] Many of the risk factors that predispose patients to atherosclerosis cause endothelial damage, which is an early marker of disease.[17,29] Endothelial cell dysfunction in lesion-prone areas leads to alterations in vascular tone, redox balance, and permeability, therefore, trapping low-density cholesterol in the subendothelial space. Endothelial dysfunction will be further discussed in the following topic.


Leukocytes are recruited into the intimal and medial layers of the vessel wall (Fig. 21.1). Circulating monocytes differentiate into macrophages, which internalize modified lipoprotein and become foam cells (lipid-laden macrophages).[30] The breakdown of local homeostasis modifies cytokines, chemokines, and growth factor production, thereby, fueling the recruitment of circulating cells and neighboring vascular smooth muscle cells (SMCs) into arterial wall layers (Fig. 21.1).[31,32] Vascular SMCs are nonstriated, nonvoluntary, contractile cells that are essential for maintaining the blood pressure of vessels through contraction and relaxation in opposition to the heart.[33] In addition, SMCs participate in remodeling the extracellular matrix (ECM).[34]

Inflammatory milieu favors structural remodeling through synthesis and degradation of ECM components and cell proliferation.[35,36] Progressive tissue remodeling results in the formation of a fibrous cap, rich in oxidized lipids, cholesterol crystals, and cellular debris, referred to as the necrotic core. Other immune cell types, including dendritic cells, T cells, and natural killer T-cells, are also abundant in fibroadipose plaques, where they contribute to a proinflammatory environment and production of proteases.[22] Foam cells release proinflammatory cytokines, such as TNF-α, that contribute to arterial calcification (Fig. 21.1).[37] TNF-α induces SMC differentiation into an osteogenic phenotype, which releases calcifying extracellular vesicles (EVs).[32] Furthermore, TNF-α upregulates endothelial cell production of bone morphogenetic protein (BMP), a soluble factor associated with the formation of bone and cartilage.[38] An abundance of proinflammatory macrophages was associated with the presence of calcification in the arterial wall.[26,39]

SMC phenotype differentiation in atherosclerosis involves downregulation of contractile proteins, increased proliferation, and ECM remodeling capacity to facilitate migration of the cells to sites within tissue.[32] Calcific vascular SMC phenotypes include osteogenic, chondrocytic, and osteoclastic. An osteo/chondrogenic phenotype is characterized by the ability to release calcifying vesicles and the gain of osteochondrogenic markers, such as RUNX2, osteopontin (OP), osteocalcin (OC), and alkaline phosphatase (ALP).[40,41] In addition, SMCs can assume adipogenic and macrophagic phenotypes.[42] Therefore, arterial plaque calcification is best conceptualized as a convergence of vascular inflammatory pathobiology and bone biology.

Arterial wall calcification demonstrates bone-like organization with lamellar structure.[43] Intimal calcification leads to arterial obstruction and plaque rupture, while medial calcification is linked to vessel stiffness, systolic hypertension, and increased pulse wave velocity favoring left ventricular hypertrophy and multiple other cardiovascular disorders (as discussed in Chapter 10).[44] Microcalcifications (<15 μm particles) are observed throughout the lesion, but become harmful when located within the fibrous cap, whereas macrocalcifications are found in the deep intima adjacent to the internal elastic lamella and tunica media. While macrocalcification contributes to vessel stiffness and potentially to plaque stabilization, it can also lead to devastating organ dysfunction depending on its location and extent, which can culminate in myocardial infarction, stroke, and valve incompetence.[45]

FIGURE 21.1 Mechanisms of different types of aortic calcification: intimal atherosclerotic calcification versus medial nonatherosclerotic calcification. (A) Intimal calcification. Endothelial injury initiates the transport of monocytes and low-density lipoprotein (LDL) into the intima, as well as the migration and proliferation of vascular smooth muscle cells (SMCs) from the media to the intima. Additionally, calcifying extracellular vesicles (EVs) contribute to fatty streak formation. Layers of foam cells and activated SMCs form fatty streaks in the intima. Intermediate lesions contain scattered collections of lipid droplets with damaged SMCs that experience phenotype trans differentiation. As this process progresses, elastin and cell degradation, along with MMPs and cathepsins, acts as a scaffold for mineral deposition and inflammation that may elevate extracellular calcium (Ca^{2+}) and phosphate (PO_4^{3-}), followed by intimal calcification. SMCs and intimal macrophages produce many calcification-regulating proteins commonly found in bone, such as osteopontin (OP), osteocalcin (OC), osteonectin (ON), matrix Gla protein (MGP), alkaline phosphatase (ALP), and bone morphogenetic protein 2 (BMP-2). (B) Medial calcification. Uremia induces a change in a number of bone-associated proteins not normally expressed in the vessel wall, including ALP, bone sialoprotein (BSP), and BMP-2. There is also evidence of downregulation of MGP bone Gla protein (BGP), which is known to inhibit medial calcification. Apoptotic bodies derived from dying SMCs and calcifying extracellular vesicles (EVs) released from SMCs are also essential contributors. Both of these cause phenotypic changes in smooth muscle cells (SMCs) forming osteoblasts, which lead to medial calcification. Separately, elastin acts as a scaffold for mineral nucleation, ultimately leading to medial calcification.

Nonatherosclerotic medial aortic wall calcification

Calcification can occur independently of atherosclerosis, thereby, affecting the medial layer of the arterial media in the ascending aorta and aortic arch, often affecting patients with CKD and diabetes.[46,47] In those cases, hydroxyapatite crystals deposit in the media along elastin fibers directly neighboring SMCs in the absence of cholesterol deposits.[48] Elastin degradation is mediated by metalloproteinases (MMPs) and serves as an initiation nidus for medial calcification (Fig. 21.1).[47] In addition, it is possible for elastic lamellae to create a barrier between SMCs, limiting calcification in the medial layer.[49] While a strong inflammatory component is sufficient to create the conditions for nucleating calcium phosphates in the absence of hypophosphatemia in atherosclerosis and CAVD, a localized inflammatory response has not been observed in medial calcification.[39] In this type of calcification both intra- and extracellular calcium deposits are present. Intracellular deposits are located in SMCs and extracellular deposits are largely associated with damaged elastic fibers embedded within the ECM[46] and other ECM components, including collagen. Even though atherosclerotic and medial calcification might be two separate entities, their pathogenesis have considerable overlap.

As medial calcification has been frequently associated with type 2 diabetes, end-stage renal disease, and is commonly associated with osteoporosis, demonstrating the central role of mineral metabolism in the pathogenesis of this disorder,[50–52] this disorder is considered a process of metabolite-induced vascular changes. However, the pathophysiological mechanisms contributing to the formation of medial calcification are not fully understood. Experimental

models are widely used to study medial calcification. The rabbit model of CKD shows early morphologic changes in the aortic media with rupture of elastic lamellae and increased ECM in the absence of a high-cholesterol diet. After 3 months of follow-up in these animals, they maintain media degeneration with calcification, but not in the intima.[53] Arteries taken from humans with CKD show calcification of the arterial media, but not the intima, even in patients with a moderate increase of serum creatinine.[48] Additionally, no lipid or cholesterol deposits were observed in the vicinity of the medial calcification in these patients.[48] In type 2 diabetes, patients' medial calcification is the most common form of vascular calcification, mostly affecting the media of peripheral arteries and is more severe in hemodialysis patients.[54,55] Elastin degradation occurs because of SMC proliferation, leading to collagen becoming the principal ECM component of the arterial wall. Collagen can be glycated in patients with diabetes, thereby, promoting arterial wall stiffening.[56,57]

Alterations in mineral metabolism and vascular inflammation induce phenotypic changes of SMCs into osteoblasts in the medial layer (Fig. 21.1). Transformed osteoblasts produce bone-associated proteins, such as ALP, bone sialoprotein (BSP), and BMP-2.[49,58] Apoptotic bodies and EVs from SMCs also contribute to medial calcification by facilitating mineral nucleation.[59]

Aside from CKD, mediastinal radiation can cause medial and intimal calcification in the aortic wall.[60,61] The cumulative incidence of radiation that leads to heart disease is between 10% and 30% and occurs on average 5–10 years after initial treatment.[62] Current radiotherapy techniques, such as those used to treat breast cancer, have measures in place that protect the heart and ascending aorta in order to minimize cardiac and aortic damage.

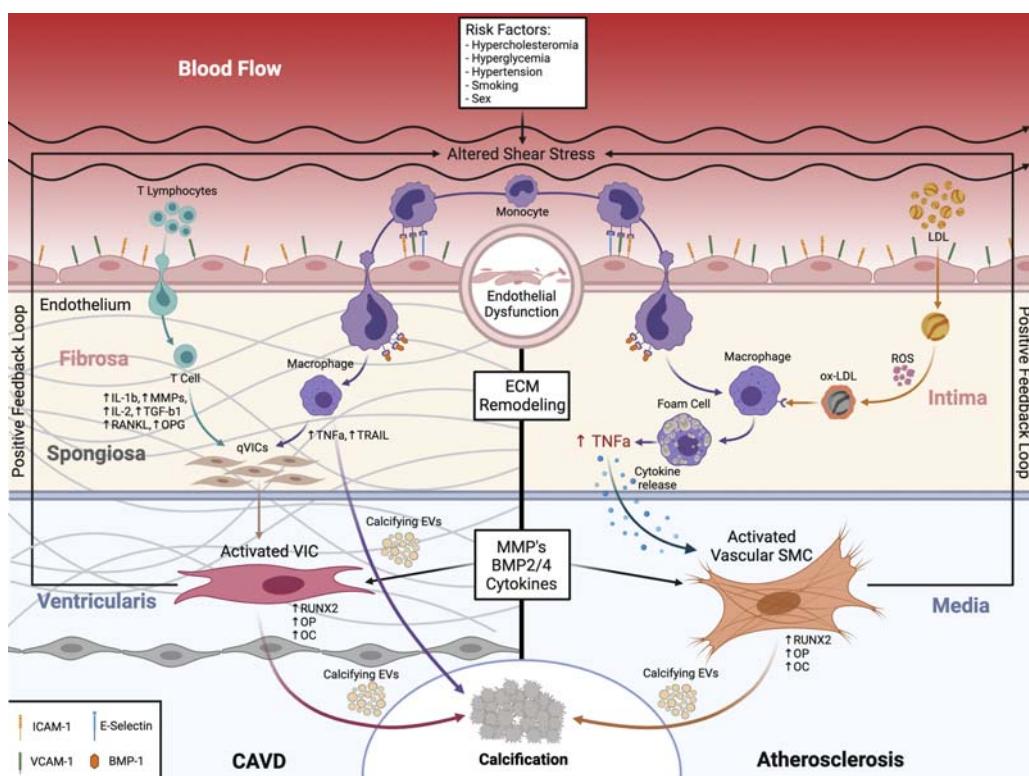
Medial calcification induces stiffening of the vessel, increased pulse pressure, and left ventricular hypertrophy, which can result in heart failure. The differentiation between intimal (atherosclerotic) and medial (non-atherosclerotic) calcification may have clinical implications, especially because it can complicate surgical aortic valve replacement and treatment of severe aortic stenosis since it is accessed via the ascending aorta.[18,19] Furthermore, large calcification in the medial layer may induce secondary changes in the intima. Medial calcification in the ascending aorta and aortic arch interferes with aortic cannulation, clamping, aortotomy, and central coronary bypass anastomosis.[63] Therefore, medial calcification increases the morbidity and mortality, especially as a result of increased operative risk. Vascular stiffness of the aorta may lead to congestive heart failure, left ventricular hypertrophy, elevated pulse pressure, coronary ischemia, or sudden death resulting from arrhythmia.

Arterial medial calcification is commonly diagnosed by manual palpation performed after sternotomy and exposure of the aorta at the time of cardiac surgery. Chest X-ray and fluoroscopy during coronary angiography might reveal a calcific outline of the ascending aorta. However, there is no accurate imaging modality to differentiate intimal and medial calcification or assess its extent.

Calcific aortic valve disease

Despite the similarities in the mechanisms of intimal and aortic valve calcification, fewer than 50% of patients develop calcification of both atherosclerotic plaques and aortic valve, indicating that those disorders involve different pathogenic mechanisms.[64] The normal aortic valve maintains unidirectional blood flow from the left ventricle into the aorta. In CAVD, the leaflets become thick, stiff, scarred, and calcified, leading to decreased pliability and narrowing of the valve orifice.[65] Early disease is characterized by aortic sclerosis, where ventricular outflow remains intact and progresses to aortic stenosis, which includes ventricular outflow obstruction.[66] Calcium nodular deposits develop within the fibrosa layer at the base of the leaflet.[67] For decades, this disease was thought to be a passive process in which the valve degenerates with age.[27] It is a fact that CAVD has a higher prevalence in the elderly population; however, is not exclusively a "senile" or "degenerative" disorder, suggesting pathological influences other than age play a role.[66]

As with atherosclerosis, valve endothelial cells (VECs) play a key role in the initiation of tissue injury, since they are positioned to sense hemodynamic forces and encounter circulating factors.[68] Oxidative stress is also an early disease event associated with inactivation of endothelial nitric oxide synthase (eNOS), contributing to an abnormal oxidative state.[69] Levels of superoxide and hydrogen peroxide are markedly increased in calcified stenotic human valves.[70]

VECs are phenotypically different from other vascular endothelial cells.[71] The role of hemodynamic forces in valvular endothelial dysfunction and its impact on cardiovascular calcification will be discussed further in the following topic. Located below the endothelium, VICs are the most abundant and diverse valve resident cells, responsible for synthesis of the ECM and expression of matrix degrading enzymes.[72] VECs interact with VICs to maintain the integrity of valve tissue, therefore, this connection may mediate disease.


Endothelium damage favors infiltration of inflammatory cells, lipid oxidation, and deposition on the valve surface.[23] Studies have shown that among VICs, there are a small number of circulating progenitors and mesenchymal progenitor-like cells, which likely form after transitioning from endothelial cells.[73,74] The local cytokine environment promotes the activation of VICs, which are a very plastic population that can differentiate into several phenotypes. In

pathological circumstances, VICs shift from quiescent resting fibroblasts to a variety of activated cell types, including myofibroblasts and osteoblasts.[75] Valve myofibroblasts express alpha-smooth muscle actin, leading to an increase in proliferative and ECM remodeling capacity.[75] Additionally, valve myofibroblasts migrate to injured sites and develop angiogenic activity.[76] VICs expressing an osteoblast-like phenotype secrete ALP, OC, OP, BMP-2, 4, and BSP (Fig. 21.2).[66] Different VIC phenotypes may exhibit plasticity and convert from one form to another. In vitro VICs undergo osteoblastic differentiation in the presence of TGF-β and BMPs.[77]

Matrix Gla protein (MGP), a γ-carboxyglutamic acid−rich and vitamin K-dependent protein, is a well-known ectopic calcification inhibitor.[78,79] MGP is a small secretory protein produced by chondrocytes and SMCs. Studies show that MGP antagonizes BMP-2 and protects against vascular calcification.[80] Treatment of VICs isolated from CAVD patients with TNF-α induces calcification and increases BMP-2 expression, accompanied by a strong decrease of MGP.[81] Experimental mouse models of MGP deficiency show early valve calcification, whereas transgenic mice that overexpress MGP are protected.[82] The MGP pathway is also implicated in atherosclerosis.[80]

Human histological studies have shown that CAVD specimens demonstrate rich lymphocytic infiltrates that are composed of macrophages, B cells, and T cells found near osteoblast-like cells and calcified areas.[23,83] Previously, Aikawa E. et al. showed an association between macrophage burden and osteogenesis in experimental early-stage CAVD and atherosclerosis by using near-infrared optical fluorescence molecular imaging. Those findings reinforce the inflammation-dependent mechanisms of calcification and identified the stages of disease progression.[25,26,39] Immune cells secrete inflammatory cytokines, including IL-2, IL-6, IL-1β, TNF-α, and MMPs, which promote the expression of genes involved in osteogenesis by VICs.[22,84] Altogether, it is a consensus in the field that many

FIGURE 21.2 Major pathogenic events underlying the mechanisms of calcification in intimal, medial, and aortic valve calcification. Altered shear stress leads to endothelial dysfunction denoted by increased expression of adhesion molecules, ICAM-1, VCAM-1, and E-Selectin, as well as trapping of low-density lipoprotein (LDL) cholesterol. The recruited LDL takes up reactive oxygen species (ROS), becoming oxidized-LDL (ox-LDL). In turn, ox-LDL binds to macrophages binding high levels of BMP-1, and become foam cells. Foam cells increase TNFα expression, releasing cytokines. Activation of quiescent VICs (qVICs) occurs through T cells overexpressing IL-1β, IL-2, TGFβ1, RANKL, OPG, and releasing MMPs. In addition, macrophages overexpressing TNFα and TRAIL contribute to qVIC activation. Taken together, these changes stimulate the differentiation of VICs and SMCs into an osteogenic phenotype, identified primarily by overexpression of RUNX2, osteopontin (OP), and osteocalcin (OC). These osteoblast-like cells release active vesicles capable of nucleating hydroxyapatite. The inflammatory process is associated with extensive remodeling of the ECM. Calcification causes a positive feedback loop of changes in the tissue affecting its architecture, cell biology, and hemodynamic parameters, which maintain a self-perpetuating pathogenic cycle.

pathogenic factors are centered on an inflammatory process affecting the valve and leading to calcification, supporting that CAVD is an inflammatory disease. Overall, recent studies support the notion that inflammation occurs secondarily in injured tissue, and CAVD is a manifestation of an inflammatory disease.

The role of hemodynamic shear stress in vascular calcification

One of the most discussed and intriguing questions in the field of vascular calcification is how the promoters of pathological cascade culminate in fibrosis and mineralization within the cardiovascular system. As a multifaceted disorder of unclear etiology, it is a very difficult question to be answered. Several studies have shown that shear stress alterations trigger vascular endothelial lesions that ultimately calcify.[85-88] Changes in tissue biology and architecture associated with calcium deposition sustain a self-perpetuating vicious cycle, as this worsens mechanical stress.[89]

The flow of blood, by virtue of viscosity, exerts force on the luminal vessel wall and endothelial surface per unit area, known as hemodynamic shear stress.[29] Physiologic, laminar shear stress is crucial for normal vascular function, as it regulates vascular caliber, acts as a protective barrier, and inhibits proliferation, thrombosis, and inflammation of the vessel wall.[89] In pathological conditions, blood flow is disturbed and/or is nonlaminar, creating force that is mechanically transduced into a biochemical signal that changes vascular behavior.[88] Systemic hypertension and stiffness of the aortic root associated with aging processes may cause abnormal mechanical stress, a common denominator of several vascular pathologies.[3] Cohort studies have demonstrated that systolic blood pressure is related to the risk of atherosclerosis and aortic stenosis, supporting the causality of hypertension and cardiovascular calcification.[90,91] Initial endothelial vascular injury has a distinctive, nonrandom pattern, which matches with points of altered hemodynamics.[68]

In the aorta, arterial branch ostia and bifurcations are prone to lesion development, since this curvature slows blood flow, creating low or oscillatory shear stress. In contrast, vessel regions that are exposed to steady blood flow generally do not develop disease.[89] Decreased shear stress leads to the reduction of eNOS production by vascular endothelial cells, therefore, impacting vasodilatation and endothelial cell repair, accompanied by an increase of reactive oxygen species (ROS).[68] *In vivo* studies show that vascular SMCs are also responsive to shear stress.[92] Furthermore, the level of shear stress is inversely correlated with intimal SMC density, whereas exposure to physiologic flow did not influence cell density.[92] It is likely that shear stress acts through the endothelium to modulate SMC gene expression. Moreover, oxidized low-density lipoprotein (LDL) uptake in the intimal layer is favored during decreased flow conditions.[93]

Large DNA array-based genomic analysis studies in endothelial cells have shown gene sets regulated in response to either physiological or mechanical altered blood flow.[87,94] Furthermore, many of the shear-regulated factors fall into functional classes directly related to endothelial cell biology, including nitric oxide (NO) and TGF-β. It was also shown that altered shear stress can prime endothelial cells through the proinflammatory transcription factor, NF-κB.[95] Decreased shear on endothelial cells enhance adhesion molecules' expression, such as ICAM-1, VCAM-1, MCP-1, and E-selectin, thereby, promoting leukocyte recruitment into the aortic wall.[88]

Endothelial-to-mesenchymal transition (EndMT) is another important pathogenic mechanism in atherosclerosis and is observed in abnormal shear stress.[85] It is also well described in valve pathology, specifically in mitral valves.[96-98] In this biological process, endothelial cells lose cell polarity, gain increased migratory capability through disruption of intercellular junctions, in addition to having higher proliferative capacity.[99] Furthermore, these cells migrate to intimal and medial aortic wall layers, where the cells become highly proinflammatory, releasing high levels of cytokines and growth factors.

Endothelial damage resulting from altered shear stress also contributes to triggering events of CAVD, as in aortic wall calcification. Pulsatile hemodynamic shear stress affects VICs through VEC mechanical transduction.[100] In normal conditions, shear stress contributes to endothelial cell alignment and homeostasis by regulating valvular biosynthetic activity.[100] However, it remains unknown the amount of disturbance needed to trigger pathological events. Valves and vasculature are different in gross morphology and cellular structure; therefore, they demonstrate specific particularities in their pathogenic processes. The cardiac cycle involves both systole and diastole, which impart different forces on the leaflets.[101] Aortic valve shear stress occurs on the ventricularis layer of the valve when blood flows past the leaflets during systole and on the fibrosa when blood pools into the sinuses during diastole. Blood flow is unidirectional and pulsatile on the ventricularis, while bidirectional and oscillatory on the fibrosa.[102] VICs are found to respond to shear stress by altering their biosynthesis of ECM components, including collagen and collagen-processing enzymes, such as lysyl oxidase and prolyl 4-hydroxylase.[103,104] The amount of collagen deposition is dependent on the degree and duration of mechanical stress.[104]

Among the three cusps, noncoronary leaflets experience more oscillatory shear forces than the coronary leaflets, which experience more laminar shear stress. Therefore, noncoronary leaflets are more prone to develop

calcification.[105] Additionally, noncoronary VICs have shown increased expression of calcific markers and mineralization potential. Another example indicating the influence of hemodynamic factors on calcification are patients with a bicuspid aortic valve, the most common congenital heart anomaly, which is found in 0.5%−1.4% of the US population.[106] The bicuspid aortic valve has more rapid progression of stenosis and calcification than in the tricuspid aortic valve.[106]

Endothelial cells that are exposed to oscillatory shear stress in vitro are more prone to increased EndMT and inflammatory capacity, as gauged by high expression of αSMA and NFKβ1, respectively.[107] Altered shear stress in the early stages of disease and increased expression of adhesion molecules (VCAM-1, ICAM1) stimulate leukocyte recruitment. This can lead to endothelial rupture, facilitating even more inflammatory cell infiltration.[23,108] Alignment and juxtaposition of endothelial cells worsen in later stages of the disease due to increased local stiffness associated with fibrosis and calcification.[109] Furthermore, endothelial disruption allows calcium from the blood to get into the tissue. Similar to atherosclerosis, altered shear stress propagates lipid infiltration, especially LDL that becomes oxidized by ROS action (Fig. 21.2).[110] Inflammatory infiltrate releases factors that differentiate VICs to an osteogenic phenotype.[66] Endothelial damage, followed by VIC activation, leads to calcium deposition in CAVD (Fig. 21.2).[111] Trilayered leaflet structures become indistinguishable in the end stage of disease and are associated with intense collagen deposition. Leaflet structure has a very important role in tissue biomechanics and, once calcified, cannot be dissipated evenly across the leaflets, thereby, worsening mechanical stress and propagating pathogenic stimuli.[112]

Mechanical stress and subsequent endothelial injury are early common events of aortic wall calcification and CAVD. Then, secondary downstream events promote activation of vascular SMCs and VICs, which have a central role in aortic wall calcification and CAVD, respectively (Fig. 21.2).[32,39,66] Crosstalk between inflammatory infiltrates and SMCs or VICs culminates in mineralization. Calcium deposits cause tissue stiffening, aortic valve stenosis, and narrowing of the aorta lumen. This, in turn, may cause even greater mechanical stress, thereby, causing disease propagation.

The major cellular events underlying aortic wall and aortic valve calcification are represented in Fig. 21.2.

Synergistic effects of risk factors in vascular endothelial dysfunction

As presented in previous topics, the vascular endothelium is a dynamically mutable interface responsive to a variety of stimuli, both biomechanical and/or biochemical and local and/or systemic. Phenotypic modulation of endothelial cells constitutes the major risk factor for vascular diseases. While the exact causes of vascular calcification are still not well understood, certain conditions and lifestyles may raise someone's likelihood of obtaining either disease through synergistic effects with endothelial shear stress.

Systemic risk factors, such as hypercholesterolemia with increased LDL serum levels, have motivated researchers to find the mechanistic link with cardiovascular calcification. *In vivo* studies conducted with a porcine model demonstrated how hyperlipidemic swine that had intense hypercholesterolemia favored rapid atheroma progression.[113] In addition, a hyperlipidemic environment increases transcytosis of cholesterol to the subendothelial matrix and reduces its efflux from the vessel wall.[114,115] Lipid accumulation in subendothelium alters structure and functionality of endothelial cells.[115] Patients who have the diagnosis of familial hypercholesterolemia have a higher probability to develop atherosclerosis and CAVD, as well as peripheral vascular disease and coronary artery disease.[116,117]

Diabetes is defined by hyperglycemia condition and can predispose atherosclerosis and aortic valve calcification.[118,119] Both diabetes type 1 and 2 show similar implications in CVD development; however, type 2 diabetes demonstrates enhanced atherosclerotic plaque burden when compared to type 1 diabetes.[120] Because type 2 diabetes involves several aspects of metabolic syndrome, the isolated role of hyperglycemia on atherosclerotic plaque formation and calcification development is difficult to determine. In type 1 diabetes, the postmortem study of young patients and children shows enhanced fatty streak formation in the absence of dyslipidemia, suggesting that hyperglycemia is an independent risk factor for early plaque development.[121] Moreover, children with type 1 diabetes show enhanced carotid intimal−medial thickness compared to nondiabetics.[122] The mechanism through which a hyperglycemic environment affects endothelial function was determined in vitro by exposing endothelial cells to high glucose cell culture media, which led to a decrease in NO production. In turn, this gave rise to the activation of NF-κB transcriptional activity, thereby, increasing inflammatory gene expression and leukocyte recruitment.[123−125] Kawakami et al. recently demonstrated that human primary macrophages stimulated with S100A9 in culture conditions mimicking diabetes release calcifying EVs contributing to the formation of microcalcifications.[126] Similar phenomenon has been previously demonstrated in mouse macrophages triggered with high levels of Ca/P, recapitulating environment of CKD.[15] CKD often results from hypertension and diabetes. Dysmetabolic patients with CKD have both intimal and medial calcification as a common pathological process.[127]

CAVD occurs in up to 45% of patients with type 2 diabetes and is associated with an increased cardiovascular mortality, independently of other established risk factors.[128] High glucose induces enhanced monocyte adhesion to VECs through the increase of cell adhesion molecules: ICAM-1, VCAM-1, and CD18.[129] A study evaluating VECs and VICs exposed to high glucose medium showed induction of BMP-2 and 4 expression in VECs and other osteogenic markers, RUNX2 and OP were expressed in VICs.[130] In addition, this same study showed that TGF-β and BMP-2 signaling pathways are triggered by high glucose levels and contribute to bone formation in valve calcification.[130] VICs exposed to high glucose cell culture media increased expression of ECM proteins and MMPs.[130]

Since unhealthy diet and lack of physical activity directly influence cholesterol and glucose serum levels, those also constitute risk factors for the development of cardiovascular calcification. In patients with obesity, adipocyte hypertrophy is accompanied by changes in its derived cytokines and adipokines, leading to a systemic proinflammatory state that can disturb the vascular endothelium.[131] This constitutes an additional mechanism of vascular endothelial damage, apart from cholesterol pathways. Increase of proinflammatory cytokine secretion by adipocytes is considered to be the link between obesity-induced inflammation and endothelial dysfunction.[131] Moreover, a high-fat diet can alter human gut microbiota, leading to gut dysbiosis. An inflamed gastrointestinal tract can impact endothelial dysfunction by systemically releasing inflammatory mediators.[132]

As mentioned in previous topics, hypertension is an age-associated disorder that shows higher prevalence in patients with obesity.[133] This disorder is not commonly a cited risk factor for calcification; however, the majority of patients with atherosclerosis and CAVD have hypertension as a clinical manifestation.[134,135] High blood pressure generates hemodynamic disturbances, impacting vascular endothelium function.[136]

Smoking represents another risk factor for CVD. Because cigarette smoke contains roughly 4000 different chemicals, it is the least understood risk factor.[137] Vascular dysfunction induced by smoking is initiated by reduced NO bioavailability and increased expression of adhesion molecules, leading to endothelial dysfunction.[138] Numerous studies have shown that exposure to cigarette smoke activates platelets, stimulates the coagulation cascade, and reduces fibrinolysis.[139] Additionally, a study showed a positive correlation between smoking and increased total serum cholesterol, very−low-density lipoprotein, LDL, and triglyceride serum concentrations.[140] Effects of smoking in CAVD and atherosclerosis are well documented throughout the literature.[141−144]

Sex differences represent important health disparities. Those differences result from a complex interaction among genetic and hormonal factors and impacts CVDs morbidity and mortality.[144] The vascular endothelium expresses estrogen receptors (ERα and ERβ), progesterone receptors, androgen receptors, and aromatase, therefore, making it susceptible to hormonal regulation.[145] Atherosclerosis and CAVD have a much higher prevalence in males.[146,147] More men die from atherosclerosis than women and at a younger age.[148] On the other hand, women develop atherosclerosis more frequently after menopause, suggesting hormones play an important role in cardiovascular calcification. However, this mechanism is better explained by differences in immune responsive cells themselves than the hormone direct effects on vascular endothelium.[146] Additionally, women who are diagnosed with an autoimmune disease (e.g., systemic lupus erythematous, rheumatoid arthritis, and systemic sclerosis) have a higher risk for atherosclerosis development.[146,149] Therefore, differences in the immune response between males and females are linked to differences in CVD disease phenotype. Risk factors can promote endothelial dysfunction since they modify vascular microenvironment. Mutual influence of risk factors and endothelial cells constitute synergistic interrelationship that feed disease onset. The endothelial response to aggressive factors is gradual and dependent on its intensity.

Experimental approaches in cardiovascular calcification

There are many challenges with creating models to study cardiovascular calcification. Because atherosclerosis and CAVD are multifaceted disorders, experimental designs reproducing them, both in vitro and in vivo, are very difficult. Interpreting data obtained from those studies is complex and hinders its translation into clinic. New experimental methods and new tools of analysis are crucial for scientific advances in this field.

Ex vivo assays using explanted aortic tissue from patients with vascular calcification bring important pathological aspects of natural context of disease. However, end-stage disease specimens may not provide accurate information about early disease processes, thereby, presenting a large biological variability and interindividual confounding risk factors. Calcification can be induced using in vitro culture models through utilizing SMCs to study atherosclerosis or VICs to investigate CAVD and cultivating them in cell culture media containing organic and/or inorganic phosphate and/or other inducers, promoting mineralization development.[150,151]

3D cell culture models have been used to produce complex tissue-like structures of aortic valve leaflets,

mimicking their layered structure.[88,152−155] *In vitro* models offer well-controlled conditions, allowing for a better understanding of the role of certain mediators and pathogenic pathways of interest. Thus, these experiments offer data with less complicating factors and variability, as compared to in vivo assays. *In vitro* simulation of mechanical stress has been used to replicate its role in the pathogenesis of atherosclerosis and CAVD through the production of physiologic and abnormal shear stresses.[155,156] *In vivo* models allow study initiation and progression of the disease and also evaluate the effectiveness of therapeutic interventions.[126,157] The most common species used for experimental atherosclerosis and CAVD are mice, rats, rabbits, and swine.[158] Calcification induction can be accelerated by diet-induced hypercholesterolemia.[159] Cost-effectiveness and small size make mice the most used model. In addition, greater ease of genetic manipulations allows specific investigation of key molecular mediators of calcification.[158,160] Mice deficient in the LDL receptor (*Ldlr−/−*) are often used. *Ldlr−/−* mice containing apolipoprotein B (ApoB) (*Ldlr−/−;Apob*) spontaneously develop hypercholesterolemia.[159] However, mice do not have the trilayer aortic valve tissue morphology characteristic of humans; therefore, they are not ideal to study CAVD.[161] Different experimental approaches have different limitations, and the choice of model varies depending on the questions being answered in a given study. More recently, multiomics approaches have been applied in cardiovascular calcification studies using different experimental models.[162] A multiomics approach includes techniques investigating genome, proteome, transcriptome, epigenome, metabolome, that can be integrated, generating a massive amount of information.[2] Large data sets can be analyzed through computational tools and development of algorithms. Thus, more recently, artificial intelligence and machine learning have been used as a strategy for data processing, which would not be feasible through a manual approach. These strategies broaden the informative capacity of the data obtained in different models, expanding the informative capacity and accelerating research translation into the clinic.

Therapeutic target discovery in cardiovascular calcification

While involving similar risk factors, both vascular and valvular calcifications have sheer stress alteration and subsequent endothelial dysfunction as a disease promoter. However, atherosclerosis and CAVD pathogenesis seems to be different.[64] Treatments that help reduce inflammation in vasculature have been shown to have no effect on valvular calcification.[111] Moreover, currently, no approved drug has shown prophylactic or therapeutic effectiveness on ectopic calcification. Therefore, cardiovascular system mineralization provides an important field for drug discovery.[2] Similarly, as in the bone, calcification is subject to remodeling and this can be explored in order to regress already established injuries. Thus, finding therapeutic targets that inhibit or slow the progression of the disease may guide research efforts in this field. Conventional diagnostic imaging is currently the best method for detecting, measuring, and assisting calcification progression and therapeutic effects on it.[25,163] This research strategy could vastly improve therapeutic discovery; however, the formation of microcalcification lay below the resolution of current imaging modalities. Positron emission tomography (PET) combined with computed tomography (CT) is a noninvasive imaging technique that allows the identification and quantification of calcium deposits and inflammation on aorta and carotid arteries.[164] However, the common PET/CT tracers usually cannot detect microcalcifications.[25] 18F-Flurodeoxyglucose is an alternative PET tracer that is directly incorporated into exposed hydroxyapatite crystals able to assess spotty cardiovascular calcification.[164] Artificial intelligence and machine learning are great allies in drug discovery for allowing the integration of image data from human long-term studies with clinical information.

Final considerations

The lack of effective therapy to treat or prevent cardiovascular calcification reflects the complexity of the disease. Influence of individual risk factors, genetic predisposition, and lifestyle directly impact its outcome besides hindering the pathogenic mechanisms. Cardiovascular calcification implicates endothelial injury as an initiating point of the disease, which in turns leads to VIC and SMC phenotypic changes that culminate in fibrosis and calcification. Hemodynamic shear stress drives initial tissue injury and continuously stimulates pathogenic processes. As demonstrated in this review, cardiovascular calcification is the result of a crosstalk between different signaling pathways and pathologic processes that reciprocally affect each other. Thus, once initiated, calcification causes a positive feedback loop of changes in the tissue affecting its architecture, cell biology, and hemodynamic parameters, which altogether sustains a self-perpetuating pathologic vicious cycle.

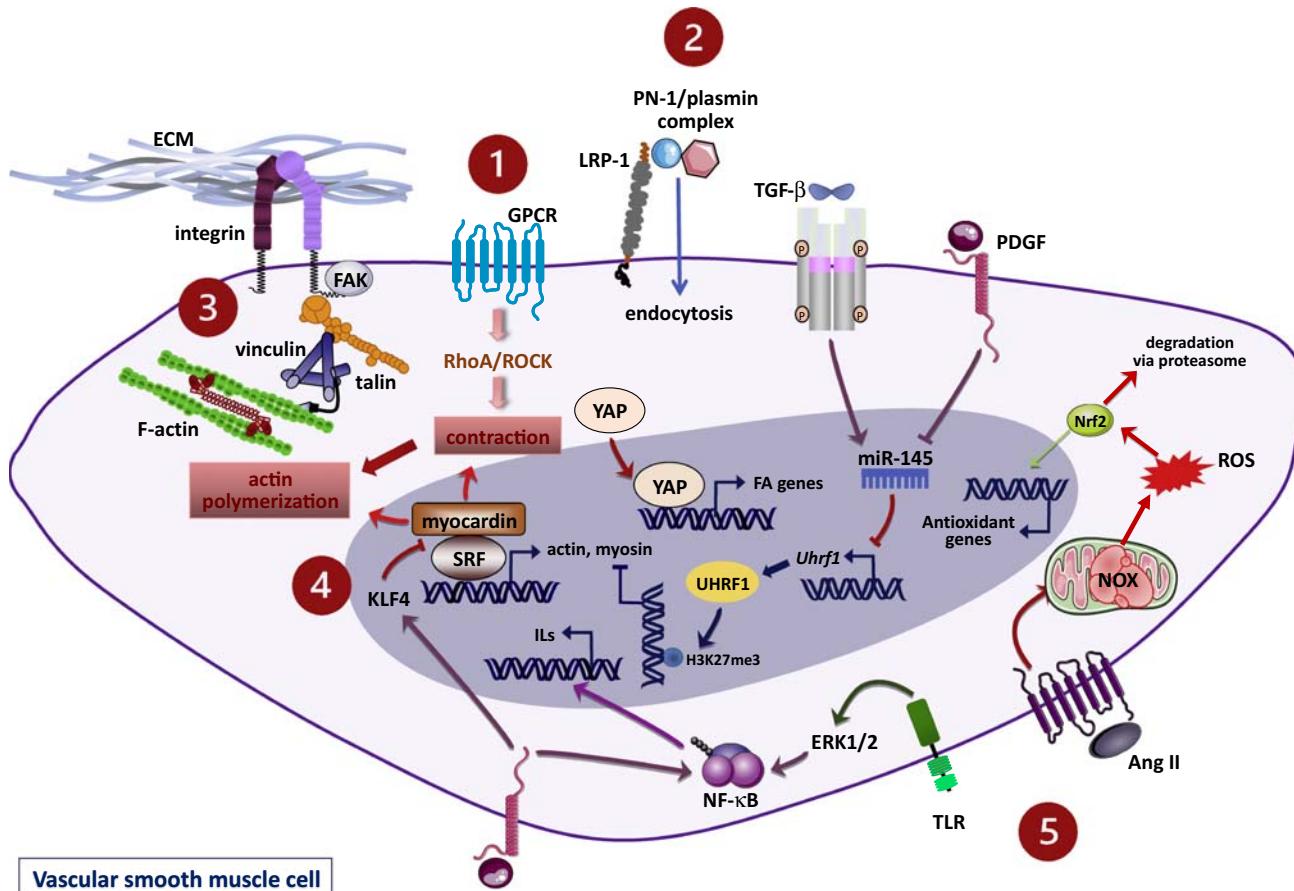
Arterial blood pressure was the last acquired hemodynamic parameter in the evolution of the structure and functions of the cardiovascular system, integrated into species' evolution.[1] This parameter is directly related to the frictional forces which progressively appeared in the arterial part of the circulation during species' life on earth, as closed "in parallel" circulations associated with cardiac septation and arterial arborescence. These important frictional forces are the fact of structural muscularization and functional tonic contraction of the arterial wall (peripheral resistances), which transfer kinetic energy generated by the beating heart into potential energy. These relations were physically defined by the Hagen–Poiseuille laws in which pressure is proportional to the blood viscosity and inversely proportional to the artery radius at power 4. The teleonomy of the arterial system is to allow localized vasodilation directly adapted to the specific biochemical energetic demand of each functioning organ, by local inhibition of the systemic arterial tone. This paradigm implies numerous bifurcations for distribution, which modify the arterial geometries and impede kinetic energy. Similarly to phylogenesis, vascular development is characterized by the presence of limited frictional forces during fetal life, which are considerably enhanced by sympathetic activation at birth, leading to high arterial pressure, in mammalian development, including humans. Therefore, the arterial circulation in mammals remains essentially a longitudinal conductance at high pressure, but frictional forces also initiate both potential energy dissipation within the wall (radial convection) and kinetic energy transfer to reflection pressure waves, a circulating cell wall colliding on arterial bifurcations.

An increase in arterial stiffening is an independent predictor of all-cause mortality and affects the cardiovascular system both globally and locally.[2] Stiffening is essentially a feature of large proximal conductance arteries, whereas control of mean arterial pressure is a feature of distal resistance arteries. Arterial stiffening has been commonly attributed to changes in extracellular matrix (ECM) proteins, mainly collagen accumulation and elastin fragmentation.[3] Beyond the cellular and molecular mechanisms that remain to be identified, one emerging concept is that vascular smooth muscle cells (VSMCs) are major contributors to arterial stiffness. Cells of the aortic wall are exquisitely sensitive to their local environment including mechanical forces, oxidative and proteolytic injuries, often inducing changes in VSMC functional properties, particularly mechanotransduction, vasomotricity, phagocytosis, efferocytosis (the process by which apoptotic cells are removed by phagocytic cells), proliferation, synthesis, and other phenotypic switching (Table 22.1). In addition, the contribution of VSMCs to arterial stiffening has been extended from aortic stiffness to include the concept of VSMC stiffness depending mainly on the architecture of cytoskeletal proteins and focal contacts to the ECM. In this chapter, we discuss molecular pathways pertaining to VSMC tone, membrane and nuclear mechanotransduction, endocytosis and phagocytosis abilities, differentiation, and immunoinflammatory activation. Fig. 22.1 shows an integrative view of signaling pathways in VSMCs underlying arterial stiffening. Fig. 22.2 is a schematic of the interactions among VSMCs, endothelial cells, platelets, and immune cells. The increasing number of studies based on

TABLE 22.1 Typical smooth muscle cell function-related markers.

Phenotype	Triggers	Markers
Contractile	Transforming growth factor (TGF)-β signaling, serum response factor (SRF)/myocardin	α-SMA, SMMHC, smoothelin, calponin-1, caldesmon, desmin, transgelin, metavinculin, α-tropomyosin, cofilin, actinin, SRF, myocardin
Synthetic and proliferative	Platelet-derived growth factor (PDGF), interleukin (IL)-1β, NADPH oxidases	Matrix metalloproteinases, calmodulin, connexin 43, cytokines (IL-6, TNF-α, MCP-1), S100 calcium binding protein A4, osteopontin, UHRF1
Endocytic—phagocytic	Convection-enhanced deliveries of blood molecules [modified low-density lipoprotein (LDL), zymogens], collision of blood cells with the wall	Scavenger receptors (SR-AI/II, LOX1, CD36, LRP-1, CD68), serpins (PN-1, plasminogen activator inhibitor-1), tissue inhibitors of metalloproteinases
Osteoblastic	Calcium phosphate crystals	Runt-related transcription factor 2 (RUNX2), bone morphogenetic protein 2 (BMP2), matrix Gla protein,
Organizer of the adventitial responses	Lipid-stimulated Peroxisome proliferator-activated receptor-γ (PPAR-γ), class II major histocompatibility complex (MHC)	VEGF, chemokines, antigen presentation, immune adaptive response

single-cell imaging and lineage tracing supports the crucial role of VSMC plasticity at the interface between mechanotransduction and epigenetic mechanisms.


Contractile tone of vascular smooth muscle cells

VSMCs are the stromal cells of the arterial wall, continually exposed to mechanical signals, biochemical and cellular components generated in the blood compartment.[4] From the aorta to distal muscular arteries, there is a progressive reduction of the number of musculo-elastic complexes and ECM together, with an increase in the density of VSMCs. Elastic large arteries have a strong elastic potential whereas small-size muscular arteries control vasomotor tone and myogenic tone. VSMCs are involved in all the physiological functions and the pathological changes taking place in the vascular wall. Owing to their contractile tone, VSMCs of resistance vessels (small-sized muscular arteries and arterioles) participate in the regulation of blood pressure and arterial diameter, thereby protecting the capillaries from any acute increase in mechanical strength. Larger nonresistance vessels also exhibit a baseline tone, which may substantially impact pulsatile hemodynamics (such as wave reflection phenomena) but have a much less prominent role in resistance (given that resistance is strongly dependent on vessel size). VSMC contractile tone is mainly dependent on sympathetic nervous system signaling, which is involved in regional blood flow changes in accordance with organ-specific metabolic demands.

Vascular tone

Arterial tone in conductance arteries is an extrinsic level of tension, mainly depending on sympathetic system signaling, also defined as tensegrity (the internal tension of VSMCs), generated within the cytoskeleton by actin/myosin interactions, inducing arterial wall compaction by binding to ECM via integrins. In contrast, abolition of VSMC tone using potassium cyanide increases in situ carotid arterial compliance in rats. The spatial organization of VSMCs is ensured by a change in their directions in the media and by attachments to each other and to the ECM microenvironment. Indeed, there is an optimal short-term regulation of the distribution of mechanical stresses in the wall that contributes to maintaining a permanent and adapted state of tensional integrity. A stiff ECM material produces a large postload to VSMC contraction. In the longer term, functional regulation of arterial diameter requires structural changes. Elastic arteries are characterized by slow changes in contractile tone unlike muscular arteries where rapid changes in contraction allow fine regulation of regional blood flow.

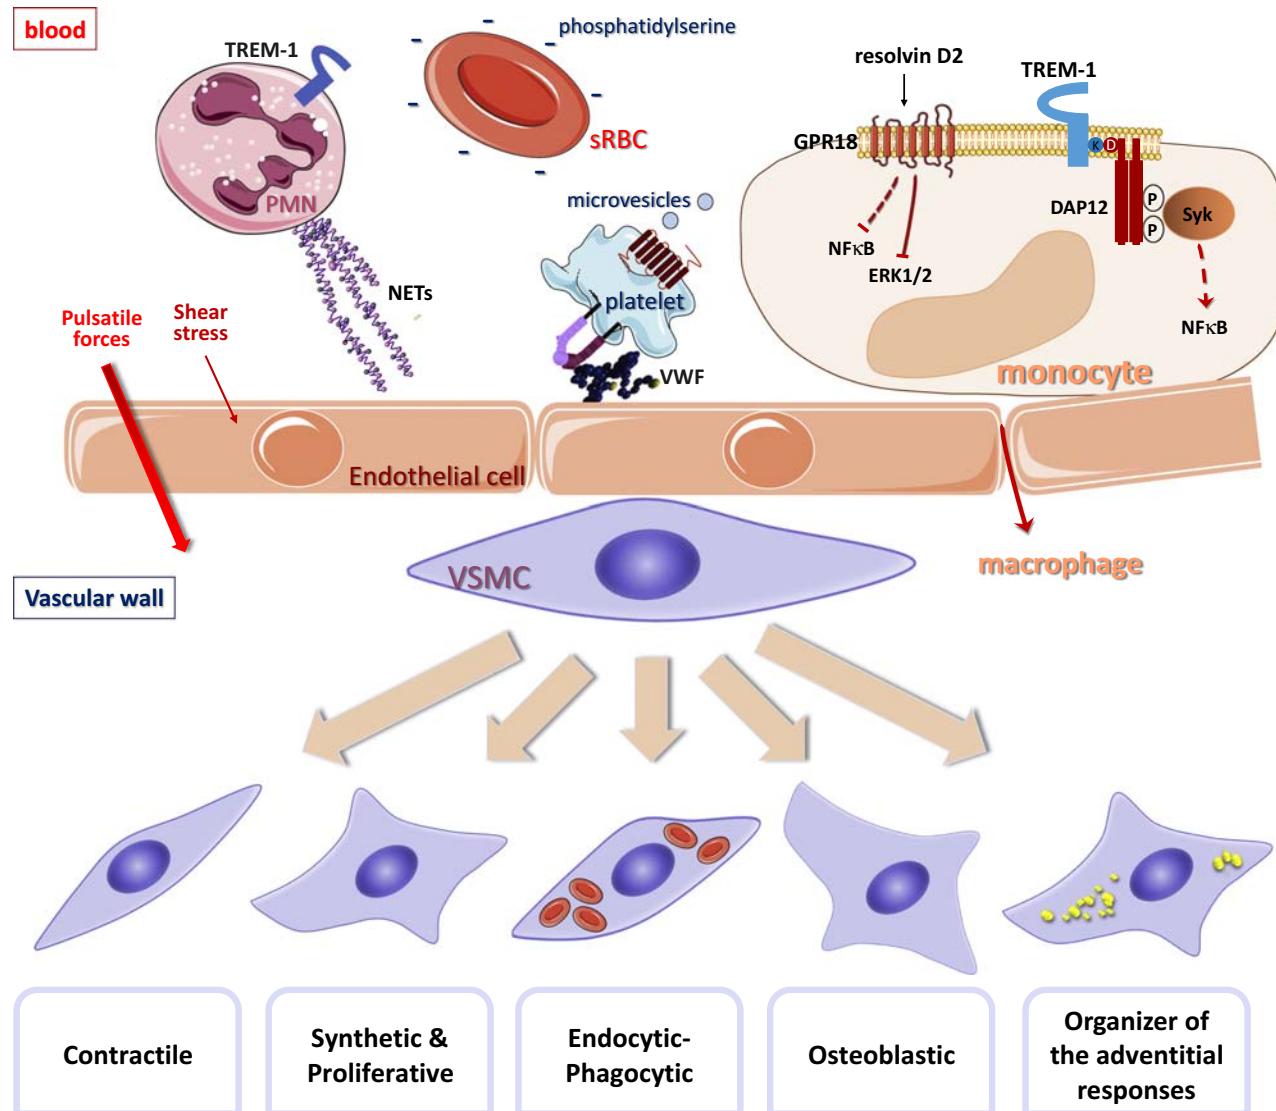
Actin/myosin interactions in VSMCs are dependent on ionized calcium (Ca^{2+}) mobilization in the cells. This entry is dependent on both the initial release of Ca^{2+} from its sarcoplasmic stores by inositol 3 phosphate and the opening of calcium channels by membrane depolarization (extra- to intracellular entry and plateau). This mobilization of calcium is dependent on the interaction of extracellular ligands (catecholamines, angiotensin II, serotonin, endothelin, etc.) with G protein—coupled receptors (GPCRs), able to


FIGURE 22.1 Molecular signaling pathways involved in vascular smooth muscle cell (VSMC) functions. ❶ Contractile tone of VSMC: activation of G protein−coupled receptors (GPCRs) and downstream effectors, RhoA/Rho kinase (ROCK) increases actomyosin interaction and contraction. ❷ Endocytosis and phagocytosis abilities of VSMCs: protease nexin-1 (PN-1) forms a complex with serine proteases such as plasmin, which is endocytosed via the low-density lipoprotein receptor-related protein 1 (LRP-1). ❸ Integrin-mediated and nuclear mechanotransduction: the local mechanical environment provided by the extracellular matrix (ECM) is transmitted via integrins, focal adhesion kinase (FAK), talin, and vinculin to the actin cytoskeleton. ❹ VSMC plasticity: platelet-derived growth factor (PDGF) induces VSMC phenotypic switching via its action on Krüppel-like factor 4 (KLF4), which disrupts the binding of myocardin to serum response factor (SRF), and binding to microRNA-145 (miR-145). ❺ Participation of inflammation and immunity in VSMC functions: angiotensin II (Ang II) increases the production of reactive oxygen species (ROS) via NADPH oxidases (NOX). In response to oxidative stress, nuclear factor-erythroid-derived 2-related factor 2 (Nrf2) drives the expression of antioxidant genes. Toll-like receptors (TLRs) activate the translocation of nuclear factor κB (NF-κB) into the nucleus, leading to the expression of proinflammatory genes such as interleukins (ILs).

activate phospho lipase-C, and promote release of both cytosolic soluble inositol triphosphate from the polar head of membranous phospholipids and hydrophobic diacyl glycerol (DAG) which remains membrane bound. Calcium binds calmodulin and activates myosin light chain (MLC) kinase. Phosphorylation of MLC promotes the binding of myosin heavy chain to actin and shortening of the actomyosin complex. In contrast with myocardium, there is no direct action of Ca^{2+} on the smooth muscle contractile apparatus. All tonic contraction is directly linked to kinase-dependent phosphorylation. In VSMC tonic contracting biology, the time of contraction is largely longer than the time of calcium mobilization. The sustained contraction is the consequence of other kinases, involving protein kinase

C translocation to membranous DAG, and phosphorylation of calponin and of caldesmon and the inhibition of MLC phosphatase (MLCP).

The Ras protein superfamily, and in particular the RhoA family of proteins, plays an essential role in the contraction and ultimately in the regulation of blood pressure.[5] Phosphorylation of MLC is a key event in contraction. MLC is dephosphorylated by calcium-independent MLCP. Genetic and pharmacological studies have shown that RhoA activation is involved in the pathophysiology of hypertension. This involves the stimulation of its target, Rho kinase (ROCK) which phosphorylates the myosin phosphatase target subunit 1 (MYPT1), a regulatory molecule of MLCP, and inhibit the activity of MLCP. There are both fast and slow forms of

FIGURE 22.2 Intercellular communications in driving vascular smooth muscle cell (VSMC) phenotypic changes. The triggering receptor expressed on myeloid cell (TREM)-1 expressed on neutrophils and monocytes promotes inflammatory pathways enhancing NF-κB nuclear translocation. Excessive release of neutrophil extracellular traps (NETs) by neutrophils leads to endothelial dysfunction and VSMC lysis. Senescent red blood cells (sRBC) exposing phosphatidylserine can be phagocytosed by VSMCs. Adhesion of platelets to the vessel wall via von Willebrand factor (VWF) and collagens disrupts the anticoagulant properties of endothelial cells and favors the expression of the prothrombotic properties of VSMCs. The interplay between immune cells and VSMCs drives the resolution of inflammation via interaction of resolvins with their receptors.

these MLC and MYPT1 molecules that accelerate contraction or promote cyclic-dependent guanosine monophosphate (GMP) relaxation. Exchange factors regulate the activation of RhoA in response to vasoconstrictor agents via GPCRs such as the angiotensin II receptor type 1 receptor. Activation of the RhoA/ROCK pathways sensitizes contractile proteins to Ca^{2+} and produces muscle tone (Fig. 22.1). An imbalance between vasoconstrictive agents, in particular those of the renin-angiotensin-aldosterone system, and vasodilating agents, in particular nitric oxide (NO) released by endothelial cells in response to flow-induced wall shear

stresses, is largely responsible for the increase in hemodynamic resistance during hypertension.

Myogenic tone

Myogenic tone is an intrinsic property of smooth muscle in resistance arteries that contracts in response to stretching (elevated blood pressure) independently of any nervous or humoral influence and contributes to dissipation of blood flow and pressure mainly in small-sized muscular arteries before the capillary system. It is only in the smallest arterioles

of the order of 100 μm that myogenic tone can significantly reduce arterial lumen in response to an increase in blood pressure. Generation of myogenic tone involves different mechanosensors which are cell membrane proteins (ion channels, GPCRs), cell-ECM interactions via integrins connected to the cytoskeleton, and intercellular junctions through cadherin-catenin complexes. Nonselective stretch-activated cation channels are key players of the myogenic response via the opening of voltage-dependent calcium channels. In VSMCs, stretch-activated cation channels opening is negatively regulated by polycystin-2, which acts by binding to filamin-A to induce actin cross-linking and to reduce the tension applied on microdomains in the VSMC membrane for a given level of blood pressure.[6] Myogenic constriction occurs mainly in small-size muscular arteries and is enhanced by integrins $\alpha_v\beta_3$ and $\alpha_5\beta_1$ and nicotinamide adenine dinucleotide phosphate oxidase (NOX)-induced production of reactive oxygen species (ROS) mainly from mitochondria (Fig. 22.1). Alterations in myogenic response cause microvascular disorders (mainly cerebral and coronary vasospasms) and may be enhanced by ECM stiffening.

Chronic low-grade inflammation is an important cause of remodeling at the macro- and microcirculatory levels, particularly in hypertension, pertaining to vascular tone. This relationship is highly dependent on activation of the renin-angiotensin-aldosterone and endothelial systems. Muscle artery remodeling is induced by increased oxidative stress and the production of growth factors such as transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), and insulin-like growth factor. The synthesis and activation of adhesion molecules leads to a reorganization of cell-matrix interactions and phenotypic changes in VSMCs. Communications between intravascular cells (endothelial cells, VSMCs, and fibroblasts) and circulating cells such as platelets, immune cells, and progenitor cells play a key role in vascular remodeling. Numerous inflammatory molecules such as cytokines controlling both innate and adaptive immune responses (monocytes, macrophages, lymphocytes, etc.) are involved in this process (see below).

Inflammation is more correlated to the elasticity parameters of the large arteries than those of the muscular arteries. It is considered to be one of the main causes of remodeling of large arterial trunks. Arterial stiffness is increased in many systemic inflammatory diseases such as rheumatoid arthritis (RA), lupus erythematosus, vasculitis, acquired immunodeficiency syndrome, and Crohn's disease. A wide variety of mechanisms are involved such as endothelial dysfunction, induction of metalloproteinases, activation of the mineralocorticoid receptor, accumulation of proteoglycans, and finally colonization of the media by inflammatory cells from the vasa-vasorum of the adventitia.

Vascular smooth muscle cell relaxation

VSMC relaxation is responsible for in vivo vasodilation. The main physiological molecule able to induce relaxation of VSMC is NO. NO is essentially produced by the endothelial cells, in which NO synthase produces NO from arginine. In large arteries, the endothelial release of NO is under the control of shear stress (increasing flow velocity increases shear stress) and Ca^{2+} entry in endothelial cells. Coupling Ca^{2+} with calmodulin displaces caveolin from NO synthase, promoting convection/diffusion of NO to subjacent VSMCs where it activates soluble guanylate cyclase, cyclic-GMP production (second messenger) and G-kinase activation, which produce relaxation by targeting numerous molecules able to inhibit all the contraction pathways. In distal resistance arteries, the relaxation mediator could also be cyclic adenosine monophosphate (AMP), generated by adenosine triphosphate (ATP) metabolism, adenosine, which interacts with its receptor, and activates the production of cyclic AMP via adenylate cyclase. Cyclic AMP (as cGMP) binds to G-kinase and inhibits all the contraction pathways, coupling vasodilation with the metabolic demand in particular in striated muscle. Endothelial NO also acts in cerebral resistance arteries, exactly coupling vasodilation with electric (depolarizing wave) neuronal activity. In the wall of large arteries (mainly aorta), VSMC relaxation is associated with increased permeability to plasma components.

In summary, systemic contraction of VSMCs determines frictional forces which define the arterial tone (peripheral resistances) which transfers flow (kinetic energy) into potential energy (arterial pressure). Local relaxation of arterial VSMCs by inhibition of the arterial tone dynamically defines the territorial tissue coupling between an organ's function and its metabolic support. Whatever the functional sense, the long-term regulation of arterial diameter requires structural changes.

Endocytosis and phagocytosis abilities of vascular smooth muscle cells

Convection is a physiological outward hydraulic conductance from the blood through the wall, corresponding to radial dissipation of potential energy (blood/adventitia pressure gradient = 100 mmHg, fluctuating within the cardiac cycle). This conveys more or less all the soluble components present in blood, including oxygen and glucose, and microparticles suspended within the blood, through the wall. Convection intensity is dependent on physicochemical properties of the conveyed molecules, arterial wall permeability, and arterial pressure. In the great majority of tissues, metabolic support delivery is the fact of diffusion from capillaries.[7] Since convection enhances

metabolic deliveries, a complete vasculature, involving capillaries, is not mandatory for the arterial wall (except the external part of the aorta in humans). The physiological principle of convection-enhanced deliveries of blood molecules, potentially explains why the arterial wall tissue is avascular. Since capillaries and venules are the privileged site of leukocyte diapedesis, the avascular character of arterial media explains also why the arterial wall is an immune privileged site, in which the tissue penetration of leukocytes is limited to the capillaries and venules-rich adventitia.[8]

In laminar conditions of flow, the particulate components of blood remain in the central axis, whereas the peripheral position of blood favors its interface with the wall. In a laminar rheological environment, red blood cells (RBCs) concentrate in the core of the stream, whereas small platelets are expelled toward the periphery, close to the endothelium. The "in parallel" evolution of the circulation, and the numerous bifurcations of the arterial tree, cause localized mechanical impairment of kinetic energy in dissipation and transfer to potential energy. These changes in arterial geometry induce collision of circulating cells with the wall due to the loss of laminarity, microscopic dissipation of circulating cells within the wall, and an increase in internal entropy of the particulate part of the blood. Collision of blood cells with the wall are mainly due to the angulation of bifurcations or the presence of luminal narrowing, but also depend on the rheology of the circulating cells. Since RBCs and platelets are the most abundant circulating cells, therefore they represent the main blood particulate elements colliding with the arterial wall in regions where biomechanical stress drives the formation of intimal tears and of small intimal hematomas.[9]

Endocytosis

In regards to the physiological convection-enhanced delivery of blood components to the wall, VSMCs acquire the capacity to endocytose or not these blood components.[10] This endocytic ability is initiated by the convection, but is also related to the ability of ECM or to cell membrane to promote retention of these soluble molecular components within the wall, at close proximity to VSMCs. For instance, blood albumin or high-density lipoproteins are convected through the wall as all soluble blood components but are not retained by interactions with the wall. Therefore these components could be used as tracers for measuring arterial wall permeability[11] and its dependency on numerous parameters: for instance, endothelial functional and structural integrity, intraluminal pressure, elastic internal lamina integrity and hydrophobicity.[12] Wall retention requires VSMC endocytosis of blood components.

The most classical example of this paradigm is physiological convection-enhanced delivery of low-density lipoproteins (LDL) to the arterial wall, their retention by interaction with glycosaminoglycans synthetized by VSMCs,[13] their potential transformation including acetylation, oxidation, aggregation, and their endocytosis after transformation, mainly by VSMCs,[14] leading to foam cell formation, containing lipid microvesicles in their cytosol.[15] Lipids internalized by endocytosis are transported to late endosomes/lysosomes, where lysosomal acid lipase digests cholesteryl esters releasing free cholesterol. Free cholesterol in turn is processed by acetyl-CoA acetyltransferase that transforms cholesterol into cholesteryl esters. Free cholesterol is exocytosed and partly recycled by ATP-binding cassette transporter A1[16] in reverse transport.[17]

Convection-enhanced delivery to the arterial wall is not limited to lipoproteins. All the blood molecules transit and could be or not retained within the arterial wall. Circulating zymogens are outwardly convected through the wall where they can be activated. For instance plasminogen, which circulates in the blood at a μmolar range is convected to the wall and retained on lysine residues of several proteins of the VSMC membrane, where it interacts with tissue and urokinase plasminogen activators forming active plasmin. Plasmin has numerous targets in the arterial wall, involving proteolytic attack of pericellular adhesive proteins, such as fibronectin and fibrillin provoking VSMC detachment and death (a process named anoikis),[18] activation of the TGF−β release[19] from its ECM storage sites, and matrix metalloproteinase activation.[20] But these proteolytic activities are challenged by the ability of VSMCs to synthetize antiproteases, able to form protease/antiproteases complexes. Due to its powerful proteolytic activities, plasmin cannot be endocytosed by VSMCs, but the complex plasmin/protease nexin-1 (PN-1, serpin E2, a tissue serpin, highly expressed by VSMCs[21]) could be endocytosed, via the low-density lipoprotein receptor-related protein 1 (LRP-1) scavenger receptor (SR),[22] which has the ability to bind and to internalize protease/antiprotease complexes (Fig. 22.1).[23] VSMCs are rich in LRP-1 and antiproteases, including tissue inhibitor of matrix metalloproteinases. The formation of complexes and their ability to be endocytosed by VSMCs represent the main defense system against the proteolytic injury of the arterial wall. Other complexes such as hemopexin/heme bind to LRP-1 are then internalized and degraded in the lysosome, representing an important defense system against hemolytic-dependent oxidation within the arterial wall.[24]

Phagocytosis

Since Brown and Goldstein's early work with macrophages, the phagocytic function in the arterial wall is canonically assumed by professional phagocytes of myeloid origin. The team of Martin Bennett was the first to show that VSMCs could assume phagocytosis of

homotypic apoptotic bodies in the arterial wall.[25] A large amount of data exists showing that the presence of nonprofessional phagocytes (VSMCs in the arterial wall) is a general feature in most tissues.[26] This point is important in pathophysiology because it suggests that professional phagocytes, macrophages for instance, are not mandatory for tissue debridement by efferocytosis.[27] For instance, primary cultures of VSMCs are able to clear (and metabolize) a load of 10^6 senescent RBCs in 5 days, whereas fresh RBCs remain intact.[28] Senescent RBCs are characterized by phosphatidylserine exposure (Fig. 22.2). Senescent RBCs are more prone to hemolysis and Fe^{2+}-derived oxidative stress, both participating to the initial stages of atheromata in the human aorta. This phagocytic capacity is not limited to dying cell but also includes crystals such as cholesterol crystals[29] or hydroxyapatite microcrystals. This ability was mainly tested on macrophages, and synoviocytes, but not yet in VSMCs. In this context, crystal phagocytosis provokes inflammasome activation, interleukin (IL)-1 release, neutrophil attraction, and cell death.[30]

Scavenger receptors and eat me signaling

The first SR of modified LDL (but not native LDL) was reported by Brown and Goldstein in 1979. They bind also numerous other ligands, including polyanionic ligands, such as high glycated proteins. An important consensus review on SRs was published in 2017.[31] This review identifies 12 classes and more than 30 SR types in human and mouse. These SRs are able to bind more or less diverse ligands including lipids, phospholipids, sugar, microvesicles, protease/antiprotease complexes, and pathogens. These endocytic schemes are essentially explored in professional phagocytes of myeloid origin, but far less in the arterial physiology and its corresponding stromal cells (endothelial cells and VSMCs). SR-AI/II are expressed by VSMCs, and their expression is enhanced by oxidation and oxidized (ox) LDL.[14] CD36 is essentially expressed by macrophages, but also in VSMCs in which its activity could be stimulated by oxLDL and fatty acids, but this effect is challenged by clinical epidemiology in humans.[32] Similarly lectin-like oxLDL receptor-1 (LOX-1) expression is upregulated in response to oxLDL exposure, oxidative stress, activation of nuclear factor κB (NF-κB), and jun-kinase pathways.[33] Nevertheless, in our own experience, LOX-1 is less expressed than other SRs in cultured human VSMCs in response to oxLDL. In contrast, LRP-1 is more expressed in cultured VSMCs in response to oxLDL and is more specific for aggregated LDL.[34] As cited above, VSMC LRP-1 plays a major role in the VSMC defense against proteolytic injury. *In vivo*, selective deletion of LRP-1 in mouse VSMCs leads to aortic aneurysm development, due to ECM degradation.[23,35]

Interesting enough is the story of CD68 and its mouse ortholog macrosialin. CD68 is a transmembrane glycoprotein essentially associated with the endosomal/lysomal compartment, through a lysosomal-associated membrane protein domain.[36] In bone-marrow leukopoiesis, CD68 expression is restricted to myeloid progenitors, but absent of lymphoid development. CD68 is an SR for oxLDL, exposed phosphatidylserine, and malaria sporozoite.[37] CD68 was mainly used (and abused) as a monocyte/macrophage lineage histochemical tracing in human atherosclerosis, but CD68 is a functional marker of lysosomal and phagosomal activity whatever the cell lineage. CD68 expression is highly regulated by powerful transcription factors, E26 transformation−specific sequence-1 and friend leukemia integration-1, which upregulate its expression in myeloid cells, whereas interferon (IFN)-regulatory factor 4 represses its expression in lymphoid lineage.[38] CD68 expression is also governed by a cell lineage differential splicing, using alternative promoters related to chromatin remodeling in the promoter region.[39] This is usually observed in arterial VSMCs forming foam cells in mice.[40] In VSMCs, expressed CD68 can quickly shuttle from the cell membrane to the lysosome/phagosome. Therefore, in VSMC foam cells, CD68 staining is essentially intracellular, associated with lysosome/phagosome in α-actin-positive vesicles, suggesting important interactions with the cytoskeleton. Therefore, CD68 could participate in the link between endo/phagocytosis, cytosolic microvesiculation, and exosome release.

Exposed phosphatidylserine is the most frequent "eat me" signal for phagocytosis. Some SRs are directly involved in phosphatidylserine exposure. Other diverse phagocytosis biological schemes have been described including phosphatidylserine multiple ligand-mediated engulfment of apoptotic bodies, senescent living cells, or parts of the cell and extracellular vesicles (EVs).[41] Recently another paradigm was published concerning too large biological objects such as large deposits of aggregated lipoproteins (fatty streaks) or dead adipocytes. Contrasting with engulfment, exophagy is characterized by a tight contact with large targets, followed by release of lysosomal acidic enzymes in the near environment of the target, sharing similarities with osteoclastic process.[42] Nevertheless, these biological procedures were experimentally described always with macrophages. The activity or not of such processes, associated with VSMC phagocytic activities remains to be explored in the cardiovascular tissues and cells.

One important point is the direct link between these intracellular inputs of endocytosed and/or phagocytosed activities and the exosomal output releasing activity. Schematically, there are two important pathways for the biological waste metabolism, the lysosomal pathway leading to complete degradation and recycling of the waste

input by lysosomal and phagosomal activity, and exosomal activity, EV and exosome releases, protecting cells against excessive intracellular stress.[43] Because of the physiological convection of blood components through the wall, as described above, these endocytic activities of VSMCs are mandatory for arterial tissue homeostasis. In pathological conditions, these activities could be overloaded in nonprofessional phagocytes, such as VSMCs, leading to death or to an excessive vesiculation and exosomal activities, participating in the pathology through the ability of exosomes to signal to the immune system, particularly to adventitia,[8] and/or to serve as phospholipids, phosphate-rich substrates for calcifications (Fig. 22.2).

In summary, the role of VSMCs in all vascular diseases cannot be interpreted independently of their endocytosis and phagocytosis abilities, as a physiological consequence of arterial blood pressure.

Integrin-mediated and nuclear mechanotransduction in vascular smooth muscle cells

VSMC−matrix interactions are key molecular/cellular mechanisms contributing to vascular stiffness and are controlled by mechanotransduction and mechanosensing.[44] Numerous cardiovascular complications where VSMC dysfunction compromises cell-ECM homeostasis can thus be envisioned as mechanotransduction disorders.

Membrane mechanotransduction

The biological responses of VSMCs to mechanical stimuli include the transduction of the signal ensured by mechanosensitive molecules and the epigenetic control of genes encoding structural components of the ECM (e.g., collagen, fibronectin, fibrillin, and proteoglycans), chemokines [e.g., monocyte chemoattractant protein (MCP)-1], cytokines (e.g., TGF-β, cardiotrophin-1, and ILs), and proteases (e.g., matrix metalloproteinases or serine proteinases) and their inhibitors (e.g., tissue inhibitor of metalloproteinases and tissue serpins). VSMCs sense their local mechanical environment mainly through an ECM fibrillar components—integrins—cytoskeletal axis. Integrins are αβ-heterodimeric transmembrane receptors highly present on the surface of VSMCs in an inactive folded conformation. Many constituents of the ECM have motifs that are binding sites for different members of the integrin family. The specificity of the binding depends on both the motifs in the ECM protein sequence and the type of α and β subunits of the integrin; as an example, integrin $\alpha_1\beta_1$ preferentially binds collagen and integrin $\alpha_5\beta_1$ binds fibronectin. In this way, integrins enable cells to evaluate both the mechanical state and the specific composition of the local ECM.

Clustering of integrins at specific sites of the VSMC membrane form focal adhesions (FAs) serving as hubs for mechanotransduction. FA formation and turnover are highly regulated in a dynamic way that can be divided into three phases: assembly, stability, and disassembly. FAs provide the bidirectional link between extracellular constituents and intracellular actomyosin cytoskeleton through the integrin receptors for the outside-in or inside-out transduction of mechanical and biological signals (Fig. 22.1). Associated integrin linker proteins [e.g., actinin, talin, vinculin, and focal adhesion kinase (FAK)] are responsible for integrin activation and the anchoring of actin filaments to the integrin intracellular domains. Integrin activation and clustering is triggered by ligand binding and recruitment of talin that binds F-actin through actin-binding or vinculin-binding sites. Talin-to-vinculin binding forms a so-called molecular clutch which increases actin polymerization and promotes cell sensing of its mechanical environment.

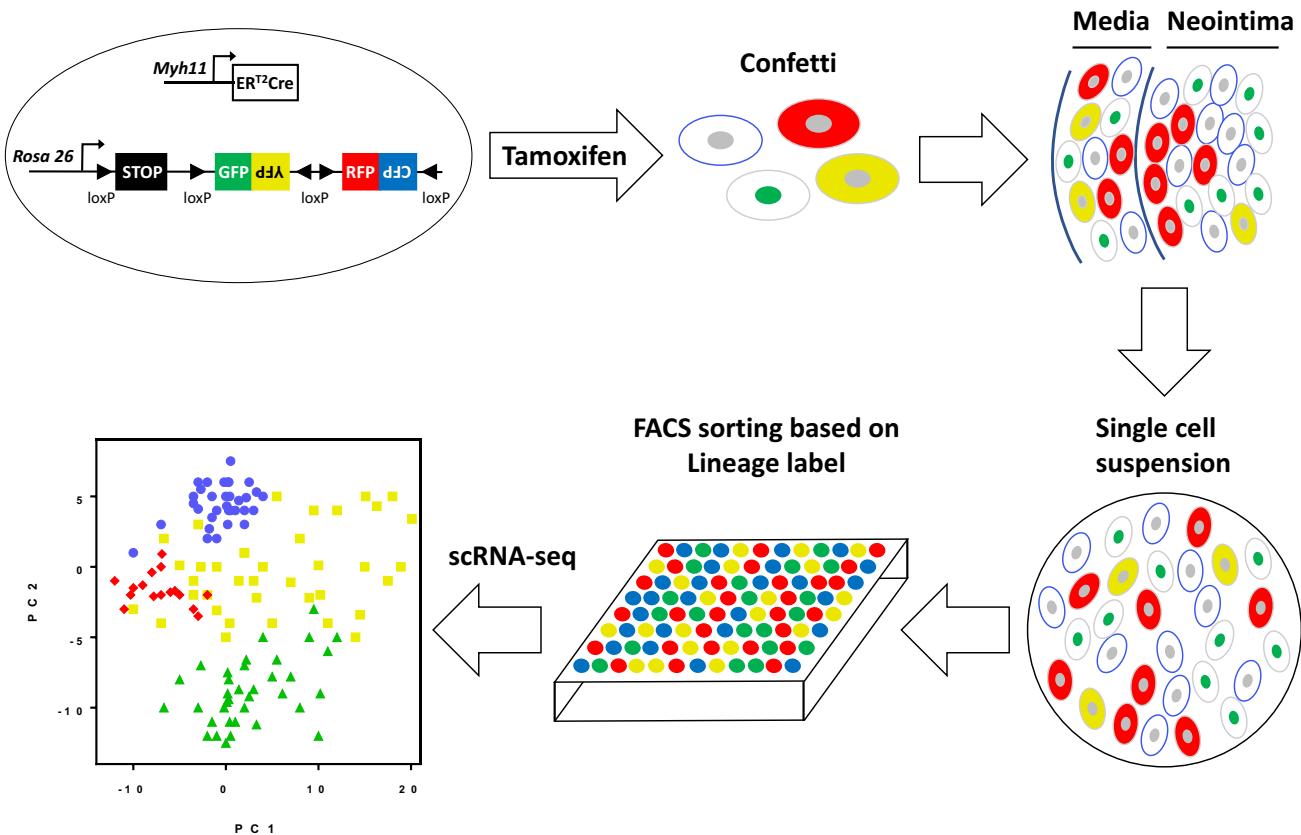
FA recruitment and strengthening ended by FA protein recycling, defining their lifetime (from 10 s up to a few minutes), depend on intracellular FAK phosphorylation and matrix stiffness. On a compliant ECM, dynamic interactions between integrins, talin, and actin are short-lived and exhibit a slip-bond behavior that does not require vinculin. In contrast, on a stiff ECM, low exchange rates of FA proteins (high association and low dissociation constants) reinforce vinculin-dependent binding of talin to F-actin and activate catch bonds. Such catch bonds are currently thought to be key actors of the stiffening of the wall components. Lifetimes also depend on the direction of the applied force (pointed end−directed and barbed end−directed loads). In addition, levels of adhesion exerted by FAs are spatially regulated with higher levels in periphery at cell edges than near the nucleus. Mechanical stresses enhance ROS production and signaling, which can regulate FA turnover. Indeed, increased expression of NOX4, a main source of ROS localized to FAs and in mitochondria, fosters arterial stiffness, at least in part, by increasing the number of persistent FAs. Actin polymerization-depolymerization and adhesive properties of FAs also contribute to cell stiffness. The FAK/Src signaling network has been reported to control VSMC stiffness.[45] There is, therefore, a need to elucidate the contribution of cellular stiffness to vascular wall stiffening.

Increased arterial stiffness has been attributed to a coupling between the integrin pathway and the mechanosensitive pathways involving GPCRs and their effectors that trigger VSMC contraction. GPCR activation and downstream signaling via RhoA/ROCK pathways maintain a high degree of phosphorylation of MLC by decreasing MLCP activity. In support of a role of ROS on integrin activity, lysophosphatidic acid has been shown to increase integrin-fibronectin adhesion via activation of β_1 and β_3 integrins. This is mediated by

GPCRs and the production of ROS, and controls the myogenic tone in resistance vessels. Intermediate filaments also participate in force transmission between FAs and the actomyosin network. It has been shown, for example, that genetic deletion of vimentin in mice increases carotid stiffness through increased FA turnover and VSMC contractility. It should thus be anticipated that acting on FAs or G-protein—coupled contractility could modulate arterial stiffness.

Nuclear mechanotransduction

The mechanical environment of VSMCs not only impacts the ECM—integrin—cytoskeletal axis but also the nuclear membrane, which becomes physically linked to some FAs through the cytoskeleton and can act as a mechanosensor. The nuclear pore complex, which form a stable scaffold embedded in the nuclear envelope where the inner and outer membranes are fused and decorated with intermediate filaments, serves as the primary gateway regulating the macromolecular traffic between the nucleus and cytoplasm. The linker of nucleoskeleton and cytoskeleton (LINC) complex also couples actomyosin with the lamina scaffold. These two networks ensure the nuclear transmission of the tensile forces in the VSMC microenvironment, thereby affecting gene expression by altering chromatin organization and regulating epigenetic pathways via lamin A and emerin. Highly compacted inactive chromatin (heterochromatin) is associated closely with the lamina scaffold at the periphery of the nucleus (inaccessibility of promoters of genes) while the loosely compacted active chromatin (euchromatin) is present at the center of the nucleus (increased accessibility). In response to matrix stiffening, forces transmitted via assembled actin filaments increase recruitment of FAs and LINC complex proteins, and stabilization of lamin A. In addition, it induces phosphorylation of emerin, which contributes to reinforce the LINC complex. Taken together, this balances outside and inside forces. In support of the key role of lamin A, a mutation in the gene encoding lamin A is responsible for Hutchinson—Gilford progeria syndrome (HGPS), a disease hallmarked by altered mechanotransduction and the inability of the nucleus to respond dynamically to mechanical stress together with disappearance of VSMCs. The consequences are an acceleration of vascular aging and arterial stiffening leading to premature death. HGPS VMSCs exhibit increased phosphorylation of histone H2A.X, which is required for activation of the DNA damage response.

Recently, the Hippo pathway effectors Yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ) have been shown to act as downstream sensors of ECM stiffness to regulate FA assembly following nuclear shuttling.[46] YAP/TAZ nuclear localization activates RhoA/ROCK signaling and increases the expression of several FA genes (Fig. 22.1), including α_v


and β_3 genes. YAP and TAZ drive VSMC migration and proliferation, as well as cell renewal. The YAP/TAZ pathway also regulates arterial stiffness as a target of Rac-GTPase involved in TGF-β1—induced fibrotic signaling.

Epigenetic mechanisms are involved centrally in arterial diseases. Classically, the dynamics of the epigenetic code are mainly orchestrated by DNA damage and oxidative stress, causing changes in chromatin regulatory elements (DNA methylation and histone acetylation, methylation, and phosphorylation) as well as in nonprotein-coding RNAs (microRNAs and long noncoding RNAs). Hypomethylation of the promoter region of the integrin-binding protein 2 gene has been reported to be associated with decreased arterial stiffness in the TwinsUK cohort, thus supporting the contribution of epigenetic regulation of arterial stiffness. Hypomethylation of the microRNA-203 promoter induces decreased expression of FA proteins and altered FAK signaling resulting in increased VSMC stiffness.

In summary, mechanotransduction in VSMCs can be resolved into extrinsic (hemodynamic dependent) and intrinsic (actomyosin activation) mechanisms. Outside-in transduction refers to the transmission of the initial stretch of the ECM to the cytoskeleton and nuclear envelope via integrins, FAK et GPCRs. This process drives chromatin remodeling and changes in gene expression. Inside-out transduction, which is initiated by the sliding of myosin onto actin, leads to VSMC shortening and thus compaction of the vascular wall. The effects on cell and tissue physiology can be recapitulated as stretch versus shortening and distension versus compaction.

Vascular smooth muscle cell plasticity

Despite being highly specialized, VSMCs retain the remarkable capacity to modulate their phenotype in response to changes in their environment. These phenotypic modulations drive the functional diversity of VSMCs and their role in arterial physiology and vascular disease. The plastic nature of VSMCs has been extensively studied in vitro for the past 30 years.[47,48] From these studies, Gordon and Julie Campbell established the concept of VSMC phenotypic switching, a model in which VSMCs shift from a differentiated, contractile phenotype to a dedifferentiated, "synthetic" phenotype (Table 22.1). Yet, the investigation of VSMC phenotype and function in vivo has been a decade long challenge in the field due to the inner difficulty and ambiguity to identify dedifferentiated VSMCs because of a strong repression of traditional VSMC marker gene expression (e.g., *MYH11*, *ACTA2*, and *TAGLN*).[49] This major limitation motivated the development of reliable in vivo fate mapping system, based on the specific and stable labeling of medial VSMCs, first developed in the early 2000s by Robert Feil's group.[50—52]

FIGURE 22.3   Schematic showing strategies for lineage labeling of vascular smooth muscle cells (VSMCs) and single-cell RNA-sequencing. Tamoxifen treatment activates Myh11-driven inducible Cre-recombinase resulting in VSMC-specific excision of the stop codon in the multicolor Confetti reporter inserted into the Rosa26 locus. VSMC lineage cells, randomly labeled with one of four fluorescent proteins (GFP, YFP, RFP, and CFP), can be tracked in medial and neointimal layers. After preparation of a single-cell suspension and fluorescence-activated cell sorting (FACS) based on the expression of lineage label, transcriptional profiling is performed by scRNA-seq and principal component analysis.

VSMC fate mapping combined with immunofluorescent staining and high-resolution confocal microscopy have demonstrated the significant contribution of VSMCs in the development and progression of vascular disease and their remarkable phenotypic plasticity (For details, see the basic concept box and Fig. 22.3).[53]

Unbiased analysis of the heterogeneity between VSMCs within and between different healthy vascular beds was enabled with the development of single-cell RNA-sequencing combined with VSMC lineage tracing.[54] For example, such an approach has been used to track subsets of cells expressing the mesenchymal stem cell marker Sca1 among distinct VSMC clusters (Myh11-lineage) identified by single-cell RNA-sequencing on whole aorta and to evaluate their potential contribution in atherosclerotic lesions.[55,56] Thus, VSMC phenotypic characterization and identification of a particular signature at the level of single-cell profiling may provide insight into disease predisposition and response.

The age- or disease-related phenotypic modulation of VSMCs often manifests as a change from a mature quiescent contractile phenotype (differentiated) to a more migratory, proliferative phenotype (dedifferentiated). Dedifferentiation to synthetic and proliferative states leads to ECM accumulation or hypertrophy of the vascular wall, which affects directly arterial stiffness. The differentiated or intermediate states of VSMCs are classically hallmarked by a repertoire of markers including smooth muscle-specific contractile proteins [e.g., α-smooth muscle actin (SMA), smooth muscle myosin heavy chain (SM-MHC) and calponin], cytoskeletal molecules (e.g., actin and actinin), transcription factors [e.g., serum response factor (SRF) and ETS-like transcription factor 1 (Elk-1)], inflammatory-related factors [e.g., phospho-extracellular signal-regulated kinases (ERK) 1/2, intercellular adhesion molecule 1, TGF-β, and pro-collagen 1], epigenetic factors [e.g., sirtuins (SIRTs)], and ECM stiffness.

Environmental molecular changes drive a phenotypic modulation characterized by reduced expression of SMC-specific contractile proteins as well as increased cell proliferation and production of proinflammatory cytokines. These phenotypic changes contribute to intimal thickening

and calcifications. Additional phenotypic changes are common in diseases, including differentiation of VSMCs toward myofibroblast-like, macrophage-like, and mesenchymal stem cell—like cells, among others. Aberrant phenotypic transitions are exemplified in arterial calcification where VSMCs undergo an osteo/chondrocytic conversion with active release of matrix vesicles triggering the mineralization process. Another new concept is that of progenitor cell transition. Differentiated VSMCs can migrate from the outer media into the inner adventitia and express progenitor cell markers on induction of the transcription factor, Kruppel-like factor 4 (KLF4). Resident SMC-derived progenitor cells contribute to medial repair by differentiating into medial VSMCs.[57] A key question is to determine whether phenotypic modulation occurs in all VSMCs (polyclonal hypothesis) or only in subsets of VSMCs (monoclonal/oligoclonal hypothesis). Another challenge is to develop an integrated dynamic analysis of the early (reversible) and late (irreversible) phenoconversion of VSMCs, particularly in relation to arterial stiffening development.

Regulation of vascular smooth muscle cell differentiation by growth factors and transcriptional factors

PDGF and TGF-β are master regulators of VSMC phenotypic plasticity. PDGF-BB and PDGF-DD promote downregulation of VSMC-specific contractile genes by activation of their receptor PDGFR-β. Canonically, the action of PGDF-BB depends on the transcription factors KLF4 and Elk-1. Alternatively, PDGF-BB has been reported to degrade contractile proteins by activation of autophagy which also elicits cytoprotective effects through removal of proteins damaged by increase in oxidative stress. VSMC phenotypic modulation is hallmarked by the inflammatory state of VSMCs. While both IL-1β and PDGF-DD repress SMC differentiation marker genes and upregulate proinflammatory genes, the transcription factor NF-κB is a critical mediator of the effects of IL-1β. PDGF-DD primarily induces downregulation of the proinflammatory chemokine (C—C motif) ligand 20 (CCL20) and upregulation of the regulator of G-protein signaling 17 (RGS17) involved in cell proliferation and migration.

In contrast to PDGF, TGF-β promotes the contractile phenotype through phosphorylation of Smad2/3 and Smad1/5/8 signaling. This increases phosphoSmad2/3 binding to α-SMA, calponin, and SM22α promoters. The opposite effects of PDGF and TGF-β on VSMC phenotype switching is tightly regulated by microRNAs, in particular microRNA-143/145, microRNA-221 and microRNA-222, microRNA-21 and microRNA-24. In the context of intimal proliferation, elevated TGF-β/Smad3 upregulates

canonical Wnt/β-catenin signaling thereby promoting VSMC proliferation.

The SRF/myocardin-dependent control of VSMC plasticity illustrates the role of transcriptional pathways.[58] Binding of the trans-acting factor SRF to a DNA sequence called the CArG box (cis-acting element) induces transcription of VSMC marker genes of differentiation. Interaction of SRF with VSMC coactivators including myocardin and myocardin-related transcription factors A and B strongly enhances its affinity for the CArG elements of specific contractile genes. In contrast, interaction with members of the ternary complex factor family of Ets domain proteins such as Elk-1 increases the expression of immediate-early genes (e.g., c-fos) and VSMC dedifferentiation. Stimulation of the mitogen-activated protein kinase (MAPK) pathway by growth factors shifts the binding of SRF toward Elk-1 and thereby represses VSMC gene expression by disrupting myocardin-SRF interactions. KLF4 has also been identified as a potent repressor of contractile genes through interaction with phosphorylated Elk-1, modifications of chromatin structure of CArG box-containing promoters, sequestration of SRF, and reduction of myocardin expression (Fig. 22.1). VSMC stiffness mechanisms occurring in hypertension depend on the activation of SRF co-factors. An inhibitor of SRF activity normalizes VSMC stiffness paralleled by an improvement of aortic elasticity that precedes the reduction of blood pressure in spontaneous hypertensive rats.

Exaggerated production of ROS and cell senescence are hallmarks of vascular aging. The transcription factor, nuclear factor-erythroid-derived 2-related factor 2 (Nrf2) orchestrates the transcriptional response of cells to oxidative stress by driving the expression of antioxidant genes via its binding to antioxidant response elements in their promoters (Fig. 22.1). Age-related downregulation of vascular Nrf2 expression as well as dysfunction of the nucleocytoplasmic shuttling of Nrf2 sensitize VSMCs to oxidative stress-induced damage.

Altogether, aging and hypertension are associated with a shift toward VSMC dedifferentiation mainly orchestrated by PDGF and SRF/Elk-1 in parallel with a lower activity of the differentiation program triggered by SRF/myocardin and TGF-β. Decrease in Nrf2 with aging acts additionally by reducing the expression of antioxidant genes leading to loss of VSMC plasticity and increased senescence.

Epigenetic determinants of vascular smooth muscle cell plasticity

While VSMC phenotypic switching appears as a causal mechanism responsible for arterial stiffening, characterization of VSMC plasticity at the epigenetic level is a new

area in this topic. Epigenetic regulation directly affects expression of differentiation genes by modulating chromatin remodeling, DNA methylation or histone modifications, and noncoding RNAs.

SIRTs have emerged as the first epigenetic modifiers of arterial stiffness. It has been demonstrated that SIRT-1, an oxidized nicotinamide adenine dinucleotide (NAD$^+$)-dependent class III protein deacetylase, slows down the development of arterial stiffness in the presence of neointimal formation after vascular injury or diet-induced obesity. The mechanisms are likely due to its antiinflammatory and antioxidant effects. SIRT-1 inhibition is caused by disruption of zinc binding that is critical for the enzymatic activity of SIRT-1. In nonhuman primates, the SIRT-1 activator resveratrol prevents the increase in pulse wave velocity in response to Western diet. Increased peroxynitrite-mediated SIRT-1 inhibition in response to nicotine contributes to arterial stiffness in mice. In further support of this protective role, the decline in SIRT-1 protein levels with age drives increased inflammation and premature VSMC senescence. The predominant localization of SIRT-1 in the nucleus confers it the means to exert its effects through transcriptional mechanisms and epigenetic pathways. For example, the antiinflammatory action has been described to be dependent on casein kinase II-mediated phosphorylation of SIRT-1, which promotes its deacetylase activity on the methyltransferase enhancer of zeste homolog 2 (EZH2) and thereby suppresses the EZH2-mediated H3K27 trimethylation of the SM22α promoter region and subsequent gene silencing.

In addition, noncoding RNAs can control the expression of epigenetic regulators. For example, the ubiquitin-like containing PHD and RING finger domains 1 (UHRF1) binds to promoters of genes that govern VSMC differentiation (*MYH11*, *ACTA2*, and *SM22*) and inhibitors of the cell cycle (*CDKN1A* and *CDKN1B*), leading to repression of these genes via DNA and histone methylation (increase in H3K27me3) (Fig. 22.1). In addition, microRNA-145, upregulated by PDGF-BB and downregulated by TGF-β, decreases UHRF1 expression. Inhibition of UHRF1 has been seen to reduce aneurysm severity in experimental models.[59] Altogether, these mechanisms indicate that the Hippo pathway YAP/TAZ as well as UHRF1 may be positioned at the crossroads of nuclear mechanotransduction and epigenetic regulation of arterial stiffness. Finally, the maintenance of the progenitor phenotype dependent on KLF4 and progenitor cells are characterized by loss of the H4Ac chromatin mark and retention of the H3K4Me2 mark. This demonstration suggests that this physiological in situ VSMC reprogramming could be critical in determining the trajectories of vascular aging, normal vascular aging, or early vascular aging.

Cell senescence

As described in detail in Chapter 23, cell senescence is a durable, irreversible, cell cycle arrest of replication with cells which remain metabolically active and become resistant to apoptosis due to the upregulation of antiapoptotic proteins.[60] VSMC senescence with that of endothelial cells is one of the common and early mechanisms that produce reduced vasodilation and increased vasoconstriction, oxidative stress and inflammatory cytokine production in vascular aging.[61] The most highly expressed markers are senescence-associated β-galactosidase (SaβG), a lysosomal enzyme present in endothelial cells, VSMCs and fibroblasts, and the senescence-associated secretory phenotype (SASP) cytokines: IL-6, tumor necrosis factor (TNF)-α, and MCP-1. The presence of telomere-associated DNA damage foci (markers of double stranded DNA breaks) consecutive to SASP appears to be a more specific marker than SAβG because it provides information on the senescent cell and its environment. Indeed, persistent activation of DNA damage and ROS production via the SASP impact adjacent cells, leading to an increased senescence burden. The others, also nonspecific, are those related to irreversible growth arrest with telomere shortening, loss of proliferation markers, and of specific microRNA or proteins, such as lamin B1, CDKN2A (p16), CDKN1A (p21), and TP53 (p53). Leukocyte telomere length, a marker of cell senescence, is inversely correlated with increased arterial stiffness.[62]

The change in expression of a marker in VSMCs in physiopathology is also difficult to interpret because the markers are not lineage specific. Cell senescence is also dependent of epigenetic regulation. Therefore, the combination of markers of the epigenetic signature of VSMCs (dimethylation and acetylation of promoters of the smooth muscle-specific genes, e.g., *SM-MHC* gene) with classical senescence markers is of major interest to determine the origin of the different cells and the stage of progress of vascular senescence. For example, replicative senescence of VSMCs is linked with their propensity to undergo transdifferentiation toward an osteochondrogenic or macrophagic lineage. The age-induced decline in SIRT1, a key epigenetic regulator of TP53 which induces its degradation via deacetylation, reinforces age-related VSMC phenotypic changes. Recent work also indicates that noncoding RNAs play a key role in SASP cytokine release at the interface between cell senescence and vascular aging.[63]

In summary, phenotypic regulation governs the functional diversity of VSMCs and their role in cellular stiffness and arterial stiffness. Changes in their local mechanical environment regulate their gene expression through transcriptional regulatory pathways and epigenetic programming. VSMC senescence can lead to arterial stiffening but

ECM stiffening can also lead to VSMC senescence. In view of the multiple roles of VSMCs and feedback controls, computational models can be used to build protein networks in relation to epigenetic factors.

Participation of inflammation and immunity in vascular smooth muscle cell functions

Increased systemic inflammation, as seen in e.g. in RA, systemic lupus erythematosus, systemic vasculitis, human immunodeficiency virus, and inflammatory bowel disease, is associated with an elevated cardiovascular risk and also with increased arterial stiffness,[64] even in the absence of prevalent cardiovascular comorbidities.[65] Since a longer disease duration of RA is an independent predictor of vascular stiffness, the notion emerges that exposure to chronic inflammation may be causally linked to arterial stiffening. This is further supported when considering that each year of life with RA contributes to a higher rate of vascular stiffening than a patient's year of life without RA.

Arterial stiffening goes hand in hand with chronic inflammation promoting the interactions of different innate and adaptive immune cells and platelets with the vessel wall. This contributes to the immunoinflammatory response by multifactorial mechanisms, including endowing the vascular wall with a proinflammatory phenotype, fostering leukocyte recruitment and infiltration, promoting alterations in intracellular metabolic pathways, and amplifying close interplay between macrophages and VSMCs. Increased proliferation and migration, production of proinflammatory mediators and loss of contractile phenotype hallmark VSMC changes in an inflammatory environment.

Cytokines et chemokines

VSMCs express toll-like receptors that play a critical role in the production of components of the inflammasome associated with the innate immune response (e.g., IL-1β. IL-6, and IL-18) (Fig. 22.1). Angiotensin II acts on T-helper lymphocytes to produce IL-2, TNF-α, and IFN-γ, and Th2 lymphocytes for the cytokines IL-4, IL-5, IL-6, and IL-10. In this context, IL-6 produced by adaptive immune cells and VSMCs contributes to angiotensin II-induced hypertension through the phosphorylation of Janus kinase 2 and signal transducer and activator of transcription 3. Accumulation of IL-17 in the medial layer in thoracic aorta causes vascular dysfunction. The mechanisms involve a synergistic effect with TNF-α to trigger the expression of VSMC proinflammatory genes. IL-18 enhances the angiotensin-II-induced NOX1-dependent VSMC proliferation and migration. Disruption of IL-1β signaling induces a change in cell composition in atherosclerosis characterized by a reduction of VSMCs and an increased proliferation of resident macrophages. Recently, the long noncoding RNA H19, which is located in VSMCs and infiltrating aortic macrophages has been shown to increase IL-6 expression in VSMCs via competition with let-7a target gene IL-6, thus promoting vascular inflammation and cell senescence.

Increased adhesiveness of platelets at the vessel wall and vascular leukocyte infiltration elicit an endothelial dysfunction (Fig. 22.2). This results in a loss of anticoagulant role of endothelial cells together with the expression of the prothrombotic properties of VSMCs that express high levels of tissue factor, which in turn generates various proteases, including activated factor X (factor Xa) and thrombin. Factor Xa acts on protease-activated receptor (PAR)1 to control VSMC proliferation and migration while thrombin-mediated mitogenic effects on VSMCs were found to be dependent on integrin $\alpha_v\beta_3$ via activation of FAs. Activation of PARs by thrombin also promote the proinflammatory phenotype of VSMCs by enhancing the synthesis and release of cytokines and chemokines (e.g., IL-6, C-X-C motif chemokine ligand 8) via activation of MAPK pathways.

Innate immunity and extracellular vesicles

Infiltrating macrophages, EVs, and neutrophil extracellular traps (NETs) are key mediators of vascular inflammation (Fig. 22.2). Activated macrophages exhibit increased glycolysis enhancing cytokine production. Changes in metabolism control macrophage polarization. While several intermediate phenotypes exist that modulate the innate immunity, enhanced glycolysis and tricarboxylic acid cycle activity hallmark proinflammatory M1 macrophage activation while antiinflammatory M2 macrophages show enhanced oxidative phosphorylation, including fatty acid β-oxidation. It has become increasingly evident that EVs mediate cell−cell interactions and could stimulate immune responses. Macrophage-derived EVs have been reported to transport α_5 and β_1 integrins to the surface of VSMCs, which in turn activates the ERK and Akt pathways and fosters VSMC adhesion and migration. VSMC reprogramming has also been found to initiate inflammation. Expression of progenitor cell markers by VSMC migrating into the adventitia, a process regulated by KLF4, potentially results in differentiation into macrophages. NETs are histone-DNA components of dying cells involved in the defense of the host against pathogens. Excessive release of NETs can cause vascular tissue lesions and triggers thrombotic events, particularly in systemic autoimmune diseases.[66] In addition, the release of NETs induces endothelial cell death leading to infiltration of neutrophils and VSMC lysis in atheroma.

Among the potential candidates acting as amplifiers of the innate immune response, the triggering receptor expressed on myeloid cells (TREM)-1 appears to play a central role.[67] TREM-1 is expressed by neutrophils,

macrophages, and mature monocytes (CD14high), as well as by hypoxic dendritic cells, platelets, endothelial cells, and VSMCs. The cytoplasmic tail of TREM-1 associates with the adaptor molecule DNAX activation protein of 12 kDa (DAP12), which becomes phosphorylated and thereby provides a docking site for the spleen tyrosine kinase that promotes signal transduction via several pathways including NF-κB (Fig. 22.2). The engagement of TREM-1 with agonist monoclonal antibodies has been shown to stimulate the production of proinflammatory cytokines and chemokines such as IL-8, MCP-1, MCP-3, and macrophage inflammatory protein-1α, along with rapid neutrophil degranulation and oxidative burst. The activation of TREM-1 in presence of toll-like receptor-2, -4, or nod-like receptors ligands amplifies the production of proinflammatory cytokines (TNF-α, IL-1β, granulocyte-macrophage colony−stimulating factor), as well as the inhibition of IL-10 release. In response to inflammatory stimuli, the expression of TREM-1 is increased, and this mediates proliferation and migration, and shift toward a proinflammatory phenotype of VSMCs.

Failure in the resolution of inflammation

Inflammation is a recognized risk factor and therapeutic target in cardiovascular disease.[68] Chronic cardiovascular inflammation results from both a continuous immune activation and a failure in the resolution of inflammation.[69] Lowering LDL cholesterol decreases inflammatory markers such as C-reactive protein, emphasizing the close interplay between lipids and inflammation.[70] Furthermore, direct antiinflammatory treatments have shown additional beneficial effects in studies of secondary prevention in high risk patients. As an alternative to inhibiting proinflammatory signaling, cardiovascular inflammation could potentially be disrupted by actively promoting an effective resolution of inflammation.[69] Importantly, omega-3 fatty acid−derived lipid mediators called resolvins promote the resolution of inflammation.[71] In addition to their effects on immune cells (Fig. 22.2), resolvin receptors are expressed on VSMCs[72] and may contribute to slow down arterial aging.[58] For example, resolvins, and other specialized proresolving mediators, decrease proliferation, collagen deposition, and phosphate-induced calcification in VSMCs in vitro.[73] These direct inhibitory actions of resolvins on VSMC maladaptive responses indicate potential beneficial effects on vascular stiffness from actively promoting the resolution of chronic vascular inflammation.

Present at the physiological level in the resolution of inflammation, the interactions between blood components with matrix and/or cellular elements associated with mechanical stress are main determinants in the early phase of vascular diseases for atheroma development. In addition to this, the vascularization of the adventitia (capillary- and postcapillary venules) in the aorta allows the lymphocytes diapedesis able to promote locally adaptive immunity and endothelial cell sprouting to form neoangiogenesis in the media. The neovessels formed are partly immature and thus highly susceptible to foster rupture and intraplaque hemorrhage.

Inhibition of immunoinflammatory signaling without immune-suppressive side effects is thus clearly warranted in vascular pathologies. Tailored disruption of intercellular communications or targeting of immune checkpoint proteins [e.g., cluster of differentiation 40 (CD40) and CD40 ligand, TNF receptor superfamily member 18 (TNFRSF18) and TNF ligand superfamily member 18 (TNFSF18)] expressed by VSMCs could be a promising approach.[74]

In summary, infiltration of inflammatory molecules and immune cells in the vascular wall can cause VSMC migration and proliferation as well as the induction of oxidative stress. Other cellular mechanisms more involved in the resolution of inflammation at the VSMC level in addition to other cells may also play a key role in vascular disease priming.

Conclusion

The emergence of VSMCs in the understanding of cellular and molecular mechanisms of vascular diseases highlights the role of hemodynamics factors and the links between VSMCs and ECM in which they reside and also that of other specific cells in the arterial wall including endothelial cells, inflammatory and immune cells, fibroblasts, and progenitor cells. It appears difficult to discriminate atherosclerosis and accelerated arterial aging since they evolve in parallel with hemodynamic changes, calcification, and arterial stiffening, all involving VSMC plasticity. Hemodynamics, structural factors, and signaling pathways are now considered in a single complex biology network (mechanobiology) where the interactions between the different compounds are ordered according to highly variable dynamics of action over time.[75] This field has benefited from new methodologies, in particular lineage tracing, single-cell RNA-sequencing associated with single-cell genome-wide DNA methylation, and high-precision microscopic techniques such as atomic force microscopy or velocity protein mapping, which allows to visualize in real time the location of individual proteins in the assembly and disassembly processes of FAs in relation with actomyosin coupling.

A new direction will also be to correlate these fundamental results with those of genetics, for example, how rare or common variants of certain genes or loci interfere with the differentiation of VSMCs or the viscoelastic response of the arterial wall, and to integrate epigenetic markers and the effects of noncoding RNAs. At a more clinical level, the prevention or treatment of

arterial stiffness requires the transfer of information from cell-matrix interactions and genetics into biomarkers of vascular remodeling and tissue homeostasis. The multiplicity of regulatory or counter-regulatory loops makes this biomarker search difficult. In this sense, proteomic analyses offer new possibilities. The development of biobanks open to the entire scientific community and the constitution of large, perfectly targeted populations strengthen the research continuum in this field. Finally, in addition to VSMC markers (mainly senescence markers and inflammatory molecules) that are measurable in blood, human-induced pluripotent stem cells as a source of well-controlled VSMCs or for creating models of mechanotransduction have therapeutic promise in the dynamics of vascular aging and diseases.

Basic concept box—SMC lineage tracing and single-cell RNA-sequencing

Genetically modified mouse models to fate map VSMCs should combine (1) the efficient and definitive labeling of VSMCs and their progeny with reporter systems (e.g., fluorescent proteins, LacZ); (2) its conditional expression with high specificity for the VSMC lineage; and (3) an inducible system permitting activation of the tracking system in mature VSMCs at a given time upon treatment with tamoxifen.[50–52] Recent VSMC lineage tracing studies have employed tamoxifen-inducible *Myh11*-CreER[T2] mouse model crossed with loxP-STOP-loxP-reporter mouse models to track the fate and phenotype of VSMCs expressing smooth muscle myosin heavy chain (SM-MHC).[76–78] The R26R-Confetti mouse (LoxP site in the *Rosa26* locus) shows a stochastic recombination of four fluorescent markers (nuclear GFP, cytoplasmic YFP or RFP, or membrane CFP) upon Cre activation (Fig. 22.3).

These conditional and inducible Cre recombinase systems allow for the labeling of mature VSMCs (single-cell resolution by Z-stack confocal analysis or multiphoton microscopy) prior to injury or development of vascular disease and the ability to follow their fate independently of marker gene expression while critically avoiding the labeling of cells acquiring the expression of these marker genes during disease or injury.

Cell isolation (enzymatic digestion followed by sorting based on lineage label) leads to the selection of VSMC clusters by single-cell RNA-sequencing. Principal component (PC) analysis allows the identification of differential gene expression between clusters (Fig. 22.3).

Introduction

The prevalence of chronic, noncommunicable diseases, including atherosclerosis, diabetes, heart failure, dementia, and kidney dysfunction, increases with aging, and these diseases tend to cluster in older individuals.[1] The diseases shorten the healthy lifespan and increase the burden on healthcare systems in many societies.[2,3] Geriatric syndromes, including frailty, immobility, and cognitive impairment, also increase with aging and reduce quality of life by limiting daily activities. Aging is a physiological biological process and not pathogenic itself, however, it is closely connected to pathologies in age-related diseases, and our understanding of the respective processes remains limited.

Back in the 1960s, Hayflick et al. demonstrated that fibroblasts have limited potential to replicate.[4] This finding indicated that aging also occurs at the cellular level, a process that is currently described as "cellular senescence." Interestingly, most of the molecules involved in aging phenotypes also regulate cellular senescence, suggesting a causative link between the two. In age-related disorders and chronological aging, senescent cells have central roles for the development and progression of tissue remodeling. Several studies reported that senescent cells accumulate in atherosclerotic arteries[5] and in adipose tissue in diabetes and age-related metabolic dysfunction.[6–8] In mouse experiments, transplantation of senescent cells reduced activity levels and lifespan.[9] Recent studies in a transgenic mice system revealed that elimination of senescent cells—a process called senolysis—can alleviate multiple phenotypes in progeroid mice, naturally aged mice, and mice with age-related diseases, such as atherosclerosis.[8,10–12] Thomas Sydenham, a 17th century physician, wrote that "Man is as old as his arteries," and evidence has accumulated for an involvement in endothelial cell (EC) senescence not only in vascular dysfunction and atherosclerosis but also in diabetes, obesity, and heart failure. In this review article, we introduce pathological aspects of EC senescence and discuss therapies for vascular diseases that target senescent ECs.

In vivo evidence of cellular senescence in age-related diseases

Aging is a major risk factor for many diseases,[13] including cardiovascular disease,[14] dementia,[15] cancer,[16] type 2 diabetes,[17] and idiopathic pulmonary fibrosis.[18] Since the discovery of replicative senescence by Hayflick and Moorhead in the early 1960s (4), studies have indicated a close connection between cellular senescence and aging (4). However, identifying and isolating senescent cells in vivo remains challenging because of the lack of specific markers for senescent cells. Increased senescence-associated β-galactosidase (SA-β-gal) activity and elevated levels of p16Ink4a and p53/p21 are representative markers for cellular senescence, but the lack or presence of these markers does not necessarily indicate that cells are actually senescent in the classical meaning of the term. Similar to primary cultured cells undergoing cellular senescence, vascular cells

in human atherosclerotic coronary arteries were previously shown to have strong staining for SA-β-gal.[19] These cells are predominately localized at the luminal surface of the plaque and have been identified as ECs. Interestingly, in the same patients, SA-β-gal—positive cells were not detected in the internal mammary arteries that were exhibiting minimal atherosclerotic changes.[19]

Senescent cells have been found in various organs of animal models, as well as in elderly humans and individuals with age-related disorders. In addition to adipose tissues in type 2 diabetes and age-related metabolic dysfunction, as mentioned above, cells expressing markers for cellular senescence are also found in the aorta in aged or atherosclerotic animals,[10] and in lung in idiopathic pulmonary fibrosis.[12] These findings suggest the presence of cellular senescence in aging and age-related diseases in vivo. Senescent cells themselves are dysfunctional cells, and by acquiring the senescence-associated secretory phenotype (SASP) phenotype, they induce chronic inflammation and vascular remodeling. For this reason, senescent cells are now well recognized to have causal roles for the progression of vascular disorders.[19]

Molecular mechanism of cellular senescence

Since the initial identification of cellular senescence, significant progress has been made in our understanding of this biological process. Cellular senescence is triggered primarily in response to damage and becomes a defense system for suppressing uncontrolled proliferation and expansion of dysfunctional cells. Cell cycle arrest in the G1 phase develops when DNA is damaged and is thought to give cells sufficient time for DNA repair, thereby avoiding the proliferation of abnormal cells. This process is the first defense mechanism against tumorigenesis. The cell cycle resumes once the damage has been repaired; however, if the damage is extensive the cell will undergo apoptosis as a second defense. In the third defense system, cells that did not undergo apoptosis eventually enter a state of irreversible growth arrest termed cellular senescence. Cellular senescence is indeed a well-designed, ingenious system for tumor suppression. However, senescent cells acquire the SASP phenotype and become antiapoptotic, so they contribute to the development of chronic sterile inflammation and tissue remodeling, making animals or humans prone to cardiovascular-metabolic diseases.

One widely accepted driver of cellular senescence is telomere attrition.[20] Telomeres are non-nucleosomal DNA-protein complexes located at the end of chromosomes. They serve as protective caps and contribute to stabilizing chromatin structure. In somatic cells, the telomeres are shortened as a result of cell replication; once this shortening has reached a critical level, it is recognized as DNA damage, which initiates replicative cellular senescence. Another type of cellular senescence is described as stress-induced premature senescence; it develops in response to various stress stimuli, such as DNA damage induced by irradiation; reagents, including DNA synthesis inhibitors; exposure to high levels of reactive oxygen species (ROS); and oncogenic and metabolic stress. Although various stimuli can induce cellular senescence, it is mediated mainly by either the p53/p21 or p16^{Ink4a}/pRb(rRb; retinoblastoma) pathway, depending on the species or type of cells.

Mechanism of cell cycle arrest in senescent cells

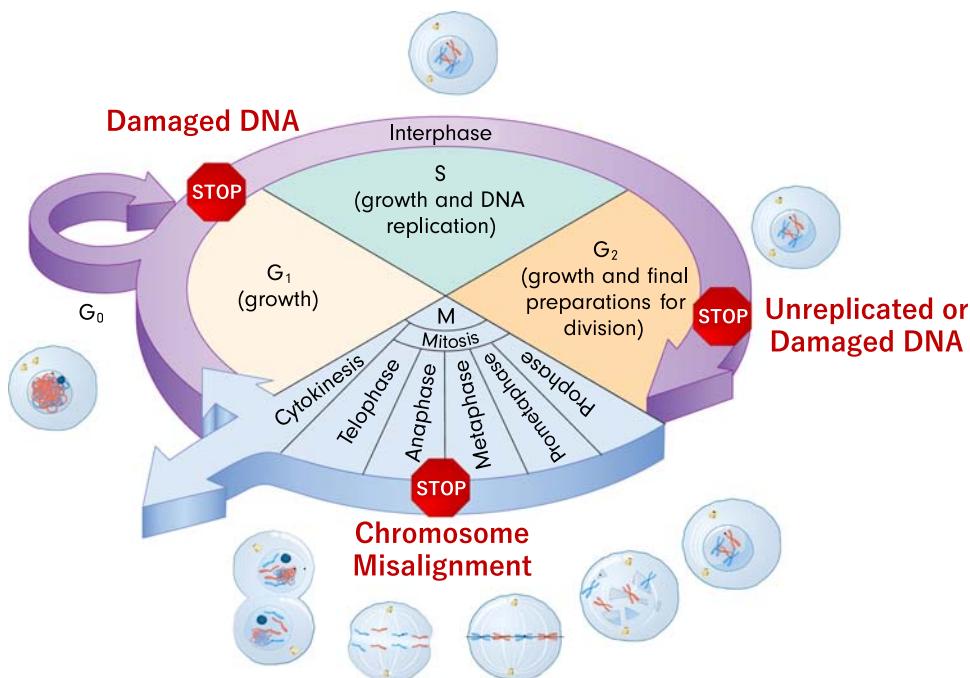
The basic mechanisms for the induction of senescence cell cycle arrest have been well documented.[21] The eukaryotic cell cycle consists of four distinct phases: G1, S (synthesis), G2, and M (mitosis and cytokinesis); phases G1, S, and G2 are collectively known as the interphase (Fig. 23.1). Cell cycle events are monitored at cell cycle checkpoints that occur at the G1/S boundary, in the S phase, and during the G2/M phases. These checkpoints are a series of control systems that enable proliferation only in the presence of stimulatory signals, such as growth factors. The checkpoints are also activated by DNA damage stimuli; this activation stops growth, allowing the cell to repair the damage. In mammalian cells, the p53/p21 or p16^{Ink4a}/Rb pathways are activated by DNA damage and induce cell cycle arrest, which is mediated by cyclin-dependent kinase inhibitors (CDKI), the cyclin-dependent kinase (CDK) interacting protein/kinase inhibitory protein (KIP/CIP) family CDKI (p21^{Cip1}, p27^{Kip1}, and p57^{KipII}), and the inhibitor of CDK4 (INK4) family CDKI (p16^{Ink4a}, p15^{Ink4b}, p18^{Ink4c}, and p19^{Ink4d}).[22] In proliferating cells, CDKI expression is low; however, in response to DNA damage, *p21^{Cip1}* and *p16^{Ink4a}* gene expression significantly increases and the cell cycle is arrested.[23,24] In the case of persistent DNA damage, such as telomere shortening, p21^{Cip1}and p16^{Ink4a} expression are simultaneously upregulated and all CDKs, including CDK2, CDK4, and CDK6, are inactivated. Both p53/p21 and p16^{Ink4a}/Rb play a critical role in tumor suppression and cellular senescence.


FIGURE 23.1 Phases of the eukaryotic cell cycle.

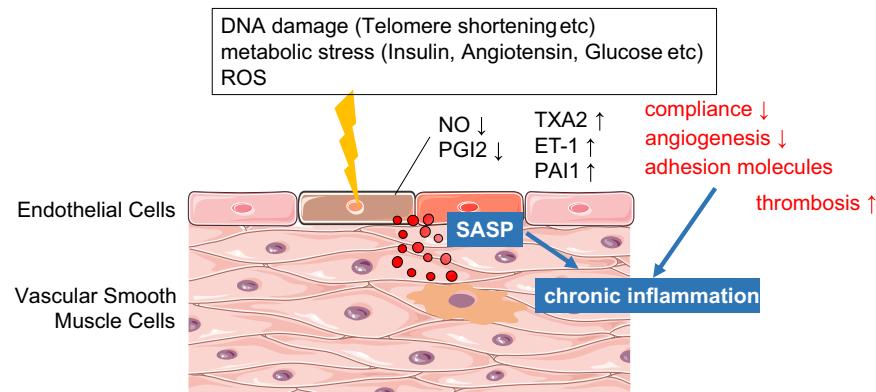
Endothelial cell senescence in age-related disorders


Senescent ECs exhibit various functional abnormalities, such as decreased expression of endothelial nitric oxide (NO) synthase; incremental production of ROS; and increased expression of proinflammatory molecules, including intercellular adhesion molecule-1,[19,25−27] IL-1,[28] IL-6,[29] IL-8,[30] MCP-1.[30] These abnormalities lead to decreased bioavailability of NO and increased formation of peroxynitrite.[31] Furthermore, production of prostacyclin (prostaglandin I2; PGI2) is significantly decreased, whereas production of thromboxane A2 and endothelin-1 is significantly increased.[32−34] Senescent vascular ECs also show an upregulation of plasminogen activator inhibitor-1.[28,35,36] All of these changes are likely to be involved in both the impaired endothelium-dependent vasodilation and the increased trend for thrombogenesis that occur in human atherosclerosis (Fig. 23.2). As described above, a number of studies reported that many of the changes in senescent vascular cells are consistent with those seen in human atherosclerosis and vascular dysfunction, suggesting a critical role of cellular senescence in vascular disorders. Both NO production and endothelial NO synthase (eNOS) activity were reduced in senescent human vascular ECs.[19] Interaction between monocytes and vascular ECs promotes atherogenesis, and this interaction is also enhanced by EC senescence.[37] This process appears to be mediated by upregulation of adhesion molecules and proinflammatory cytokines and decreased production of NO and prostacyclin by senescent ECs.[6,26,29] Senescent ECs have been reported to show diminished capacity for angiogenesis. In addition to the impaired capacity of senescent ECs to form capillaries, bone marrow−derived circulating endothelial progenitor cells (EPCs) show reduced growth and ability to form capillaries in vitro.[38] EPCs are known to participate in postnatal neovascularization and vascular repair.[39−41] Indeed, the function, proliferation capacity, and telomere length of EPCs show a negative correlation with various risk factors for coronary atherosclerosis, including age and circulating vascular ECs, resulting in decreased neovascularization and vascular homeostasis.[42,43]

As described above, EC senescence is induced by a range of factors. A number of studies indicated that telomere shortening occurs also in human vessels and may be related to age-associated vascular diseases. Telomere length in ECs from abdominal aorta and iliac arteries was previously reported to show a strong inverse correlation with age.[44,45] Telomere shortening develops faster in ECs of iliac arteries than in those of internal mammary arteries, suggesting that exposure to higher hemodynamic stress may enhance the rate of EC turnover and induce cellular senescence. Telomere attrition is also more advanced in ECs from coronary arteries in patients with ischemic heart

FIGURE 23.2 Endothelial senescence. Various stimuli that cause DNA damage such as metabolic stress promote endothelial cell senescence. Senescent endothelial cells exhibit functional abnormalities such as decreased production of nitric oxide and increased expression of inflammatory molecules (senescence-associated secretory phenotype [SASP] factors), both of which could accelerate atherogenesis.

disease than in ECs from healthy individuals.[46] Loss of telomere function induces EC dysfunctions in aged arteries, and inhibition of telomere shortening suppresses these senescence-driven alterations in vitro.[19]

The length of telomeres in white blood cells from healthy people showed an inverse correlation with pulse pressure, and this correlation was independent of the person's chronological age.[47] Telomere shortening in white blood cells may increase adhesion or proinflammatory molecules in senescent ECs.[47]

Both premature EC senescence induced by metabolic stress and telomere shortening were also found in lifestyle-related diseases.[25,46,48,49] Insulin/insulin-like growth factor-1/phosphatidylinositol 3-kinase (PI3K)/Akt signaling is preserved in organisms ranging from yeast to mammals. This signaling is well described to regulate the longevity pathway. Genetic studies demonstrated that loss-of-function mutants of this signaling extended the lifespan of *Caenorhabditis elegans*.[50] In contrast, treatment with high-dose insulin resulted in increased Akt phosphorylation and p53/p21 expression, which reduced the lifespan of human ECs, suggesting that insulin/Akt signaling induces EC senescence.[25] Conversely, restriction of calorie intake is known to extend longevity and prevent various age-dependent changes, including atherosclerosis, a decline of immunity, and an increase of inflammatory parameters.[50–52] The plasma level of glucose, insulin, and insulin-like growth factor-1 decreases with calorie restriction, which may contribute to extend the lifespan.[51] Oxidative stress is the chief driving force for human aging and cellular senescence.[53] Oxidized low-density lipoprotein was shown to inactivate telomerase by suppressing the PI3K/Akt pathway in vascular ECs[5] and to induce premature senescence.[29]

Lifestyle-related diseases, including hypertension, diabetes, and dyslipidemia, synergistically enhance the accumulation of senescent cells in systemic organs. The angiotensin II (Ang II) signaling cascade increases with aging and contributes to the pathogenesis of atherosclerosis. Inhibition of Ang II activity has been demonstrated to improve morbidity and mortality in cardiovascular disease.[54] Recently, Ang II was reported to induce premature senescence in human vascular smooth muscle cells via the p53/p21-dependent pathway.[55] Inhibition of this signaling effectively ameliorated the premature senescence and proinflammatory cytokine production caused by Ang II.

Antisenescence therapy

Studies have indicated the critical role of EC senescence in aging and various age-related diseases, and antisenescence therapy is now emerging as a novel strategy for the treatment of such diseases, including atherosclerosis, diabetes, and heart failure. Currently, three approaches are available for antisenescence therapy: (1) inhibition of cellular senescence; (2) suppression of SASP; and (3) elimination of senescent cells (senolysis). These approaches are discussed below.

Inhibition of cellular senescence

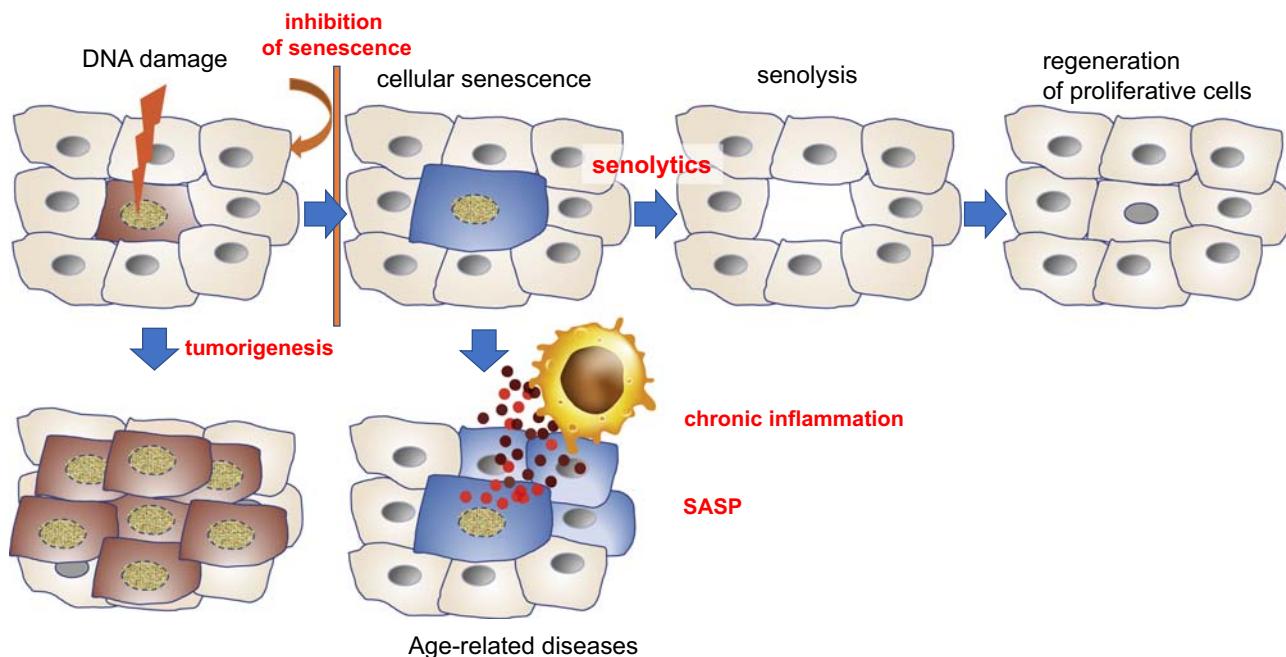
Activation of p53 has been observed in aged vessels and failing hearts and has been implicated in atherosclerosis and heart failure.[56] Furthermore, in mice excessive calorie intake caused p53-induced inflammation in adipose tissue, leading to systemic insulin resistance. Suppression of cellular senescence in adipose tissue in adipocyte-specific p53 knockout mice markedly ameliorated the senescence-like phenotypes and improved insulin resistance and glucose tolerance in obese mice.[6] A murine left ventricular pressure overload model exhibited p53-induced chronic sterile inflammation in visceral fat, which enhanced systemic metabolic dysfunction.[57] Inhibiting p53 in adipose tissue suppressed inflammatory processes in visceral fat and ameliorated systemic insulin resistance and cardiac dysfunction.[57] These data indicate that the p53/p21 pathway has a crucial role in age-related diseases and that

inhibition of cellular senescence targeting these pathways could become a novel therapy for age-related disorders.

Studies in EC-specific p53 KO (EC-p53 KO) mice revealed that endothelial senescence is involved in the pathophysiology of aging and age-related diseases.[58,59] In the diabetic state, endothelial-p53 expression was significantly upregulated and endothelium-dependent vasodilatation was impaired in wild-type mice, whereas eNOS-mediated vasodilatation was markedly improved in EC-p53 KO mice. In addition, inhibition of EC senescence by targeting p53 also significantly enhanced angiogenesis in a hind limb ischemia model. Conversely, activation of endothelial p53 reduced both endothelium-dependent vasodilatation and ischemia-induced angiogenesis. The beneficial effect of EC-p53 inactivation on endothelial function was abolished in eNOS-deficient EC-p53 KO mice. These results indicate that EC-p53 negatively regulates endothelium-dependent vasodilatation and ischemia-induced angiogenesis, suggesting that inhibition of endothelial p53 could be a novel therapeutic target in patients with metabolic disorders.[58]

In another report, EC-p53 KO mice fed a high-calorie diet showed improved insulin sensitivity and less fat accumulation and vascular dysfunction. EC-p53 negatively regulated glucose uptake into skeletal muscle by down-regulating glucose transporter 1 expression. Conversely, p53 activation ameliorated metabolic abnormalities. These results indicate that inhibition of endothelial p53 could be a novel therapeutic target to block the vicious cycle of vascular dysfunction and metabolic abnormalities in obesity.[59]

In addition, p53 signaling has been implicated in mediating the pathogenesis of heart failure. In response to pressure overload, the expression of p53 was upregulated in cardiac ECs and bone marrow cells. This upregulation was followed by an upregulation of both ICAM1 expression in ECs and integrin expression in bone marrow cells. Inhibition of EC-p53 and bone marrow cells markedly down-regulated ICAM1 and integrin expression, which ameliorated cardiac inflammation and systolic dysfunction during left ventricular pressure overload. Norepinephrine markedly increased p53 expression in ECs and macrophages. Reducing β2-adrenergic receptor expression in ECs or bone marrow cells attenuated cardiac inflammation and systolic dysfunction during left ventricular pressure overload. These results suggest that activation of the sympathetic nervous system induces cardiac inflammation by upregulating ICAM1 and integrin expression via p53 signaling, thus promoting cardiac systolic dysfunction. Inhibition of p53-induced inflammation could be a novel therapeutic strategy for heart failure.[60]

These reports indicate that inhibition of EC senescence by targeting p53 could improve age-related diseases such as hypertension, atherosclerosis, diabetes, and heart failure. p53 antagonists are available[61]; however, p53, p21, and p16 systemic knockout mice have a high prevalence of cancer and therefore a shorter lifespan than wild type control mice. As already mentioned, cellular senescence is an antitumorigenic system, so suppression of cellular senescence will not become a first-line therapy.


Inhibition of senescence-associated secretory phenotype

Because SASP has a crucial role in inducing chronic inflammation and progression of age-related disorders, it could become another target for antisenescence therapy. Several reagents, including metformin, rapamycin, and ruxolitinib (a JAK1/2 inhibitor), were reported to attenuate SASP. Metformin ameliorated a series of age-related disorders, including cardiovascular disease, cancer development, cognitive dysfunction, and diabetes.[62] It may even increase five-year survival in elderly humans.[63] Rapamycin and related agents increased lifespan and delayed age-related phenotypes, including frailty, heart failure, cancers, cognitive impairment, and immune dysfunction.[64,65] Ruxolitinib alleviated age-related diseases, such as insulin resistance, and stem cell dysfunction.[8] These reports indicate that SASP inhibitors suppress aging and cellular senescence in humans (62−65). However, potential issues related to the specificity of these inhibitors and off-target effects could lead to serious side effects, so SASP inhibitors must have specific targets.

Elimination of senescent cells (senolysis)

In 2011, a breakthrough occurred in aging research: Baker and colleagues reported that removal of senescent cells can prevent or delay tissue dysfunction and extend the healthy lifespan.[11] As explained above, cellular senescence is a state in which damaged and dysfunctional cells irreversibly stop proliferating. The group hypothesized that eliminating senescent cells, termed senolysis, would be a more promising approach for counteracting aging and treating age-related diseases than suppressing cellular senescence (Fig. 23.3). Furthermore, because senolysis eliminates damaged cells, the risks for cancers would also diminish. To establish proof of concept, the researchers made a genetic mouse model with senolysis (INK-ATTAC), enabling inducible elimination of p16Ink4a-positive senescent cells upon administration of a drug. Elimination of senescent cells alleviated multiple phenotypes in progeroid mice, naturally aged mice, and mice with age-related diseases.[8,10−12] Another group showed by transplanting senescent cells that senescent cells caused the aging phenotype.[9] Transplanting relatively small numbers of senescent cells into young mice was sufficient to cause persistent physical dysfunction. Under this condition, senescent cells spread to host tissues, which then also showed reduced survival. In contrast, the senolytic approach improved the physical function of the mice in this implantation model.[9]

FIGURE 23.3   Scheme of antisenescence therapy. Cells with DNA damage develop tumors. Cellular senescence could protect against tumorigenesis, but accumulation of senescent cells causes chronic inflammation that leads to the onset and progression of age-related diseases. Senolytic treatment eliminates senescent cells and rejuvenate aged tissues.

The finding that senescent cells are more resistant to apoptosis than young cells indicated that senolytics could be useful drugs.[66] To find such drugs, Zhu et al. analyzed senescent cells and revealed that they have increased expression of prosurvival pathways, named senescent cell antiapoptotic pathways (SCAPs). Studies with small interfering RNAs showed that ephrins (EFNB1 or 3), the phosphatidylinositol- 4,5-bisphosphate 3-kinase delta catalytic subunit (PI3KCD), the cyclin-dependent kinase inhibitor 1A (p21), BCL-xL, and plasminogen-activated inhibitor-2 could become candidates for SCAP suppression by mediating cell death in senescent cells.[67] The tyrosine kinase inhibitor dasatinib is also known to inhibit EFNB-dependent suppression of apoptosis, and this inhibition eliminated senescent human fat cell progenitors.[68,69] Another compound, quercetin (a natural flavonoid that is known to interfere with PI3K), induced cell death in senescent ECs.[67] A combination of dasatinib and quercetin successfully reduced senescent cell burden in chronologically aged mice.[67] Another group reported that navitoclax, which targets components of the antiapoptotic molecule Bcl-2, also exhibited senolytic ability and alleviated age-related disorders.[70] So far, several reagents have been confirmed as senolytics, as follows: the specific BCL-XL inhibitors A1331852 and A1155463,[71] fisetin,[72] piperlongumine,[73] and FOXO4-related peptide.[74] Several reagents are also effective at causing cell death in senescent ECs (Table 23.1).

TABLE 23.1 List of senolytics.

Senolytics	Target molecules
Dasatinib	Src kinase, tyrosine kinase, etc
Quercetin	Bcl-2 family, p53/p21/serpine, PI3K/AKT
Navitoclax (ABT-263)	Bcl-2 family (Bcl-2, Bcl-xl, Bcl-w)
TW-37	Bcl-2 family (Bcl-2, Bcl-xl, Mcl-1)
ABT-737	Bcl-xl, Bcl-w
Fisetin	PI3K/AKT
A1331852	Bcl-2 family (Bcl-xl)
A1155463	Bcl-2 family (Bcl-xl)
FOXO4-DRI	FOXO-p53 interaction
Alvespimycin (17-DMAG)	HSP90
Tanespimycin (17-AAG)	HSP90
Geldanamycin	HSP90
Piperlongumine	p53/p21, Bcl-2 family (PUMA)
Panobinostat	Histon deacetylase
UBX0101	p53-MDM2/p21
Ruxolitinib (INCB18424)	Selective JAK1/2 inhibitor
CD153 vaccine	CD153

Transgenic and pharmacological approaches to eliminate senescent cells improved atherosclerosis in low-density lipoprotein receptor-deficient (LDL-R) knockout mice. Navitoclax administration alleviated atherogenesis and stabilized plaques in LDL-R knockout mice,[75] and dasatinib and quercetin led to clearance of senescent cells from multiple tissues in apolipoprotein E knockout mice, another model of atherosclerosis.[10] Dasatinib and quercetin also enhanced aortic vascular reactivity, i.e., they caused a modest improvement in endothelium-dependent relaxation elicited by acetylcholine and substantially improved vascular smooth muscle cell relaxation in response to nitroprusside in old mice.[10] Senolytics could become a promising next-generation therapy for atherosclerotic disorders. It is well known that the process of arterial aging involves elastase-mediated proteolysis, inflammation and fibrosis, and senolytic treatment also could delay this process.

Conclusion

This chapter summarizes the undesirable aspects of EC senescence in aging and age-related diseases. In many societies, age-related diseases, including heart failure, diabetes, and atherosclerotic disorders, have become major healthcare problems that reduce the healthy lifespan. Accumulating evidence indicates that EC senescence has central roles in the pathogenesis of these age-related disorders. Senescent ECs have limited capacity to produce vasculoprotective factors, including NO and PGI2; in contrast, they produce vasoconstrictors and prooxidants and promote prothrombotic properties, leading to chronic inflammation and vascular remodeling. Three strategies are suggested to target senescent cells: inhibition of cellular senescence, suppression of SASP, and senolysis. Senolysis is a promising strategy that aims to clear the burden stemming from senescent cells, and several clinical studies on senolytics are underway. In 2019, two pilot studies were reported that showed that dasatinib and quercetin treatment improved physical function in patients with idiopathic pulmonary fibrosis[76] and eliminated senescent cells from adipose tissue and skin in patients with diabetic kidney disease.[77] Whether this approach will be useful in cardiovascular diseases in humans remains to be explored.

Chapter 24

Autonomic and neuroendocrine modulation of arterial stiffness and hemodynamics

Philip J. Millar[1,2], Massimo Nardone[1] and John S. Floras[2,3]

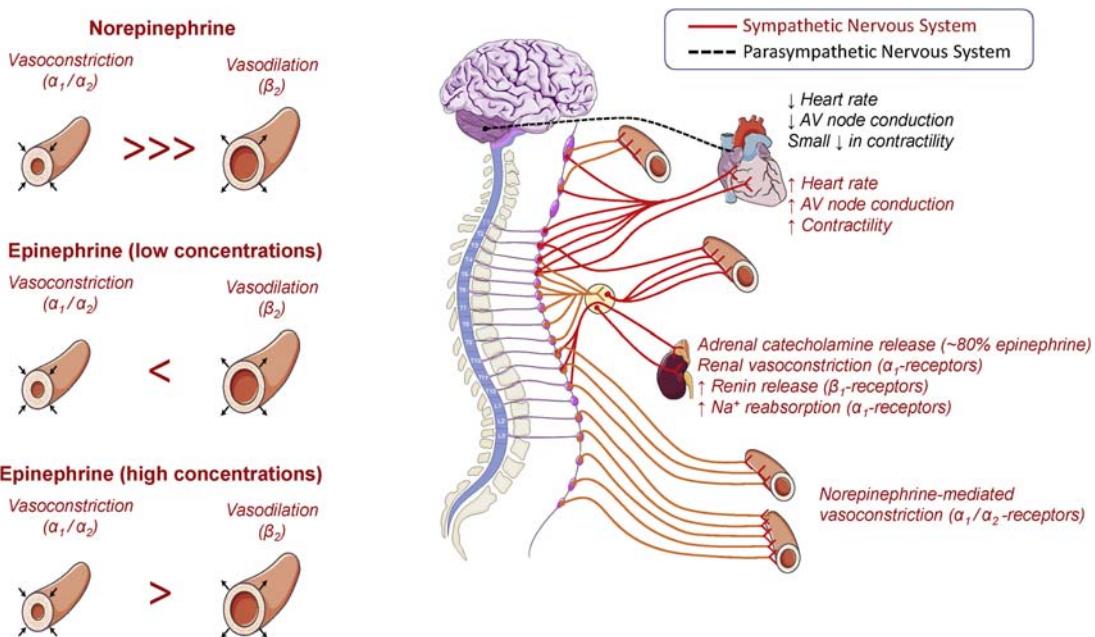
Compliant blood vessels are a fundamental characteristic of the cardiovascular system, enabling pulsatile synchronization between blood ejected from the heart and the arterial tree. Large elastic vessels, such as the aorta, are responsible for dampening the pulsatile pressure caused by left ventricular ejection (i.e., Windkessel effect) and enable anterograde blood flow throughout the cardiac cycle.[1] Large-artery stiffness is gaining clinical recognition as an important measure for patient risk stratification.[2] Such stiffness can impair ventricular-arterial coupling, increasing pulse pressure, ventricular afterload, and downstream microvascular perfusion pressure, which can facilitate end-organ damage,[3,4] and associate independently with major adverse cardiovascular events and mortality in a range of patient cohorts.[5]

The autonomic nervous system maintains tonic and reflex control of arterial pressure through parasympathetic and sympathetic regulation of neural outflow to the heart and circulation. In developed societies, elevations in efferent sympathetic nerve activity and large-artery stiffness occur with healthy aging and are amplified in many cardiovascular disease states (e.g., hypertension and heart failure).[6–10] Whether these observations represent a causal relationship or epiphenomenon has remained controversial. A major reason for this uncertainty remains the inherent difficulty of altering neural outflow independent of changes in arterial pressure and thus the mechanical stress-strain relationship of the vasculature. This chapter will discuss the controversies stimulated by human cross-sectional data and recent evidence supporting the concept that acute increases in muscle sympathetic outflow can augment central and peripheral arterial stiffness. The moderating effects of neuroendocrine factors on arterial stiffness, including the


influence of sex hormones on the relationship between sympathetic outflow and pulse wave characteristics, will also be reviewed. Preference has been given to human work unless such data are unavailable.

Autonomic control of the cardiovascular system

Neural control of the cardiovascular system is mediated primarily by parasympathetic innervation of the heart and sympathetic innervation of the heart, kidneys, vasculature, and adrenal medulla (Fig. 24.1).

Parasympathetic nervous system

Parasympathetic (vagal) projections to the heart innervate the sinoatrial and atrioventricular node.[11] Efferent vagal discharge stimulates postsynaptic release of acetylcholine, which binds to muscarinic (M_2) receptors and ultimately decreases sinoatrial membrane potential by altering ionic flux via inhibitory G-protein−coupled mechanisms.[12,13] The resultant hyperpolarization decreases sinoatrial node firing rates (i.e., heart rate) and atrioventricular node action potential conduction velocity.[14,15] Tonic sinoatrial parasympathetic activity produces a lower resting heart rate compared to the intrinsic heart rate; blocking vagal activity increases heart rate.[16] A key feature of parasympathetic modulation is its rapidity of onset and offset; heart rate slows within milliseconds of vagal stimulation and rises a few seconds after the onset of external stress or exercise due to brisk parasympathetic withdrawal and acetylcholinesterase kinetics.[17] Parasympathetic neurons also

FIGURE 24.1 Neurohumoral regulation of the cardiovascular system. Left side: Humoral regulation of resistance vessels. Norepinephrine possesses a higher affinity for α adrenergic receptors causing vasoconstriction. The effects of epinephrine on vascular smooth muscle cell adrenergic receptors are concentration dependent. At low concentrations, epinephrine possesses a higher affinity for β2 adrenergic receptors promoting vasodilation, while a high concentrations epinephrine stimulates α adrenergic receptors causing vasoconstriction. Right side: Neural cardiovascular regulation. Schematic of the sympathetic and parasympathetic divisions of the autonomic nervous system involved in the control of the heart and circulation. Parasympathetic outflow is directed principally at the heart, whereas the sympathetic nervous system innervated the heart, kidney, adrenal medulla, and vascular smooth muscle.

innervate cardiac myocytes[11] and when stimulated can cause small reductions in cardiac contractility.[18,19]

Sympathetic nervous system

In the heart, postganglionic sympathetic neurons densely innervate the sinoatrial and atrioventricular node, and ventricular cardiac myocytes.[20,21] Efferent sympathetic outflow stimulates the translocation and release of norepinephrine which binds to β-adrenergic receptors causing an excitatory G-protein−coupled increase in intracellular cyclic adenosine monophosphate (cAMP). This increases sinoatrial node membrane potential and ultimately firing rate (i.e., heart rate) and atrioventricular node action potential conduction velocity.[13,14] Increased intracellular cAMP also increases intracellular $[Ca^{2+}]$ within cardiac myocytes to enhance contractility.[13,22]

The sympathetic nervous system also innervates vascular smooth muscle, where released norepinephrine can bind to α_1, α_2, and β_2 adrenergic receptors. Stimulation of α_1 and α_2 adrenergic receptors initiates a signaling cascade that increases intracellular $[Ca^{2+}]$, which binds to calmodulin (to create a Ca^{2+}-calmodulin complex) to activate myosin light chain kinase.[23,24] This in turn increases myosin ATPase activity, initiating myosin power strokes on actin to elicit vasoconstriction.[23,24] Stimulation of β_2 adrenergic receptors activate cAMP, inhibiting myosin light chain kinase causing vascular smooth muscle vasodilation.[25,26] Norepinephrine has a higher affinity for α

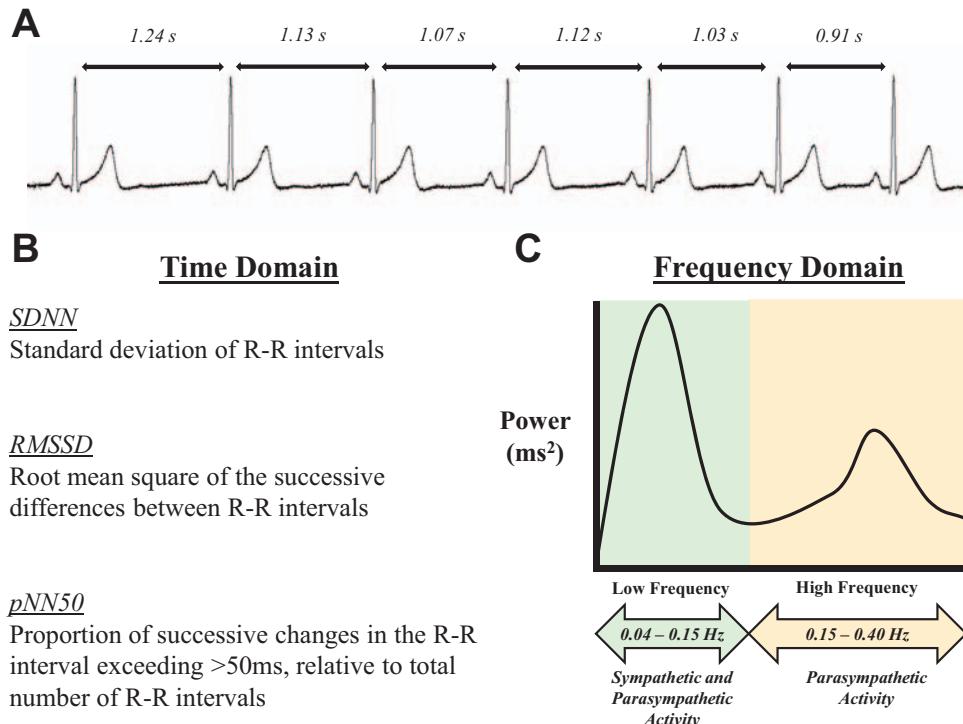
compared to β adrenergic receptors, and therefore the net vasomotor response to sympathetic outflow is vasoconstriction.[27] Sympathetic nerve terminals also contain presynaptic α_2 adrenergic receptors which inhibit norepinephrine by negative feedback.[27] Sympathetic innervation of the kidneys not only initiates α adrenergic-mediated renal vasoconstriction[28] but also β_1 adrenergic-mediated release of renin from juxtaglomerular cells[29−31] and α adrenergic-mediated sodium reabsorption at the renal tubule.[31−33] There is evidence, as well, for co-release of both neuropeptide Y and ATP with norepinephrine under conditions of intense sympathetic stimulation.[34−38] The importance of sympathetic outflow for maintaining tonic vasoconstriction can be appreciated by the substantial reductions in peripheral vascular resistance and arterial pressure following ganglionic blockade.[16] Lastly, sympathetic innervation of the adrenal medulla is responsible for the release of circulating catecholamines, primarily epinephrine.[39] As the principal endogenous ß2 agonist, epinephrine induces vasodilation, but when administered exogenously to achieve higher plasma concentrations it elicits predominantly α_2−mediated vasoconstriction.[27]

Overall, the control of tonic and reflex parasympathetic and sympathetic outflow directed to these end-organs are influenced by a combination of central rhythm generators within the brainstem, and input from higher order cortical regions and a variety of peripheral afferents (e.g., baroreceptors, arterial and muscle chemoreceptors, and muscle mechanoreceptors) to govern cardiovascular homeostasis.[8,40]

Assessing autonomic modulation of large-artery stiffness: methodological considerations

The curvilinear nature of the stress–strain relationship implies that arterial stiffness progressively increases at higher levels of vascular deformation.[41] For example, increased circumferential stress caused by higher arterial pressure alters vascular loading patterns and increases arterial stiffness.[42] In humans, direct measurements of intra-arterial pressure and carotid-femoral pulse wave velocity (PWV), the in vivo noninvasive gold standard assessment of arterial stiffness,[43] have demonstrated independent associations between static or distending (i.e., mean arterial pressure) and pulsatile (i.e., pulse pressure) components of arterial pressure and large-artery stiffness.[44–47] It is also relevant to note that pacing-induced elevations in heart rate can increase large-artery stiffness in rats,[48–50] independent of the sympathetic nervous system.[49] This may be caused by alterations in the frequency dependence of the viscoelastic components of the arterial wall and diminished time to recoil.[48,51] The influence of heart rate on aortic PWV is arterial pressure–dependent in rats, with the largest effects at higher levels of mean arterial pressure.[50] Similar findings in humans have found that atrial pacing can increase carotid-femoral PWV,[52,53] and decrease radial and carotid artery distensibility[54,55] and the augmentation index (AI$_x$),[56] while ivabradine-mediated reductions in heart rate can decrease carotid-femoral PWV.[57] It should be noted that carotid-femoral PWV possesses stronger associations with left ventricular contractility and ejection time than heart rate.[58] Nonetheless, given that the autonomic nervous system is important to the beat-to-beat regulation of arterial pressure, through the modulation of cardiac chronotropy and inotropy, and vascular smooth muscle tone, this presents an inherent challenge in determining whether the effects of neural modulation on large-artery stiffness are the result of hemodynamic changes or represent a pressure-independent effect on mechanical elements of the vessel wall.

Parasympathetic modulation of large-artery stiffness

There is currently no direct method for measuring parasympathetic activity in humans. Instead, tonic parasympathetic modulation is commonly estimated using heart rate variability (*See Basic Concept Box—What is heart rate variability?*). This method involves the computation of time- and frequency-domain indices based on the variability in electrocardiogram-derived R-R intervals.[59] Indirect assessments of reflex parasympathetic modulation involve examining the changes in R-R interval for a given change in systolic arterial pressure, also known as cardiac baroreflex sensitivity.[60,61] Both methods represent sinoatrial parasympathetic modulation[62] and have shown the capacity to predict poor outcomes after myocardial infarction.[63–65]


Several cross-sectional studies have evaluated the association between heart rate variability measures associated with sinoatrial parasympathetic modulation and large-artery stiffness in healthy participants[66–68] and patients with cardiometabolic diseases.[69–72] In healthy participants, greater high frequency power (i.e., higher sinoatrial parasympathetic modulation) is correlated with a lower brachial-ankle PWV[66] and carotid-femoral PWV.[67,68] However, in subsequent multiple linear regression analyses, controlling for arterial pressure failed to identify high frequency power as an independent predictor of PWV.[66–68] In this case, heart rate variability may act as a cardiovascular marker and not a causal determinant of arterial stiffness. For example, Mäki-Petäjä and colleagues[68] observed that participants in the highest tertile of high frequency power also had the lowest resting mean arterial pressure. Additional studies in clinical populations have found associations between heart rate variability and carotid artery wall stiffness[69] or carotid-femoral PWV[72] but have mostly failed to adjust for arterial pressure. An independent association between carotid-femoral PWV and high frequency power was observed in patients with orthostatic intolerance but explained only 1.5% of the variability in high frequency power.[71]

Overall, it remains difficult to reconcile how differences in sinoatrial parasympathetic modulation are causally related to large-artery stiffness independent of changes in heart rate, stroke volume, or arterial pressure. A more biologically plausible hypothesis is that chronic changes in large-artery stiffness modify mechanosensitive baroreceptive inputs leadings to alterations in tonic parasympathetic modulation. Such a hypothesis is supported by several cross-sectional studies showing strong pressure-independent relationships between carotid-femoral PWV and cardiac baroreflex sensitivity,[73–75] as well as, prospective work demonstrating correlations between reductions in carotid-femoral PWV or increases in carotid artery compliance and increased cardiac baroreflex sensitivity following endurance exercise training.[75,76]

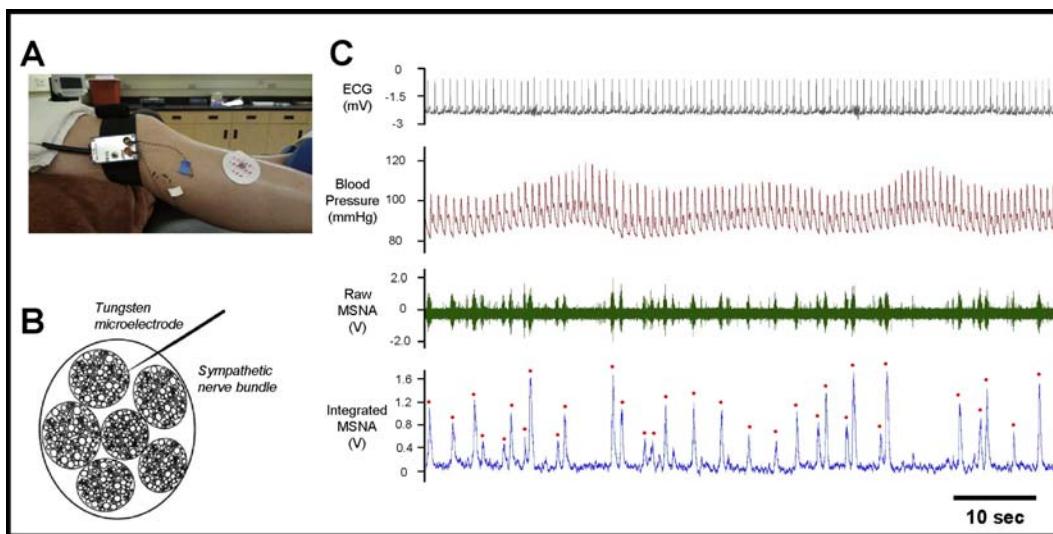
Basic concept box—What is heart rate variability?

Heart rate variability represents a noninvasive method of indirectly assessing cardiac sympathetic and parasympathetic modulation through the analysis of the spontaneous fluctuations in R-R interval from the electrocardiogram (typically 5–10 min [short-term] or 24 h [long-term] in recording length).[59] The most common methods of assessing heart rate variability involve quantification of time and frequency domain variables (Fig. 24.2), though nonlinear metrics have also been employed.[77] In the time domain, common assessments include the measurement of the standard deviation of normal R-R intervals, a measure of overall variability influenced by both parasympathetic and sympathetic factors, and the root mean square of the successive differences between adjacent normal R-R intervals, the primary time-domain index of sinoatrial parasympathetic modulation.[77] In the frequency domain, a fast Fourier transformation is applied to continuous recordings of spontaneous R-R intervals to calculate the spectral power within the very low frequency (0.0033–0.04 Hz), low-frequency (0.04–0.15 Hz), and high-frequency (0.15–0.4 Hz) bands. In general, the high frequency power spectrum is considered to reflect sinoatrial parasympathetic modulation,[78,79] with data showing a positive correlation with integrated vagal nerve activity in dogs.[80] The low frequency power band is thought to reflect modulation by both the parasympathetic and sympathetic nervous systems[81–83] and more recently has been suggested to reflect baroreflex control of neural outputs.[77,84] The ratio of low frequency to high frequency power has been frequently considered to represent an index of sympathovagal balance,[59] although the assumptions underlying this assertion have been proven false.[85] The heart rate variability spectrum incorporates also broad-band nonharmonic noise that exhibits fractal characteristics, with greatest spectral power within the very low frequency range.[86,87] In addition, the very low frequency band can be modulated by the renin-angiotensin system, physical activity, thermoregulation, and endothelial factors[77] and in healthy individuals attenuated markedly by parasympathetic blockade with atropine sulfate.[88] Despite its widespread adoption, heart rate variability has several limitations that preclude its clinical application as a measure of sinoatrial autonomic modulation. These include its being affected by the mechanical effects of atrial stretch, respiration, and the prevailing heart rate,[85,89,90] which are often not controlled for when data are acquired, and the lack of a precise understanding of the relative proportion of autonomic and nonautonomic contributions to frequency- or time-domain indices of interest in health or specific disease states.

FIGURE 24.2 Representative electrocardiographic (ECG) tracing showing beat-to-beat variability in heart period (Panel A). Heart rate variability is commonly calculated across two different quantitative domains: the time domain (Panel B) and the frequency domain (Panel C). The principal representations of physiological or clinical interest are high frequency (HF; 0.15–0.40 Hz) and low frequency (LF; 0.04–0.15 Hz) spectral power, less so very low frequency power (<0.04 Hz). *Credit: Authors' original work.*

Sympathetic modulation of large-artery stiffness

Several lines of evidence link sympathetic tone to arterial stiffness. *In vitro* experiments show that cytoskeletal proteins involved in contraction within vascular smooth muscle cells stiffen in models of aging and hypertension.[91,92] Canine and rabbit models have shown that α-adrenergic vascular smooth muscle cell activation can produce acute increases in descending thoracic aorta, abdominal aorta, and carotid artery stiffness,[51,93–97] while in humans, altering the contractile state of vascular smooth muscle cells using norepinephrine and nitroglycerin can increase and decrease brachial artery stiffness, respectively.[98–101] The effects of α-adrenergic vascular smooth muscle contraction on artery stiffness are lower in the elastic thoracic aorta compared to more distal segments (or conduit vessels),[93] which would be considered more muscular[102] and densely innervated.[103–106] This distinction between elastic and muscular vessels is important as carotid-femoral PWV predicts morbidity and mortality,[5] whereas the stiffness of the brachial artery does not.[107,108]

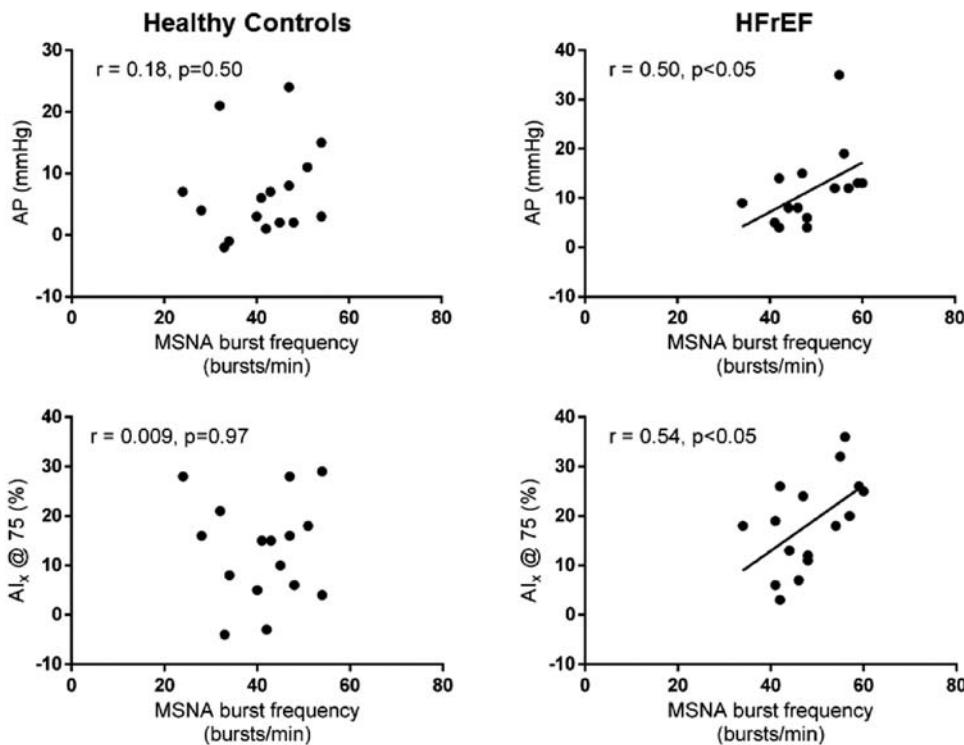
Chronic sympathetic outflow can also alter muscular and elastic artery stiffness through vascular smooth muscle cell remodeling. In rats, sympathetic activity can increase contractile protein expression within vascular smooth muscle cells,[109] while α adrenergic stimulation can upregulate pathways associated with vascular smooth muscle cell hypertrophy.[110–112] In a porcine model, thoracic sympathectomy decreased smooth muscle density in the ascending aorta, arch, descending thoracic aorta, with smaller changes in the abdominal aorta, in parallel with increases in collagen and elastin. The result was an increase in stiffness in the ascending aorta, arch, and descending thoracic aorta at low and physiological stress levels.[113] In healthy humans, sympathetic activity is associated positively (with the exception of premenopausal women) with increased femoral[114] and carotid[115] intima-media thickness. These data do not provide insight into whether the changes are mediated by atherosclerotic changes in the intima layer or physiological remodeling of the media layer. However, relative wall thickness is inversely proportional to the compliance of the vessel,[41] and thus stiffer arteries generally have increased intima-media thickness and decreased compliance.[43] Similar to measures of arterial stiffness, carotid artery intima-media thickness is positively associated with systolic arterial pressure.[116] Finally, endothelial cells are involved in regulating vascular smooth muscle tone and extracellular matrix composition through the release of nitric oxide.[117–119] Increases in sympathetic outflow to blood vessels can reduce endothelium-dependent vasodilation.[120–122] Collectively, these studies provide evidence supporting the hypothesis that acute and chronic changes in sympathetic activity can produce vascular smooth muscle cell-mediated alterations in arterial stiffness.


Based on this knowledge, the majority of work has examined associations between arterial stiffness and sympathetic outflow directed toward skeletal muscle resistance vessels (termed muscle sympathetic nerve activity [MSNA]) (*See Basic Concept Box—What is muscle sympathetic nerve activity?*). The strengths of this method are that nerve firing is highly reproducible within an individual over time[123,124] and that it permits instantaneous detection and beat-by-beat quantitation of changes in nerve firing in response to acute interventions designed to perturb sympathetic activity. Although MSNA does not measure the quanta of norepinephrine released from the nerve terminal, correlations with plasma norepinephrine have been reported at rest[125,126] and during exercise.[126] Other studies report indirect measures of sympathetic activity, including plasma norepinephrine, heart rate variability, and spectral analysis of systolic blood pressure.[68,127–130]

Basic concept box—What is muscle sympathetic nerve activity?

Using a technique called microneurography,[131,132] a high impedance, finely tipped tungsten microelectrode is inserted percutaneously into a superficial peripheral nerve (typically the ulnar, radial, or fibular nerves), while a low impedance ground microelectrode is placed 1–2 cm away (Fig. 24.3A and 24.3B). The raw MSNA neurogram is amplified (x75-100,000), bandpass filtered (e.g., 0.7–2.0 kHz), rectified, and integrated using a 0.1-s time constant to produce "bursts" of multiunit MSNA (Fig. 24.3C). Careful examination of the action potential discharge in response to a startling response, light skin stroking, and an end-expiratory apnea are necessary to confirm the recording from postganglionic muscle sympathetic nerve fibers as opposed to skin sympathetic fibers.[131,132] The most distinctive feature of multiunit MSNA is its phase-locked nature to the cardiac cycle, highlighting the strong regulatory influence of the arterial baroreflex (each sympathetic burst occurs ∼1.1–1.3 s after the preceding R-wave of the electrocardiogram), and which ultimately limits the number of potential sympathetic bursts to the prevailing heart rate.[133] The multiunit signal is analyzed using a minimum 3:1 signal-to-noise ratio threshold for burst discrimination. Bursts thus identified are then used to calculate MSNA burst frequency (number of bursts per minute), burst incidence (number of bursts per 100 heartbeats), burst amplitude or area (most commonly normalized to an individual's largest burst in order to reduce the bias of electrode distance to the discharging fibers, and presented as a percent), and total MSNA (the product of burst frequency and normalized burst amplitude or area).[131,132,134,135] The majority of cross-sectional work relies solely on measures of MSNA burst frequency and incidence as these are considered less biased by potential interindividual differences in microelectrode placement.[132] Within the present context, MSNA burst frequency is the principal variable of interest, in so far as neurovascular transduction is proportionate to the quanta of norepinephrine released per unit of time.

FIGURE 24.3   Panel A: Representative image of a microneurography set-up involving a tungsten microelectrode inserted into the fibular nerve (white flag) and a corresponding ground microelectrode (blue flag). Panel B: Schematic illustration of a tungsten microelectrode inserted into a peripheral nerve and manipulated until positioned near clusters of postganglionic muscle sympathetic neurons. Panel C: Representative tracing of heart rate, arterial pressure, and the raw and integrated muscle sympathetic nerve activity (MSNA) signals. Multiunit bursts are identified by red dots within the integrated signal. Noteworthy, it can be observed that MSNA is decreased during periods with elevations in arterial pressure and reflexively increased during falls in arterial pressure supporting strong arterial baroreflex regulation. *Credit: (Panel B) Image used with permission from Macefield VG.* **Handb Clin Neurol.** *2013;117:353−364. doi: 10.1016/B978-0-444-53491-0.00028-6.*

Relationships between sympathetic activity and arterial stiffness: cross-sectional studies


A growing number of cross-sectional studies in healthy cohorts have identified bivariate associations between resting MSNA and measures of arterial stiffness, including carotid-femoral PWV,[129,136,137] carotid-brachial PWV,[129] AI$_x$,[138] AI$_x$ at a controlled heart rate of 75 bpm (AI$_{x@75}$),[139,140] or carotid artery compliance.[129,141] Similar bivariate relationships have been found between MSNA and radial artery compliance[130] and augmentation pressure or AI$_{x@75}$ in patients with heart failure with reduced ejection fraction (Fig. 24.4),[142] while in renal transplant patients, MSNA correlated negatively with brachial but not carotid artery distensibility.[143] In contrast, MSNA was unrelated to central or peripheral PWV in a cohort of premenopausal women with a history of healthy or preeclamptic pregnancy.[144] It is plausible that the relationship between MSNA and arterial stiffness can be modulated by the presence of sex hormones (discussed in greater detail later in this chapter), as premenopausal women demonstrate a negative association between MSNA and AI$_x$[139] compared to positive associations found in postmenopausal women[138] and men.[139] However, arterial stiffness is only one determinant of AI$_x$,[10,43,145] and in the largest study to date, the positive association between MSNA and carotid-femoral PWV was similar in both men and women.[129]

One consideration of current cross-sectional work has been the exclusivity of examining MSNA-arterial stiffness associations using measures of MSNA burst occurrence

without deliberation of the contributions of burst strength. This is relevant as both occurrence and strength can influence the quanta of norepinephrine release, and shown to be regulated differently in older men and women.[146] Several cross-sectional studies employed multivariate analyses to control for confounding factors, including arterial pressure, and demonstrate MSNA to be an independent predictor of carotid-femoral and carotid-brachial PWV,[129,136] brachial artery distensibility,[143] and carotid artery compliance.[129] For example, the relationship between MSNA burst frequency and carotid-femoral PWV was maintained following adjustment for mean arterial pressure, heart rate, sex, and the waist-to-hip ratio but lost once age was included in the model (Fig. 24.5). The moderating effects of age in the model are expected as MSNA and arterial stiffness both increase over the lifespan.[147−149] A similar finding has been reported for 24 h urine norepinephrine content and carotid-femoral PWV.[150]

It is necessary to highlight the reciprocal nature of neural−vascular interactions, with increased carotid and aortic stiffness being associated with reduced sensitivity of arterial baroreflex control of MSNA.[151] Thus, stiffer central vessels permit less transduction of the mechanical stimulus needed to evoke reflex changes in sympathetic outflow in response to arterial pressure fluctuations—similar to reports involving cardiac baroreflex sensitivity.[73−75]

In contrast to the consistent relationships with MSNA, the majority of studies have failed to detect a significant correlation between plasma norepinephrine and arterial

FIGURE 24.4 The relationship between muscle sympathetic nerve activity (MSNA) burst frequency and the augmentation pressure (AP; top panels) and the augmentation index at a heart rate of 75 bpm (AI$_x$@75; bottom panels) in healthy controls (left panels) and patients with heart failure with reduced ejection fraction (HFrEF; right panels). *Credit: Millar PJ, et al. **J Card Fail**. 2019;25(5):404−408. doi: 10.1016/j.cardfail.2019.03.005.*

stiffness,[130,143] while those that have, display weaker associations than observed with MSNA.[129] These findings are unsurprising based on the knowledge that plasma norepinephrine measurements exhibit lower reproducibility than MSNA,[123,152] can be influenced by norepinephrine reuptake and clearance independent of release,[153] and are not specific to sympathetic outflow directed toward the skeletal muscle vasculature.[154] Urinary norepinephrine (but not epinephrine) has been correlated with carotid-femoral PWV,[150,155] but this relationship is unlikely to have causal relevance, since, relative to its plasma concentration, a greater proportion of this catecholamine is of renal origin.

Can acute modulation of sympathetic activity alter large-artery stiffness?

Studies aimed at addressing this question have utilized a variety of well-known provocations to modify sympathetic activity, including both sympathoexcitatory (lower body negative pressure, cold stress, mental stress, isometric handgrip exercise, lower leg venous occlusion, and adrenergic agonists) and sympathoinhibitory (ganglionic blockade, anesthesia, and guided-breathing) maneuvers. As mentioned earlier, it must be acknowledged that the majority of these stressors produce changes in heart rate,

stroke volume, and arterial pressure which themselves could be responsible for changes in large-artery stiffness. Table 24.1 provides an overview of the effects of common laboratory stressors on MSNA and hemodynamic responses.

One sympathoexcitatory maneuver with the capacity to overcome this limitation is lower body negative pressure. This stimulus commonly involves sealing the lower body up to the iliac crest in a custom-made chamber. Supine exposure to a select negative pressure level (e.g., −10 to −60 mmHg) causes the translocation of blood from the upper body compartment.[156] The result is a graded reduction in central venous pressure, which can unload mechanically sensitive baroreceptors located in the cardiopulmonary and arterial circuits causing net reflex activation of MSNA[156,157] to maintain mean arterial pressure. Low levels of lower body negative pressure (e.g., −5 mmHg), simulating upright or standing posture, can increase MSNA without decreasing arterial pressure, while a greater lower body negative pressure stimulus (e.g., ≤ −15 mmHg) can increase MSNA and may also decrease mean arterial pressure concurrently.[156,158,159] The subsequent sections will discuss the diverse experimental models that have been utilized to evaluate the neural contributions to muscular and elastic large-artery stiffness.

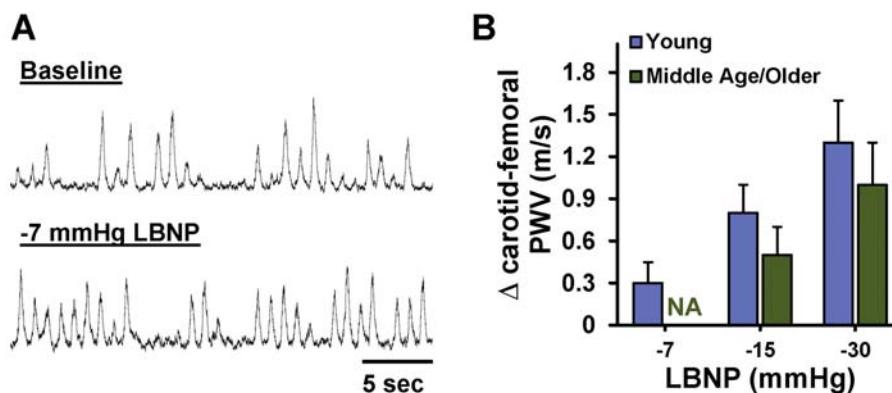
Evidence from muscular arteries

Initial human work demonstrated that radial artery compliance was reduced during sympathetic activation using mental stress and the cold pressor test.[160] Similarly, both cigarette smoking and low-dose intravenous infusion of the α_1 adrenergic agonist phenylephrine were observed to decrease radial artery compliance independent of changes in arterial pressure.[130] These results are consistent with observations showing that −15 mmHg lower body negative pressure or a cold pressor test can both decrease brachial artery distensibility.[161,162] More recently, −30 mmHg lower body negative pressure was also found to increase carotid-brachial PWV.[129] Complimentary work has examined the effects of acute sympathoinhibition following brachial plexus or subarachnoid anesthesia and found increased radial and femoral artery compliance, respectively.[130,163] In disagreement, cold pressor stress was also shown to increase radial artery compliance.[164]

Importantly, relative to elastic vessels, these arteries contain a higher proportion of vascular smooth muscle,[46,165] exhibit denser adrenergic innervation,[166,167] and are less subject to stiffening with age.[148,168] When specifically studied with lower body negative pressure, this sympathoexcitatory stimulus did not alter the distensibility of the elastomuscular proximal brachial artery.[169]


Evidence from elastic arteries

In contrast to brachial artery stiffness, which lacks prognostic significance,[107,108,170] carotid-femoral PWV is a strong independent predictor of major adverse cardiovascular events and mortality.[5] The first studies examining acute sympathetic modulation of elastic artery stiffness reported that sympathoexcitation evoked by lower body negative pressure did not alter compliance or distensibility of the abdominal aorta[171] or common carotid artery or carotid arterial bulb[172] (i.e., local stiffness). More recent work demonstrated that isometric handgrip exercise and lower body negative pressure, two sympathoexcitatory stressors, produced divergent effects on AI_x, timing of the reflected wave, and pulse pressure amplification, caused by underlying differences in heart rate and arterial pressure responses rather than a direct effect of sympathetic activation on vascular smooth muscle per se.[173]

In contrast, work relying on measures of carotid-femoral PWV, a more global assessment of elastic large-artery stiffness, has produced more consistent support for a relationship with sympathetic vasoconstrictor drive. A high (~ -68 mmHg) but not moderate (~ -34 mmHg) lower body negative pressure stress was found to increase carotid-femoral PWV in young healthy men.[128] A strong bivariate correlation was demonstrated between changes in PWV and systolic blood pressure variability, an indirect estimate of sympathetic vasomotor modulation;[82] however, it should be noted that substantial reductions in pulse pressure and increases in heart rate and total peripheral resistance were also noted during the severe hypovolemia.[128] Subsequent studies using larger sample sizes and more modest levels of lower body negative pressure confirmed increases in MSNA and noted parallel rises in carotid-femoral PWV without alteration of arterial pressure, pulse pressure, or heart rate.[129,174] In these studies, lower

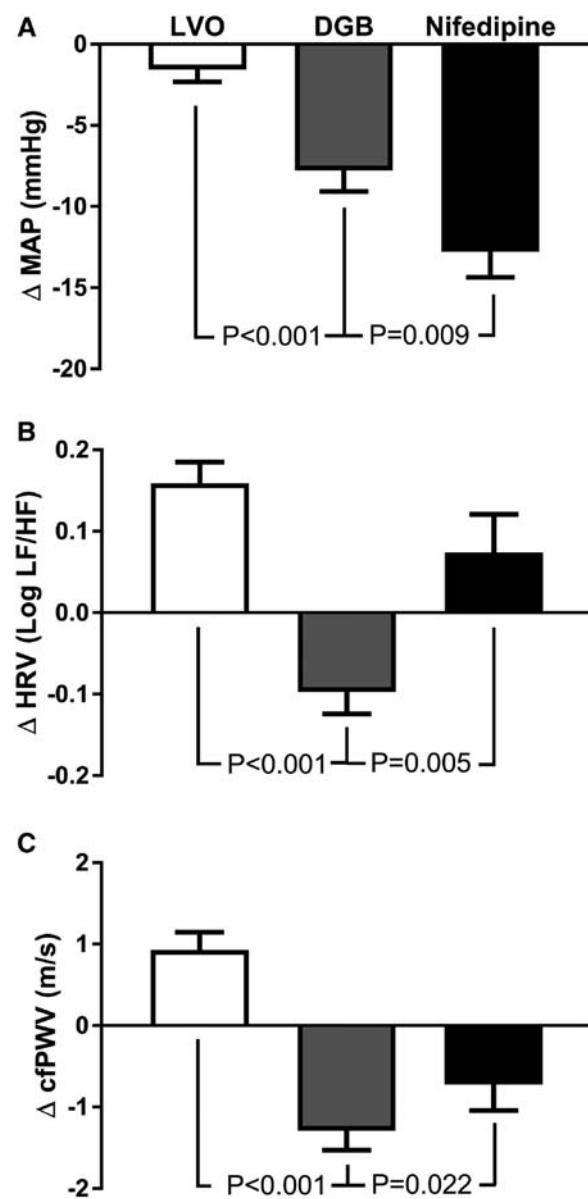
General responses in muscle sympathetic nerve activity (MSNA), mean arterial pressure (MAP), stroke volume (SV), and heart rate (HR) during commonly used sympathoexcitatory and sympathoinhibitory laboratory interventions. Single arrows reflect mild responses, while double arrows reflect larger responses. Note: the responsiveness of these variables can be influenced by the dose, duration, or intensity of the intervention. This table is meant to highlight the difficulty in separating the neural sympathetic and hemodynamic actions during routine stressors.


FIGURE 24.6 Panel A: Representative tracings showing an increase in muscle sympathetic nerve activity (MSNA) during −7 mmHg lower body negative pressure (LBNP). Panel B: Change in carotid-femoral pulse wave velocity (PWV) during acute elevations in MSNA using increasing levels of LBNP in young and/or middle to older healthy individuals. NA, represents no data available for the middle to older age range at −7 mmHg LBNP. *Credit: Panel B. Re-drawn from Nardone M, et al.* **J Am Heart Assoc**. *2018;7(3):e007971. doi: 10.1161/JAHA.117.007971 and Holwerda SW, et al. Hypertension. 2019;73(5):1025−1035. doi: 10.1161/HYPERTENSIONAHA.118.12462.*

body negative pressure at −7 mmHg, −15 mmHg, and −30 mmHg increased carotid-femoral PWV by Δ+0.3 m/s, Δ+0.8 m/s, and Δ+1.3 m/s, respectively, in young healthy men and women (Fig. 24.6).[129,174] A similar dose-response pattern for carotid-femoral PWV was observed in middle-aged/older healthy adults, though −15 mmHg and −30 mmHg only reduced carotid artery compliance in young adults.[129] MSNA burst frequency was also positively associated with carotid-femoral

PWV at baseline and during lower body negative pressure stress.[129] In another comparison of young versus older healthy individuals, −20 mmHg lower body negative pressure was associated with a Δ+0.3−0.5 m/s increase in carotid-femoral PWV and a decrease in AI_x despite a small reduction in systolic arterial pressure.[175] This study also investigated responses to the cold pressor test, noting larger increases in carotid-femoral PWV and AI_x in young individuals which were mediated by a greater pressor

response.[175] Isometric handgrip exercise was found to increase carotid-femoral PWV, but the statistical significance of this change was lost after adjusting for the rise in mean arterial pressure.[68] Head-up tilt, another sympathoexcitatory stimulus, caused a reduction in mean arterial pressure and carotid-femoral PWV in patients with severe autonomic failure but an increase in carotid-femoral PWV in healthy controls which was not explained by changes in mean arterial pressure.[176] In a large cohort of hypertensive middle-aged men and women, administering lower-limb venous distention, to reduce cardiac preload and stimulate reflex sympathetic activation, caused an acute increase in ultrasound-derived aortic PWV and tonometric carotid-femoral PWV despite small reductions in mean arterial pressure and pulse pressure.[127] Collectively, these studies support the capacity of acute sympathetic activation to increase elastic large-artery PWV, independent of age.

An alternative approach has been to determine whether acute suppression of sympathetic outflow leads to reductions in large-artery stiffness. Bolus infusion of the ganglionic blocker pentolinium in young adults failed to alter carotid-femoral PWV.[68] However, in these experiments, pentolinium reduced heart rate variability but caused an unexplained increase in mean arterial pressure,[68] suggesting incomplete blockade of ganglionic neurotransmission and paradoxical pressor effects via other mechanisms. In contrast, infusion of the ganglionic blocker trimethaphan reduced central and peripheral arterial pressure and lowered carotid-femoral PWV (Δ-1.3 m/s)—but only in postmenopausal, not premenopausal women.[137] This discordance may reflect the lower sympathetic firing rates of the latter.[147] However, subsequent analysis showed that the differences in carotid-femoral PWV responses between pre- and postmenopausal women were abolished after adjusting for mean arterial pressure responses to trimethaphan.[137] Postmenopausal women also exhibited reductions in augmentation pressure and $AI_x@75$; the change in augmentation pressure correlated negatively with the change in MSNA burst incidence.[137] A single dose of clonidine, a α_2 adrenergic agonist which reduces central sympathetic outflow, was associated with reductions in carotid-femoral PWV, but the independence from parallel reductions in arterial pressure was not tested in that study.[177] Finally, a recent study attempted to separate the neural and pressure-mediated effects on large-artery stiffness by comparing the effects of lower leg venous occlusion, device-guided breathing, and device-guided breathing plus the calcium channel blocker nifedipine (shown previously to increase MSNA[178]) on carotid-femoral PWV.[127] As shown in Fig. 24.7, despite larger reductions in mean arterial pressure with device-guided breathing plus nifedipine, the changes in

FIGURE 24.7   Change from baseline in mean arterial pressure (MAP, A), heart rate variability (HRV, B) and carotid-femoral pulse wave velocity (cfPWV, C) after lower-limb venous occlusion (LVO), device-guided breathing (DGB), and nifedipine (10 mg). *Used with permission from Faconti L, et al. **J Am Heart Assoc**. 2019;8(15):e012601. doi: 10.1161/ JAHA.119.012601.*

carotid-femoral PWV were smaller, coincident with elevations in the low frequency to high frequency ratio of spectral heart rate variability, interpreted by these authors as indicating sympathetic activation.[127] Caveats acknowledged,[85] such data are concordant with the concept that sympathetic activation can impede pressure-mediated reductions in elastic large-artery stiffness.

Does chronic sympathetic modulation contribute to large-artery stiffness?

The majority of clinical conditions associated with exaggerated sympathetic outflow also possess increased large-artery stiffness; these include healthy aging, hypertension, heart failure with reduced ejection fraction, renal failure, chronic obstructive pulmonary disease, obstructive sleep apnea, and others.[8–10,179] If sympathetic activation contributes to the mechanical properties of the vasculature, it would support treatments that specifically target central sympathetic outflow for improving large-artery stiffness.

Evidence from muscular arteries

Radial artery distensibility was increased in two men following hand transplantation and returned toward values similar to the contralateral control hand after ∼four months coincident with qualitative signs of neural reinnervation.[180] Similarly, femoral artery distensibility was increased one month following unilateral lumbar ganglionectomy (but unchanged in the contralateral leg) in five patients with peripheral artery disease.[163] Thus, the stiffness of muscular arteries appears to be mediated by tonic levels of sympathetic outflow.

Evidence from elastic arteries

Patients suffering from pheochromocytoma, a condition characterized by catecholamine-secreting tumors commonly found in the adrenal medulla, exhibit chronic elevations in plasma and urine norepinephrine.[150,181] These patients demonstrate elevated carotid-femoral PWV (but not $AI_{x@75}$) compared to age- and sex-matched controls, even following the adjustment of heart rate, arterial pressure, and fasting plasma glucose.[150] Patients with the greatest catecholamine excess also possess the highest brachial-ankle PWV.[182] With respect to the chronic implications, one year after successful tumor resection, patients with pheochromocytoma demonstrate similar 24-hr urine norepinephrine, arterial pressure, heart rate, and carotid-femoral PWV compared to controls.[150] In patients with chronic obstructive pulmonary disease, inhibiting the carotid chemoreceptors with dopamine infusion reduced MSNA, mean arterial pressure, and carotid-femoral and carotid-radial PWV, but the interdependence of these changes were not evaluated.[183]

The recent development of device-based therapies to target sympathetic overactivation has offered insight into the potential relationships with large-artery stiffness, though these interventions are tested on patient groups with severe disease progression and likely vascular remodeling. In a small cohort of patients with heart failure with reduced ejection fraction, six months of chronic baroreflex activation using carotid sinus electrical stimulation decreased MSNA by ∼30%[184] but did not alter arterial pressure, carotid-femoral PWV or AI_x.[185] In contrast, an uncontrolled trial in resistant hypertensives reported that six months of chronic baroreflex activation reduced carotid-femoral PWV and AI_x.[186] Renal artery denervation in resistant hypertensives has also been found to reduce carotid-femoral PWV to a greater extent than predicted by reductions in arterial pressure,[187] while in another series arterial pressure, MSNA and finger-derived AI_x were reduced concurrently—but the individual changes were not related.[188]

Pharmacologically, several common antihypertensive drugs, namely angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers, have been found to reduce MSNA.[189] These classes have also been shown to decrease elastic large-artery stiffness despite similar reductions in arterial pressure as other drug classes.[190,191] One explanation for these interdrug discrepancies could involve the potential for some antihypertensive medications to cause reflex-mediated increases in MSNA,[178,192] which may attenuate pressure-mediated reductions in artery stiffness.[127] For example, concurrent angiotensin II receptor blocker and diuretic (losartan-hydrochlorothiazide) therapy produce larger reductions in arterial pressure than losartan monotherapy, but similar magnitude changes in AI_x and the cardio-ankle vascular index.[193] Losartan-hydrochlorothiazide has been shown to cause reflex-mediated increases in resting MSNA.[192] Losartan can produce greater reductions in carotid-femoral PWV and AI_x compared to hydrochlorothiazide despite similar blood pressure−lowering capacities.[194] The mineralocorticoid receptor antagonist spironolactone can reduce MSNA and carotid-femoral PWV.[189] Centrally acting sympathoinhibitory medications, such as moxonidine, can reduce large-artery stiffness when used concurrently with the angiotensin II blocker valsartan,[195] but eight week moxonidine monotherapy, which lowered MSNA burst frequency by ∼6 bursts/minute without changing arterial pressure, did not alter carotid-radial PWV or AI_x in obesity-related hypertensives.[196] In the latter study, moxonidine also led to an increase in plasma aldosterone.[196] Peripherally acting sympathoinhibitory medications such as doxazosin can reduce carotid-femoral PWV[197] and AI_x[198] in hypertensive patients. Finally, lipophilic statins (e.g., atorvastatin and simvastatin) have also been shown to be capable of lowering MSNA[199,200] and improving carotid-femoral PWV.[201]

Neuroendocrine modulation of arterial stiffness

Renin-angiotensin-aldosterone system

Experimental and human work consistently support an association between activation of the renin-angiotensin-aldosterone system (RAAS) and increased large-artery stiffness.[202,203] Recall that renal sympathetic activation

promotes the release of renin[29–31] (Fig. 24.1). Animal studies have shown that upregulating ACE activity can increase vascular smooth muscle hypertrophy,[204] while elevated angiotensin II can increase oxidative stress in vascular smooth muscle cells[205] and stimulate adverse remodeling of the extracellular matrix and vascular smooth muscle cells.[206–208] Spontaneously hypertensive rats treated with ACE inhibitors possess greater aortic elastin density and lower aortic PWV than controls.[209,210] Aldosterone has also been shown to increase carotid artery hypertrophy and stiffness in aldosterone-salt treated rats.[211] Importantly, the crosstalk between angiotensin II and aldosterone can upregulate genomic and nongenomic signaling cascades that synergistically increase vascular smooth muscle proliferation, fibrosis, and inflammation.[212] Local tissue RAAS systems are also likely to be involved in mediating arterial stiffness.[117,213]

In normotensive humans, a higher aldosterone-to-renin ratio was associated positively with carotid-femoral PWV but not arterial pressure.[214] Intravenous angiotensin II infusion increases carotid-femoral PWV,[215,216] which was abolished following administration of the angiotensin receptor blocker valsartan.[216] Subsequent analysis found that blunting the angiotensin II–mediated arterial pressure rise explained only 30% of the change in carotid-femoral PWV, suggesting pressure-independent mechanisms are also involved.[216] Normotensive participants demonstrate increased radial artery compliance following ACE inhibition,[217] while in patients with hypertension, ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists have consistently been shown to reduce carotid-femoral PWV and the AI_x.[190,191,202,218] The concurrent arterial pressure reductions with these drug therapies play a large role in passively attenuating arterial stiffness, though evidence suggests that reductions in arterial stiffness following RAAS inhibition are in part pressure-independent.[219] In coronary artery disease patients, ACE inhibition decreased carotid-femoral PWV independent of the change in mean arterial pressure.[220] Treatment with hydrochlorothiazide or losartan produce similar arterial pressure reductions in hypertensives, but only losartan reduced carotid-femoral PWV and the AI_x.[194] Captopril and valsartan produce similar reductions in arterial pressure and carotid-femoral PWV, yet in combination they produce synergistic reductions in carotid-femoral PWV after correction for arterial pressure.[221] Lastly, spironolactone reduced both mean arterial pressure and carotid-femoral PWV, while bendroflumetazide decreased MAP but was unable to alter carotid-femoral PWV in hypertensive patients.[222] These studies highlight that therapeutically targeting RAAS can reduce arterial stiffness, including through mechanisms beyond the passive unloading of the arterial tree.

Lastly, animal work has highlighted that angiotensin II plays a significant role in modulating central and peripheral sympathetic outflow.[223] It is plausible that RAAS-mediated sympathoexcitation or inhibition can indirectly alter arterial stiffness through neural mechanisms. However, the influence of activation or inhibition of RAAS components in humans has yielded inconsistent findings regarding its neuromodulatory role in healthy, hypertensive, or heart failure populations.[224–232] Therefore, future work is required to delineate the role of RAAS-mediated sympathetic modulation, and whether it can influence large-artery stiffness.

Endothelin-1

Endothelin-1 is a potent endothelial-derived vasoconstrictor.[233] Its over-expression leads to increased collagen deposition and arterial stiffening.[234] Endothelin-1 can also increase inflammation and reduce nitric oxide bioavailability leading to stiffening.[235] Endothelin-A receptor antagonism in normotensive and hypertensives blunts the baroreflex-mediated increase in MSNA to reductions in arterial pressure activity,[236] supporting the concept that endothelin-1 is involved in regulating tonic sympathetic vasoconstrictor activity. Cross-sectional work has shown a pressure-independent association between endothelin-1 and carotid-femoral PWV in young men,[237] with a similar bivariate relationship found in middle-aged patients with coronary artery disease.[238]

Experimental work in anesthetized sheep found that intra-arterial infusion of endothelin-1 increases iliac artery PWV and endothelin-A receptor antagonism decreases iliac artery PWV.[239] Similar findings have been observed in young healthy men, such that: (1) intravenous infusion of endothelin-1 increases carotid-femoral PWV and the AI_x; (2) endothelin-A receptor antagonism decreases carotid-femoral PWV and the AI_x; and (3) arterial stiffness responses are unchanged following co-infusion of endothelin-1 and endothelin-A receptor antagonist.[240] Carotid artery compliance is also increased following endothelin-A/B receptor blockade before, but not after, aerobic exercise training suggesting a role of decreased ET-1 on exercise-mediated changes in arterial stiffness.[241] In patients with chronic kidney disease, acute[242] and chronic[243] endothelin-A receptor antagonism decreases carotid-femoral PWV. Although parallel changes in arterial pressure and arterial stiffness are observed during infusion of endothelin-1 agonists or antagonists, these findings highlight a potential physiological role for modulating elastic large-artery stiffness in humans.

Insulin

Patients with type 1 and 2 diabetes demonstrate increased arterial stiffness,[244–246] while insulin sensitivity and plasma insulin concentrations are independently associated with markers of central and peripheral arterial stiffness.[247–254] In addition, euglycemic hyperinsulinemia attenuates AI_x in healthy humans,[255–257] suggesting that insulin can acutely reduce arterial stiffness. These responses are mediated in part through insulin-mediated endothelial-dependent vasodilation.[258] Patients with type 2 diabetes have attenuated insulin-mediated reductions in AI_x,[257] likely driven by impaired insulin-mediated endothelial nitric oxide production,[259] and adverse remodeling of vascular smooth muscle cells and extracellular matrix.[260] Lastly, in healthy normoglycemic participants, euglycemic hyperinsulinemia increases MSNA,[261–264] highlighting a sympathoexcitatory role of insulin. Indeed, type 2 diabetics have elevated MSNA which is related positively to insulin levels.[265] Insulin-mediated sympathoexcitation may contribute, in part, to the observations of increased arterial stiffness in this population.

Testosterone

Cross-sectional and experimental work has highlighted that sex hormones can modulate arterial stiffness. For example, in healthy middle-aged and older men without cardiovascular disease, serum testosterone was negatively correlated with carotid-femoral PWV[266,267] and carotid artery stiffness,[268] independent of mean arterial pressure and age.[267,268] Similar negative correlations have been reported in men undergoing hemodialysis and may underlie the relationship between low testosterone and cardiovascular mortality.[269] Participants with testosterone deficiencies also demonstrate increased carotid-femoral PWV compared to controls,[267,270–272] while 90 days of testosterone replacement therapy can decrease total systemic arterial compliance.[273] In conflict with human work, animal studies have shown that testosterone can increase collagen protein expression and increase arterial stiffness.[274–276] The mechanisms responsible for a testosterone-mediated benefit to arterial stiffness are poorly understood but may relate to its role as a vasodilator or atheroprotective and antiinflammatory factor.[277] It is unlikely that a neural mechanism is involved given the positive relationship between androgens and MSNA.[278,279]

Estrogen

Women demonstrate increased arterial stiffness compared to men before menarche and after menopause suggesting a vascular protective effect of sex hormones.[45,280,281] Estrogen-mediated signaling cascades can inhibit cellular processes that cause adverse remodeling of the extracellular matrix[282] and medial layer[283] of the aorta. Incubating human aortic cells with estrogen or progesterone increased elastin and decreased collagen protein expression.[274–276] Estrogen can increase nitric oxide bioavailability[284] and decrease oxidative stress,[285] both of which can reduce arterial stiffness.[286] Temporal investigations across the menstrual cycle have found higher radial arterial distensibility,[287] whole body arterial compliance,[288] or carotid compliance[289] during ovulation (i.e., when estrogen is first rising), while AI_x@75 is lowest during the luteal phase (i.e., when estrogen and progesterone are both elevated).[290,291] In contrast, a growing number of studies have reported that carotid-femoral PWV,[288,291–294] AI_x,[293,295] carotid artery stiffness,[294] or carotid and femoral artery compliance[296] are unchanged throughout the menstrual cycle. A similar lack of responsiveness in elastic large-artery stiffness has been reported across different phases of oral contraceptive use,[293,294] while active hypoestrogenic premenopausal women with functional hypothalamic amenorrhea have lower resting systolic arterial pressure, pulse pressure, and AI_x@75 compared to fitness-matched eumenorrheic controls[297] in spite of their exaggerated MSNA responses to graded lower body negative pressure.[298] Numerous randomized controlled trials have sought to determine prospectively the effects of estrogen or combined hormone replacement therapy on arterial stiffness in postmenopausal women. However, the overall results have been equivocal.[299]

Do sex hormones modify the relationship between muscle sympathetic nerve activity and arterial stiffness?

Several lines of evidence suggest that female sex hormones can modify the association between sympathetic vasoconstrictor drive and large-artery stiffness. First, premenopausal women have a smaller drop in arterial pressure following ganglionic blockade supporting a reduced reliance on sympathetic vasoconstrictor tone.[300] This aligns with data showing lower MSNA in premenopausal women versus men[147] and likely reflects the role of estrogen as a central sympatholytic.[301] Second, compared to men, premenopausal women have attenuated reductions in peripheral vascular conductance during graded norepinephrine infusions,[302] which is the result of greater β_2 adrenergic vasodilation.[26,302] The latter findings may explain the positive relationship between MSNA and AI_x in men and postmenopausal women[138,139] but negative association in premenopausal women.[139] However, the positive relationships between MSNA and carotid-femoral PWV or carotid artery compliance were similar in men and women[129] suggesting that sex differences in pulse wave reflection are likely caused downstream of the aorta.

Summary

Greater conduit artery stiffness and central sympathetic outflow have each been identified as an independent marker of increased cardiovascular risk. There is accumulating evidence from many, but not all studies in humans, for a bidirectional relationship between these alterations, with increased sympathetic outflow inducing acute or chronic arterial stiffening and with decreased compliance, in turn, diminishing stimulation by stretch of sympatho-inhibitory arterial baroreceptors. There is, however, little evidence thus far that therapeutic attenuation of sympathetic discharge can reduce cardiovascular risk by improving arterial elasticity. Trials of such interventions will be required to affirm this concept.

Introduction

Vascular aging is characterized by a gradual loss in vascular integrity. The latter is characterized by a combination of structural and functional properties of the cardiovascular system designed to meet the demands of blood delivery to target organs at pressures that allow distribution through the capillaries on metabolic demand. Accelerated vascular aging is associated with an increased risk for premature cardiovascular disease (CVD), the leading cause of death worldwide.[1] From a clinical point of view, vascular aging can be defined as a gradually developing process characterized by age-related alterations in both quantitative and qualitative structural properties of passive elements of the vascular wall accompanied by the decline in endothelial-dependent dilatation resulting in an increased vascular tone, the loss of arterial elasticity, and increased arterial stiffness. Vascular aging is significantly exaggerated when accompanied by the presence of certain risk factors and/or disease states, which are primarily related to metabolic disorders, hormonal imbalance, uremic toxin accumulation, nutritional characteristics, and/or obesity, physical inactivity, smoking habits, cholesterol and glucose levels, among other factors.[2,3]

Normal aging affects various organs and processes in the body, including the vascular tree. Experimental animal models and human studies have identified interconnected processes driving aging, which primarily include genomic instability, telomere attrition, epigenetic alterations, loss of proteostasis, dysregulated nutrient-sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication. Common factors triggering the aforementioned processes include oxidative stress, vascular inflammation, endothelial dysfunction, and calcification. The processes described contribute to early vascular aging (EVA), which is primarily characterized by accelerated vascular remodeling, followed by functional decline of target organs such as heart, brain, and kidney.[4] Therefore, in some conditions (such as chronic kidney disease (CKD), diabetes mellitus, obesity, etc.), the biological vascular age is discrepant from the chronological age.[5] Arterial aging processes launch early in the life course and are either accelerated (regarded as EVA[6,7]), normal (so called Healthy Vascular Aging),[8] or slower than usual (SUPER normal Vascular Aging).[9] The latter is characterized by very low carotid−femoral pulse wave velocity (cfPWV) for an individual's chronological age and sex. As reviewed in several other chapters of this book, accelerated vascular aging has been related to CVD, cognitive dysfunction and dementia, CKD, and adverse pregnancy outcomes, such as preeclampsia.[4,7]

During aging, the arterial wall undergoes complex structural changes that affect its hemodynamic function, and in the presence of comorbidities and/or additional toxic milieu (such as uremic toxins), those processes will be gradually exaggerated. The structural changes are primarily related to loss of wall elasticity with accumulation of collagen, elastin fragmentation in the media, which result in reduced arterial compliance and adverse pulsatile hemodynamics.[10] The importance of vascular aging as an indicator of biological aging in humans is increasingly recognized.[5]

review the effect of aging on arterial structure and hemodynamic function. This chapter deals primarily with the fundamental cellular biologic processes that contribute to aging of the arterial wall.

Effects of aging on the arterial tree

Endothelial dysfunction

Endothelial dysfunction has been responsible for initiating vascular remodeling. Endothelial cells sense the flow-mediated shear stress or frictional force of tensile stress and release vasodilating nitric oxide (NO) in addition to other vasoactive factors to preserve vascular homeostasis including vascular tone, coagulation, inflammation, and proliferation of vascular smooth muscle cells (VSMCs). A number of studies show that in the presence of conditions that increase the risk of CVD, endothelial cells switch from a protective to a proatherosclerotic phenotype with reduced NO availability and increased release of other substances important for arterial wall remodeling, including endothelin-1, thromboxane A2, prostaglandin H2, and reactive oxygen species (ROS).[11] Thus, endothelial dysfunction is seen as an early and major promoter for arterial aging. Interestingly, endothelial function in vivo can be assessed in muscular arteries by using flow-mediated dilation or in the microcirculation using techniques such as laser Doppler flowmetry.[12] There are also other available in vitro methods, such as endothelial cell culture, isolated small artery bioassays to assess endothelium-derived relaxing factors, and analysis of circulating biomarkers related to endothelial dysfunction. However, the lack of standardization limits the clinical applicability of endothelial function assessments.[12]

Elastic arteries

As described in detail in Chapters 19–24, multiple mechanisms contribute to the changes in the structure and function of the elastic arteries seen with aging and disease.[13] Due to aging-induced imbalance between vasoconstrictors and vasodilators, and changes in the quality and quantity of passive elements of the vascular wall, elastic arteries lose their "cushioning" function and slowly become stiff, tortuous, and elongated. In addition to elastic breakdown, collagen deposition in all layers of the artery wall and decreased elastin-to-collagen ratio accompanied by VSMCs phenotypical switching and increased stiffness[14] promote an adverse vascular remodeling process.[15,16] It has also been suggested that at some point VSMCs become senescent[17] and cell division of cells residing at the arterial wall diminishes.[16] In addition to the adverse remodeling process, calcification in the media and local calcification of plaques further contribute to increased arterial stiffness.[15]

Accumulating evidence indicates the presence of regional heterogeneity within the descending aorta[18] determined during embryogenesis[19] by the different thoracic and abdominal aortic developmental origins, neural crest-derived precursor cells, and mesodermal ancestors,

respectively. Moreover, the thoracic aorta has more elastic fibers compared to the abdominal aorta (especially the infrarenal part, where a decrease in elastin relative to collagen has been observed).[20] Aortic remodeling gradually starts in childhood and becomes more accelerated in middle age,[21] with more pronounced intimal thickening and slower enlargement in diameter of the distal aorta compared to the proximal aorta.[22]

Thoracic aortic aneurysms and dissections (TAADs) are two highly lethal aortic disorders, originating from molecular disorders that impair the aortic wall and which also relate to arterial wall aging.[23] The etiology of TAAD can be divided into genetic, biomechanical, and inflammatory subgroups. A genetic example is Marfan syndrome, where a mutation in FBN1 leads to abnormal metabolism of fibrillin1, a glycoprotein of the aortic medial wall extracellular matrix (ECM).[24,25] As an example for metabolic disease origin, oxidative stress can affect telomere attrition. Several studies showed that telomeres in endothelial cells and VSMCs of patients with TAA or abdominal aorta aneurysms are shortened compared to endothelial cells and VSMCs of cadaveric control aortas.[26–28] Biomechanically, the degeneration of arterial media ECM components like collagen, fibronectin, and laminin and the pooling of glycosaminoglycans leave the aorta predisposed to aneurysm formation and dissection.[29,30] Additionally, deficiency of integrins, transmembrane proteins anchoring cells to the ECM, leads to an overall reduction in contractile force and resistance to injury.[31]

The underlying trigger for inflammatory pathophysiology within the aorta is still debated, from autoimmunity to antibody reactions against excess lipids. Nevertheless, the immune reaction involves the presence of apoptotic VSMCs and the consequential influx of lymphocytes and macrophages to the tunica media via the adventitia.[24,32] The aforementioned mechanisms predispose the arterial wall of the aorta to development of aneurysms and dissections, which until rupture are painless and unless not readily detected.

Furthermore, physiological aortic aging is connected to high aortic systolic and pulse pressures, early return of wave reflections, decreased coronary perfusion pressure, degeneration of the arterial wall through elastolysis, increased cfPWV (i.e., arterial stiffening), and abnormal microcirculation.[33] As demonstrated through magnetic resonance imaging, elongation and dilatation of the thoracic aorta, especially the ascending aorta, changes the appearance from a "candy-cane"-like shape in young adults (<30 years) to an "ear"-like shape in senior adults (>60 years).[13] During systole, a healthy adult proximal aorta alone stores about 60% of stroke volume, releasing it through elastic recoil to more peripheral arteries during diastole. Due to decreased elasticity and thus reduced aortic compliance in an aged and stiffened aorta, a higher aortic

pulse pressure in the ascending aorta has been shown to be associated with eventual elongation and widening of the descending aorta.[34−36]

Muscular arteries

Muscular arteries (e.g., common femoral artery, coronary arteries, internal carotid artery, radial artery, etc.) have been hypothesized to be less affected by aging.[37] However, muscular arteries are the main target of systemic calcification (i.e., arteriosclerosis) mainly driven by VSMCs switching from a contractile to synthetic phenotype by transformation to osteoblast-like cells.[38] The medial calcification phenomenon is independent from atherosclerosis and rarely results in narrowing of the arterial lumen[39] as an intramembranous ossification process.[38] Interestingly, intimal calcification (more prominent in elastic vessels) is also prevalent in coronary arteries and mimics the characteristics of endochondral bone formation. Medial sclerosis has been attributed to CKD, aging, diabetes mellitus, and obstructive sleep apnea.[40] Calcium depositions are found in both the intima and media. Calcification of tunica media in coronary arteries is an independent predictor of cardiovascular morbidity and mortality.[41]

The measurement of muscular arterial stiffness (e.g., carotid-radial PWV,[6] femoral-ankle PWV,[42] etc.) has a limited application to assess vascular aging.[43−45] A more accepted index of vascular aging in muscular arteries is carotid intima media thickness[46] and coronary artery calcification score, both of which are predictors of cardiovascular events and mortality.[46−48]

Small arteries

During aging, small arteries exhibit impaired endothelial function. Aging is related to senescence-associated endothelial damage as a result of increased apoptosis and diminished regenerative capacity of the endothelium.[49] Small arteries also undergo an increase in the wall-to-lumen ratio, due to increased wall thickness with hypertrophic or eutrophic remodeling. In animal models, aging is usually accompanied with an outward hypertrophic remodeling (i.e., expanded lumen diameter, increased wall cross-sectional area, and an unaltered internal lumen to tunica media ratio).[50,51] On the other hand, in human hypertension, an inward eutrophic remodeling has been reported.[52,53] In secondary forms of hypertension, such as in diabetes mellitus, an inward hypertrophic remodeling is generally observed.[54] When the lumen diameter decreases and media thickness increases, the circumferential tension decreases and reduces media stress, such that the artery wall is protected from elevated blood pressure. Small reductions in lumen diameter increase the resistance to blood flow significantly.[55] The myogenic response of VSMCs also contributes to these processes, particularly due to altered integrin expression.[56] Integrin receptor subtype forms complexes with fibronectin and therefore may play a pivotal role in VSMCs adhesion to ECM and thus regulating VSMCs tone.[56]

Aging also results in a loss of arteriolar density and a central role of the microcirculation in aging has been proposed[57] (i.e., long-term defects in the microcirculation resulting in ischemic tissue damage and target organ damage). VSMCs may contribute to these processes due to altered integrin expression, as, for example, integrin subunit β1 is predominantly expressed on the surface of VSMCs.[58] In addition, integrin receptor subtype complexes with fibronectin play a pivotal role in VSMCs adhesion to ECM and thus regulating VSMC tone.[56] Some available methods for the evaluation of resistant arteries, not yet applied in clinical practice, include measurements of retinal pulse wave velocity,[59] nailfold capillaroscopy,[60] isolated vessel analysis,[61] laser speckle contrast imaging,[62] and plethysmographic techniques to assess microvascular dilation in response to ischemia (such as cuff inflation).[63−65]

The role of the adventitia in vascular remodeling

The role of the outer layer of the arteries, the adventitia, is often forgotten. It contains fibroblasts, adipocytes, pericytes, immune cells, vasa vasorum microvessels, lymphatics, and perivascular nerves. Whereas the separation between media and adventitia is easily distinguishable in elastic arteries, it is less distinct in small arteries.[66] Collagen fibrils, synthesized by adventitial fibroblasts, are one of the main components of the adventitia. In human studies, the nanoscale elastic modulus of the adventitia in the internal mammary artery correlated with arterial stiffness measured as cfPWV, which may reflect shared mechanisms of aortic wall and mammary artery adventitial stiffening.[67] Additionally, the adventitial inflammatory response is responsible for atherosclerotic plaque instability in coronary arteries.[68]

Furthermore, since the adventitia serves as a niche for progenitor cells,[69] it creates a dynamic environment of interacting cell types that have a specific functional capacity for the control of vascular wall growth, remodeling, and disease. Exhaustion of progenitor cells during the aging process affects the biological function of vessels.[70] Importantly, although it has been shown that compromised function of highly proliferative endothelial progenitor cells (EPCs) contributes to atherosclerosis,[71] the role of EPCs in the genesis of vascular aging phenotypes in humans is not well understood and needs further investigation.

Cellular and molecular mechanisms of vascular aging

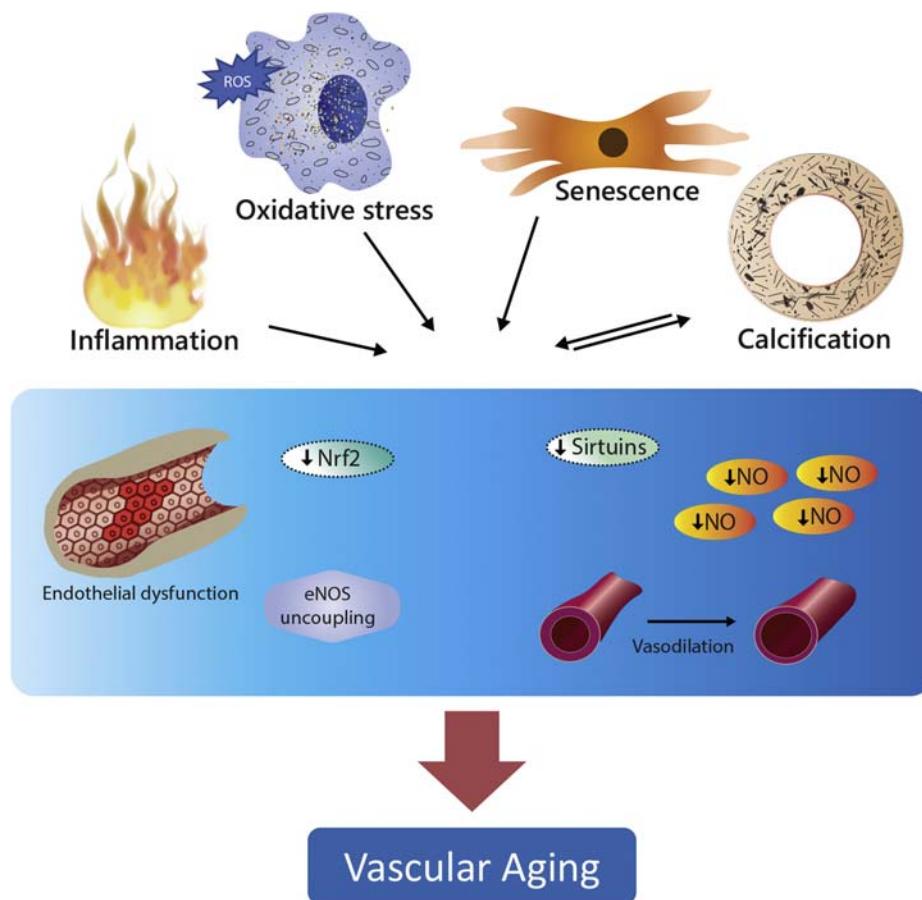
Arterial aging is described by age-related deterioration and sclerosis of the media and intimal layers within the vascular tree that will result in age-associated changes in functional and structural properties. Research into aging at a cellular level in vasculature has increased our understanding of causes and consequences of aging at this level, particularly in clinical conditions associated with increased cardiovascular risk. It is now largely acknowledged that age-associated cellular damage predominantly influences cell membrane lipids, proteins involved in metabolic and structural roles, nuclear and mitochondrial DNA, and intracellular signaling processes. In the following paragraphs, we summarize the pathophysiology and contributing factors that lead to vascular aging. In the final paragraph, we present CKD, as a clinical model for studies of EVA with following clinical implications for patients.

Vascular inflammation

It is well established that inflammation plays an important role as a driving force for the development of EVA. Experimental evidence indicates that chronic, low-grade inflammation ("inflammaging") is strongly associated with the aging process. Activation of the inflammatory process with aging plays a key role in micro- and macrovascular pathogenesis and dysfunction in a number of CVD complications,[72,73] in addition to other pathologies like blood–brain barrier disruption or Alzheimer's disease. Experimental rodent and primate studies have shown that aging, particularly EVA, coincides with a proinflammatory shift in the gene expression profile in both vascular endothelial and smooth muscle cells, which involves multiple cytokines such as tumor necrosis factor (TNF), interleukins (IL-1β, IL-6), intracellular adhesion molecule 1 (ICAM1), vascular cell adhesion protein 1 (VCAM1), chemokines, and other proinflammatory mediators.[74–76] In particular, proinflammatory IL-6 has been shown to strongly associate with age-related vascular disease.[77] In middle age and in elderly populations, C-reactive protein associates with increased arterial stiffness.[78] In addition, arteries from older adults exhibit higher expression of monocyte chemoattractant protein-1 (MCP-1) and metalloproteinase in the thickened intima layer compared with younger adults.[75] The proinflammatory microenvironment of the vascular wall ultimately leads to vascular malfunction[79] and to the pathogenesis of vascular diseases.[80] In the aging vasculature, the contribution of inflammation seems multifaceted. The activation of transcription factor nuclear factor kappa (NF-κB) in inflammation is considered as the master regulator among inflammatory molecules including IL-1β, IL-2, IL-6, TNF, chemokines, and enzymes iNOS and COX-2.[81] The increase in inflammatory markers is independently associated with CVD risk factors with arterial thickening and stiffness.[82] Moreover, an increase of inflammatory markers may also occur independently of CVD risk factors independently of age.[83]

It is important to stress that in the aged vascular wall there is a critical crosstalk between elevated oxidative stress and inflammatory processes.[84] For example, ROS activate proinflammatory signaling pathways, including NF-κB,[85] which has been suggested to be an important player for endothelial cell maintenance and even production of angiostatic agents and consequently expression of proinflammatory paracrine mediators that may promote atherogenesis.[86] Importantly endothelial and smooth muscle cells in aging exhibit significant NF-κB activation[85,87] and inhibition of NF-κB in the vasculature has been shown to restore blood flow regulation, decrease systemic inflammation, and exert beneficial metabolic effects.[88] On the other hand, inflammatory mediators may also act as potent inducers of cellular oxidative stress.[79]

TNF acts as an important inflammatory mediator, as, for example, aged coronary arteries are characterized by increased expression of TNF gene expression profile assessed in rats.[80] In addition, application of external TNF has been shown to increase oxidative stress via stimulation of endothelial dysfunction, NADPH oxidase, endothelial apoptosis, and stimulation of proatherogenic inflammatory mediators.[80,89] Administration of TNF upregulates superoxide production in human retinal endothelial cell mitochondria.[90] Moreover, TNF antagonism improves the endothelial-mediated dilatation in resistance arteries of aged animals.[91] Overall, it appears that prolonged TNF exposure could have detrimental consequences to endothelial cells by causing senescence and, therefore, chronically increased TNF levels might contribute to the pathology of chronic inflammatory diseases by driving premature endothelial senescence.[92] The endothelium performs a crucial role to maintain the vascular tone by producing vasoconstrictor and vasodilator molecules, hence regulating blood flow to vital organs. Studies have demonstrated that senescence in human endothelial cells may cause the impairment of shear stress–mediated vascular relaxation.[93] In addition aging populations display reduced endothelial-mediated dilation with decreased NO generation.[94] Hence, an aging-related proinflammatory phenotype is likely to be associated with impaired endothelial function.

Moreover, there is increasing evidence that senescence in endothelium is linked with the release of a broad spectrum of inflammatory cytokines and chemokines,[95] more specifically the "senescence-associated secretory phenotype," or SASP. Since senescent cells are an important source of local, chronic, low-grade inflammation and plaque destabilization, they are a promising upstream therapeutic target. Developing evidence shows that in the aged vasculature, senescence significantly contributes to trigger


the inflammatory process.[96] Targeting of senescent cells and aging processes therefore holds unexplored potential to ameliorate vascular aging.

The role of inflammation in arterial stiffening is discussed in detail in Chapter 20. Endothelial cell senescence is discussed in detail in Chapter 23.

Oxidative stress

The formation of ROS is a normal part of cellular metabolism, principally the oxidative phosphorylation that takes place in mitochondria for the generation of ATP. Since Harman suggested the free radical theory of aging in the 1950s,[97] many studies have been published connecting oxidative stress with vascular aging. It is now widely appreciated that ROS accumulate with age, ultimately resulting in oxidative damage of genomic DNA, cellular components, and proteins.[97] Specifically, there is a strong indication that aging is associated with elevated production of ROS by NAD(P)H oxidases[98] and mitochondria,[99,100] and those events are linked to endothelial dysfunction and stiffening of elastic arteries as shown both in laboratory animals[85,101] and humans.[102] While oxidative stress has the

capacity to affect numerous aspects of vascular function during aging, such as induction of redox-sensitive transcription factors or oxidation of vital proteins, one of its most powerful impacts is related to the inactivation of endothelium-derived NO.[103] Defective bioavailability of NO is responsible for the age-related decrease in endothelium-dependent dilation, increased vasoconstriction, and tissue perfusion dysregulation (Fig. 25.1).[104−106] Several studies indicate that oxidative stress-mediated endothelial dysfunction is responsible for defective dilation of coronary arteries,[107] stimulating myocardial ischemia and neurovascular uncoupling, and diminishing the moment-to-moment adjustment of cerebral blood flow.[108,109] NO plays potent antiinflammatory, antithrombotic, and antileukocyte adhesion effects; therefore, a decrease in NO stimulates a proatherogenic vascular phenotype in aging.[110,111] Free oxygen radicals ($\bullet O^-_2$) from increased ROS bind to NO and form highly reactive and toxic peroxynitrite ($ONOO^-$), which in turn penetrates cell membranes and leads to DNA damage and protein oxidation.[112] Indeed, increased ($ONOO^-$) staining has been demonstrated in number of pathological conditions, all associated with EVA.[113,114]

FIGURE 25.1 Proposed scheme for mechanisms involved in vascular aging. The model predicts that increased oxidative stress, inflammation, senescence, and calcification accelerate vascular aging process through mediating reduced NO bioavailability due to an eNOS uncoupling event, endothelial dysfunction, reduced vasodilation, and disrupting antioxidant mechanisms, i.e., Nrf2 and sirtuins. *eNOS*, nitric oxide synthase; *NO*, nitric oxide; *Nrf2*, nuclear factor erythroid 2−related factor 2.

It has been suggested that mitochondria act as a seed for aging.[97] The mitochondria serve as a source for endogenous oxidants. An increase in free radicals (i.e., $\bullet O^-_2$ or $ONOO^-$) in mitochondria is positively associated with tissue dysfunction.[115] Molecular oxygen and electrons from the respiratory chain can generate free radicals and ROS inside mitochondria.[116] Mitochondria are organized by heterogeneous flexible networks, which are highly sensitive to metabolic changes (i.e., high glucose) and can react to boost free ROS formation.[116] During aging, mitochondrial physiology and reactive free radical production is altered, which in turns affects ATP synthesis via interrupting the enzymes of the citric acid cycle, respiratory chain components, and mutation of mitochondrial DNA leading to enhanced apoptosis.[115] Another major alteration of mitochondria in aging includes decreased antioxidant capacity. A cytoprotective transcription factor nuclear factor-erythroid-2-related factor 2 (Nrf2) acts as a defense against oxidative stress, as discussed in the following section. Age-associated increased formation of ($\bullet O^-_2$) and (ONOO-) triggers nuclear and mitochondrial DNA damage,[117] which could accelerate mutation and dysfunction of respiratory chain segments, leading to even more ($\bullet O^-_2$) and ($ONOO^-$) generation and vascular dysfunction.[118] Increased generation of reactive ($\bullet O^-_2$) and ($ONOO^-$) are considered major contributors to EVA and endothelial dysfunction.[114,119]

Adaptation to oxidative stresses: role of Nrf2 and sirtuins

Vascular aging is characterized by elevated ROS-mediated chronic oxidative stress, which is accompanied by failure to switch on antioxidant response elements—driven gene expression.[120] Age-associated increases in oxidative stress have been shown to inactivate antioxidative defense mechanisms, in particular Nrf2 and its associated pathways of signaling. Redox homeostasis, comprising a balance between a prooxidative ROS generation and concomitant antioxidant protection, is vital for protection against oxidative stress.[121] Nrf2 is a redox-sensitive transcription factor, which regulates the antioxidant response, including upregulation of enzymes that detoxify ROS and reconstruct ROS-mediated macromolecular casualty.[122] In various cell types including vascular cells[87,120] and cardiomyocytes,[123] an impairment of Nrf2-dependent defense associates with aging. Nrf2 adaptive homeostatic mechanisms are involved in young organisms for the protection of vascular endothelial and VSMCs against increased ROS generation. Growing evidence demonstrates that Nrf2 is a key player in those events and that modulation of its action could promote both regulating the cellular redox homeostasis and physiological homeostasis in pathways associated to the maintenance of cardiovascular health.[124−126]

Aged and transcriptionally Nrf2-deficient mice show similar imbalance of antioxidative activity in experimental models,[122] suggesting that Nrf2 could act as a key modulator in the aging process. Apart from the role of Nrf2 as a master controller of oxidative defense, this cytoprotective transcription factor prevents upregulation of proinflammatory cytokine genes, regulating proteostasis and metabolism.[127,128] In addition, Calvert et al.[129] have suggested that hydrogen sulfide (H_2S)-mediated Nrf2 upregulation has cardioprotective effects. Moreover, TNF, IL-1β, VCAM1, and MCP-1 expression was decreased in endothelial cells when Nrf2 was overexpressed,[130,131] supporting its antioxidant capacity. Nrf2 is also able to regulate and ameliorate the inflammatory response. Diminished Nrf2 action leads to elevated expression of adhesion molecules and proinflammatory chemokines in endothelial cells.[132] In addition, activation of Nrf2 counterbalances the effect of ROS in T-lymphocytes and inhibits acutely induced kidney injury.[133] Boosting the Nrf2 antioxidant pathway decreases oxidative stress and improves the renal function of mice.[134] Several experimental approaches have evaluated the scope of Nrf2 to increase the expression of oxidative stress protective genes and preserve vascular health.[134,135]

The pathophysiological significance of Nrf2 in aging may go beyond maintaining the redox homeostasis. The association between aging and cardiovascular events indicates that the vasculature seems to be the prime target for Nrf2-induced protection during aging. Importantly, Nrf2 conserves the functional endothelial phenotype.[136] As aging and senescence may cause the deterioration of endothelial function, the endothelium may develop both proatherogenic and prothrombotic phenotypes.[137] Hence, in aging, Nrf2-mediated defense of endothelial cell dysfunction might be of particular importance. Since Nrf2 deficiency or inactivation associates with hypertensive kidney disease,[138] renal fibrosis,[139] atherosclerosis development,[140] and hypertension[141] in experimental animals and humans, this further supports a role of Nrf2 in prevention of EVA. Moreover, during caloric restriction, the antiaging effects are linked with induction of Nrf2-mediated pathways.[99,142] Natural and dietary compounds, such as phytosterols, resveratrol, polyphenols, and terpenoids, could be used as physiological activators for Nrf2 to improve vascular function[143] and alleviate the actions of oxidative stress and inflammation in preclinical models of CKD.[144] However, the role and mode of action of Nrf2 within the complicated vascular aging phenotype (i.e., EVA) is not fully understood. How Nrf2 expression is regulated in return to the functional and structural distortion in the cardiovascular system remains to be resolved.

Growing evidence suggests the role of sirtuins (SIRT1−7) for the control of cellular homeostasis, especially against metabolism and inflammation, and reduced action of SIRT1 possibly causes vascular inflammation in

aging.[145,146] Sirtuins are regulated by a preserved group of the cofactor nicotinamide adenine dinucleotide (NAD)-associated protein deacylases, that perform important roles in response to environmental and nutritional factors, e.g., oxidative stress, fasting, DNA damage. Primarily, their activation prompts nuclear transcriptional preparations that increase metabolic capability and boost oxidative metabolism of mitochondria with an ultimate resistance to oxidative stress.[147] Sirtuins stimulate this resistance by enhancing antioxidant processes promoting DNA damage restoration by deacetylation of repair proteins.[148]

In general, SIRT1 plays a broad spectrum of biological roles including antioxidative stress and antiinflammatory responses, DNA repair, glucose and lipid metabolism.[149] Oxidative stress can influence the activity of sirtuins in several ways, including changes in SIRT gene expression, NAD levels, protein−protein interactions, and post-translational modifications.[150] Mild oxidative stress could be beneficial by inducing the sirtuins as a compensatory system, on the other hand, severe or chronic oxidative stress could cause dysfunctional sirtuins by affecting its posttranslational modification.[151] The levels of NAD drop during the course of aging and could be an Achilles' heel, generating nuclear and mitochondrial malfunction leading to many age-related pathologies.[152] Interestingly, pharmacological use of a SIRT1 activator reduces vascular inflammation in an experimental model of aged mice.[153] In addition, elevating SIRT1, particularly in dorsomedial and lateral hypothalamic areas of the brain, lingers aging and prolongs life span in both male and female mice.[154] Promoting NAD activity by supplementing NAD intermediates could alleviate age-related functional defects. Hence, stimulation of sirtuins and NAD supplementation together may be an efficient antiaging intervention. This remains to be proven in clinical trials.

Senescence

By definition, senescence is an antioncotic mechanism, characterized as irreversible cellular arrest, although still with metabolic activity. This specifically refers to SASP, a phenotype of senescence whereby cells secrete a plethora of proinflammatory cytokines, growth factors, and proteases. In addition, senescent cells can initiate antiapoptotic pathways to protect themselves from their own SASP, thereby not allowing effective removal by the immune system. While senescent cell burden is associated with many age-related pathologies (e.g., atherosclerosis, vascular calcification (VC), type-2 diabetes, etc.), and often accumulates at the site of etiology, senescence also plays a beneficial role in physiological processes, such as embryogenesis and wound healing. Therefore, therapeutically targeting senescence to treat age-related diseases must be treated with caution.[155] In short, stressors activate either p^{53} (further activating p21) or $p^{16INK4a}$, which act to inhibit Rb, thus inhibiting the cell's ability to enter the S phase of the cell cycle. The p53/p^{21} and p16 pathways can act synergistically or alone depending on the stressor.[156]

Senescence is often classified as stress/oncogene-induced or acute/developmental senescence. Differences relating to temporal regulation exist between classes: the former is transiently present and effectively removed by apoptosis, while restricted to predefined cell types in specific processes; the latter class accumulates in tissue over time in an unprogrammed manner and can inflict similar injury on neighboring cells through their SASP, a phenomenon termed the "bystander effect." Thus, senescence is not a single static state, but rather a series of phenotypically different states, which reflects its diverse range of functions both physiologically and pathophysiologically.[157] Characteristics of stress-induced senescence includes, but is not limited to, increased senescence associated beta-galactosidase activity, telomere shortening, elevated expression of p16/p^{21}/p53, and SASP activity.[158] Experimental studies have demonstrated that SASP activity is highly heterogeneous between different cell types, thereby secreting different inflammatory components. However, IL-1α/β, IL-6, IL-8, TGF-β, TNF, plasminogen activator inhibitor 1, and monocyte chemoattractant protein 1 are among the best characterized.[159]

Since a single universal biomarker of senescence is not available, a variety of techniques are implemented experimentally to detect the presence of senescent cells. Emerging evidence indicates that senescent cells accumulate in humans and animal models with age and persist at sites of etiology in age-related diseases. Consequences of aging include exposure to increased senescence stressors, and reduced efficiency of senescent cell clearance, which may partially explain why senescent cell burden is associated with age.[160]

Numerous stressors have been linked to triggering senescence, most notably oxidative stress, cytotoxic stress, and telomere shortening. However, discovery of the bystander effect, genetic studies investigating the role of senescence-associated aging processes, and interventional studies in animal models demonstrate that senescent cell burden can, in specific organs and under certain conditions, drive disease. How senescence drives age-related disease is unknown, but is likely to be largely heterogeneous, and dependent on a plethora of factors including cell type, the pathology (or cluster of pathologies) in question, and stressors involved. Many SASP-related hypotheses have been postulated: proteases from senescent cells disrupt tissue structure and integrity, proinflammatory cytokines and chemokines attract immune cells associated with chronic tissue inflammation, such as macrophages and lymphocytes, etc.[157]

In respect to arterial aging, senescent cells accumulate in atherosclerotic plaques[161] and in the medial layer of

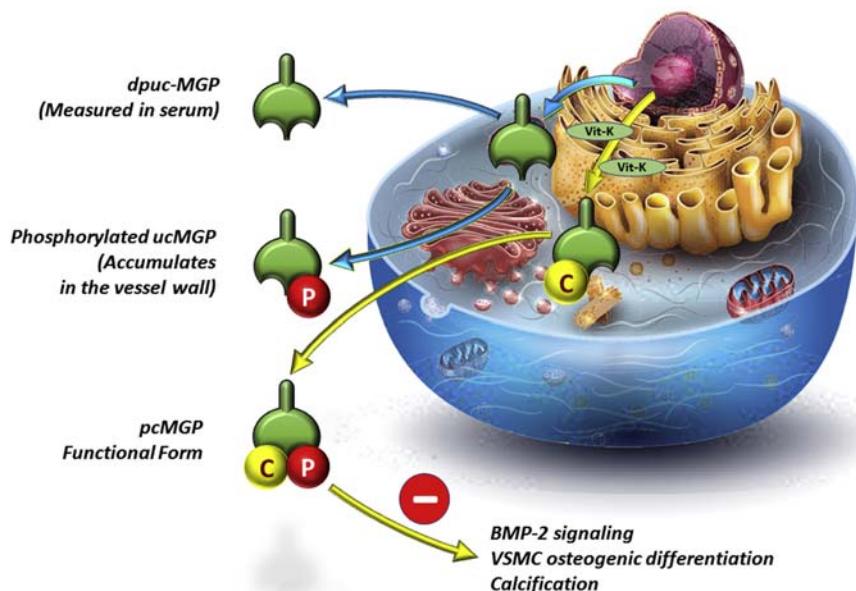
vessels such as heavily calcified uremic epigastric arteries, implying a casual role in promoting VC and thus an increase in vessel stiffness.[162] This is associated with depleted Nrf2, the master regulator of antioxidant genes; however, the relationship between senescence and Nrf2 may be bidirectional and warrants further research. Disease-specific stressors also promote VC, such as uremic toxins (e.g., indoxyl sulfate, p-cresyl sulfate, TMAO, etc.) in end-stage kidney disease (ESKD) patients.[163] Furthermore, endothelial cell senescence is a risk factor for age-associated CVD, mediated through disturbances in renin angiotensin–aldosterone system, sirtuin 1 and FGF21 pathways; however, these processes are not fully understood.[164]

By therapeutically earmarking processes which underpin aging, a cohort of age-related pathologies can be targeted simultaneously, as opposed to treating each disease as a single entity. Such a strategy may not only increase life span but also health span.[165] Since cellular senescence is a hallmark of aging, targeting senescent cells has gained much attention in recent years with the use of senolytic agents, SASP inhibitors, or immunosurveillance agents. In a landmark senolytic study, quercetin and dasatinib (in combination) prolonged life span in mice by up to 36%.[166] In addition, the same combination of senolytics attenuated VC in the aorta of aged and hypercholesterolemic mice when administered long term, and it improved endothelial function.[167] Furthermore, studies using genetic and pharmacological approaches to eliminate senescent cells in $Ldlr^{-/-}$ mice suggest that senescent cells promote atherogenesis, contributing to plaque instability by increasing vascular inflammation[168] or upregulation of matrix metalloproteases,[169] while irradiation-induced senescence in mice affects neurovascular units associated with cerebral microvascular dysfunction, resembling the aging phenotype.[170]

These findings, along with other promising preclinical studies, have led to the initiation of clinical trials using agents to target senescent cells in different patient cohorts in an attempt to exert athero-protective and antiaging effects, e.g., phase 1 study using quercetin and dasatinib senolytic cocktail in diabetic nephropathy patients.[171] However, many unknowns remain, including the required dosage and duration of therapy, the long-term effects of such treatment and whether targeting senescent cells hinders the ability of acute senescent cells to carry out their physiological functions.[172]

Chronic kidney disease as a model of early vascular aging and role of calcification

CKD is characterized by an allostatic overload due to excessive oxidative stress, uremic inflammation, and defective antiaging (e.g., decreased Klotho expression and fetuin A) systems, resulting in a large discrepancy between biological and chronological age in this patient group.[173,174] Indeed, as compared to the general population, CKD patients exhibited accelerated aging-related pathological clusters including multiple cardiovascular complications, muscle wasting, osteoporosis, frailty, depression, and cognitive decline, even before the onset of ESKD necessitating renal replacement therapy.[173–176] EVA is an evolving concept elaborating the abnormal and premature vascular aging phenomenon, with arterial stiffness as an intermediate end-point and independent predictor of cardiovascular morbidity and mortality.[4] EVA, as one of the most evident premature aging phenotypes in advanced CKD, contributes to the high risk of cardiovascular morbidity and mortality in ESKD. While the exact underlying mechanisms of EVA remain to be elucidated, DNA damage–induced cellular senescence and "inflammaging" seems to be fundamentally involved in its pathological initiation and progression.[159,177–180] Furthermore, growing evidence indicates that repressed Nrf2 signaling and vitamin K may play a critical role in the interplay between oxidative stress, DNA damage, senescence, and "inflammaging," whereby Nrf2 activation and vitamin K supplementation may provide a novel treatment target for EVA.[180]

Large-scale studies have demonstrated that coronary atherosclerotic calcification increases with age.[181] The presence of calcified arteries, in addition to osteoporosis, is typical in aged populations. Nevertheless, this condition is exaggerated in CKD patients. In CKD, the predominant EVA and arterial stiffness is largely characterized by media VC, a cell-mediated process primarily driven by VSMCs osteogenic differentiation due to excessive DNA damage, and the extent of VC may be used as a measure of the biological vascular age.[38,39] Though VSMCs calcification shares similarities with developmental osteogenesis and chondrogenesis, it is an active and pathological alteration rather than a physiological process.[182] Under normal physiological conditions, a profound defensive pathway protects VSMCs from phenotypic differentiation and ectopic calcification.[183] The inhibitory defense systems in CKD are, however, overwhelmingly declined due to excessive allostatic load resulting from oxidative stress, inflammation, and retention of toxins in the uremic milieu.[174,182] Moreover, the common coexistence of hyperphosphatemia, and hypercalcemia, in combination with hyperparathyroidism, hypomagnesemia, and vitamin K deficiency, further worsen the VC inhibitory mechanism in CKD.[184,185] For instance, fetuin-A, a circulating glycoprotein produced by liver and adipose tissue, acts as a potent inhibitor of VC through the binding of calcium and phosphate into calciprotein particles (CPPs) preventing its crystallization.[186,187] A recent study demonstrated that decreased fetuin-A in extracellular vehicles and CPPs from uremic serum could promote VC in vitro.[188] Consequently, stressed VSMCs lose their capacity to secret sufficient VC inhibitors (e.g., Matrix Gla protein


(MGP) and are predisposed to undergo phenotypic differentiation from a contractile to synthetic VSMCs phenotype).[189] Of note, MGP is a vitamin K−dependent protein primarily synthesized by VSMCs.[190] Evidence from preclinical studies has established the role of vitamin K in VC. This occurs mainly through the carboxylation of MGP, whereby it can inhibit VC by directly binding the hydroxyapatite in the arterial walls and by downregulating the function of bone morphogenetic proteins (BMPs) (Fig. 25.2).[191,192] Another culprit of deficient anti-VC system is Nrf2 signaling, which has been shown to be critical in response to various inducers in phenotypic remodeling of VSMCs. Recent studies have reported that butylhydroquinone (a Nrf2 agonist) reduces high phosphate-induced calcification of VSMCs via activation of KEAP1/NRF2/P62 signaling and hydrogen sulfide—another Nrf2 agonist—reduces circulating CPP-induced VSMCs calcification via NRF2/KEAP1 signaling and by increasing NQO1 expression in vitro.[193,194]

Given the overwhelming proatherogenic milieu in CKD, if the above-mentioned dysregulated signaling is not compensated, the activation of essential osteogenic/chondrogenic transcription factors could further induce the expression of osteogenic/chondrogenic proteins in VSMCs, such as osteocalcin, BMP-2, and type I collagen, in the context of high circulating levels of calcium and phosphate, which would eventually promote uremic VSMCs to undergo osteochondrocytic differentiation and vessel ossification.[195,196] In fact, even in the absence of hyperphosphatemia and hypercalcemia, increased phosphate

and calcium load drive a calcification process in both CKD and the general population.[197] In patients with CKD, gut dysbiosis could promote VC.[198] In addition, a recent study showed that protein-bound uremic toxins indoxyl sulfate and p-cresyl sulfate could promote VC in the aorta and peripheral vessels possibly via inflammatory and coagulation pathways.[199] For a detailed discussion regarding mechanisms of arterial wall calcification, the reader is referred to Chapter 21.

Summary

Aging affects the function and structure of the vasculature. All layers of the arterial wall are affected during aging-induced vascular remodeling. The aged tunica intima is characterized by endothelial dysfunction, whereas the tunica media is characterized by the presence of elastin degradation, collagen accumulation, proteoglycan aggregation, and the switching of the physiological contractile phenotype of VSMCs toward a synthetic VSMC phenotype, which induces VC. Furthermore, the inflammatory response of the outer adventitia that also serves as a niche for progenitor cells plays an important role in atherosclerosis. EVA develops when comorbidities emerge and a combination of various factors such as oxidative stress, inflammation, senescence, and calcification trigger exaggerated aging of the vasculature with ultimate development of cardiovascular and/or renal disease. Imbalanced redox homeostasis due to failure of master regulators of antioxidant responses, such as Nrf2 or sirtuins, results in vascular

FIGURE 25.2 Matrix Gla protein (MGP) maturation. MGP maturation requires vitamin K, the inactive form of MGP (dephosphorylated-uncarboxylated MGP, dp-ucMGP) undergoes serial posttranslational carboxylation and phosphorylation to form active pc-MGP. Carboxylation of MGP is dependent upon the availability of vitamin K in the vascular wall. The active form of MGP inhibits bone morphogenetic protein-2-induced osteogenic differentiation of VSMCs and calcification. *BMP-2*, bone morphogenetic protein 2; *dpuc-MGP*, dephosphorylated-uncarboxylated MGP; *MGP*, Matrix Gla protein; *pc-MGP*, phosphorylated-carboxylated MGP; *Vit-K*, vitamin K; *VSMC*; vascular smooth muscle cells.

damage and accelerated aging. Vascular aging causes a systemic, progressive loss of endothelial function, due to downregulation of vasodilator pathways and/or upregulation of vasoconstrictor pathways. Elevated oxidative stress and inflammation enhance the progression of cellular senescence and apoptosis, and this further exaggerates age-related deterioration of vascular health. In respect to arterial aging, senescence may also promote VC and thus an increase in vessel stiffness, in addition with depleted Nrf2 activity. All of the above-mentioned phenomena ultimately lead to increased arterial stiffness, characterized by quantitative and qualitative alterations in passive and active elements of the vascular wall. The changes in functional and structural features of vascular wall ultimately affect blood pressure and blood flow to target organs such as the brain, heart, and kidney.

The EVA concept represents a process of accelerated vascular aging. CKD may represent a suitable clinical model of EVA, because CKD is characterized by chronic inflammation and oxidative stress followed by progressive intimal and medial VC. Accelerated EVA is a hallmark of senescence and a strong predictor of cardiovascular morbidity and mortality in CKD. The cellular and molecular mechanisms that lead to arterial aging may serve as targets for interventions to delay or counter the effects of vascular aging on health and disease.

TEXTBOOK OF
ARTERIAL STIFFNESS AND PULSATILE HEMODYNAMICS IN HEALTH AND DISEASE

VOLUME 1

Edited by

Julio A. Chirinos, MD, PhD, FAHA, FESC

Associate Professor of Medicine; Director, Arterial Hemodynamics and Cardiac Imaging Quantification Core Laboratory; Co-Director, Training Program in Cardiovascular Biology and Medicine, Clinical/Translational Science; Adjunct Faculty, Center for Magnetic Resonance and Optical Imaging. University of Pennsylvania Perelman School of Medicine, USA

Most biology-oriented books misinterpret or lack an in-depth discussion of key biophysical aspects of arterial stiffness and pulsatile arterial hemodynamics. A proper understanding of the field requires both biologic/clinical and biophysical/bioengineering knowledge which *Textbook of Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease* provides in a comprehensive yet simplified manner. The resource is organized into five parts covering principles, physiology, biologic pathways, clinical implications, and therapeutics and provides a thorough overview of the field, presenting complex engineering concepts in a way that those in life science and medicine can more easily understand.

Textbook of Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease includes detailed illustrations and advanced bioengineering concepts presented in boxes for the reader who wants more in-depth biophysical knowledge. This is a must-have reference for students, researchers, and clinicians interested in learning more about this rapidly growing field.

Key features

- Provides a comprehensive review of the clinical implications of arterial stiffness and pulsatile hemodynamics and its role in human disease
- Incorporates mathematical principles explained in a conceptual manner without complicated formulas
- Features chapter contributions from leading international researchers and clinicians

Contents of Volume 2

30. Arterial stiffness and pulsatile hemodynamics in diabetes and obesity

Jordana B. Cohen, Stuart B. Prenner and Julio A. Chirinos

31. Cardiovascular risk prevention in clinical medicine: current guidelines in the United States and in Europe

Chee H. Liew and John W. McEvoy

36. Arterial stiffness and pulsatile hemodynamics in heart failure

Julio A. Chirinos

37. Ventricular—arterial coupling and arterial load in aortic valve disease

Ezequiel Guzzetti, Nancy Côté, Marie-Annick Clavel and Philippe Pibarot

38. Arterial stiffness and atherosclerosis: mechanistic and pathophysiologic interactions

Kazuomi Kario

39. Arterial stiffness and pulsatile hemodynamics in coronary artery disease and other forms of atherosclerotic vascular diseases

Junichiro Hashimoto

46. Arterial stiffness and pulsatile hemodynamics in congenital heart disease

Michael A. Quail

47. Infection and arterial stiffness

Vicente F. Corrales—Medina and Julio A. Chirinos

48. Arterial stiffness, hemodynamics, and microvascular complications in conditions characterized by low arterial pulsatility

Barry J. McDonnell, William K. Cornwell, III and Eric J. Stöhr

Section VI
Arterial stiffness and pulsatile hemodynamics in the pulmonary circulation

55. Pulsatile hemodynamics and ventricular–arterial interactions in the pulmonary circulation: physiologic concepts

*Berend E. Westerhof, Anton Vonk
Noordegraaf and Masafumi Fukumitsu*

Foreword

Ernesto L. Schiffrin, CM, MD, PhD, FRSC, FRCPC, FACP

Physician-in-Chief, Sir Mortimer B. Davis-Jewish General Hospital, Director, Hypertension and Vascular Research, Lady Davis Institute of Medical Research, Distinguished James McGill Professor and Associate Chair, Department of Medicine, McGill University, Montreal, Canada; Editor-in-Chief, The American Journal of Hypertension

Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease, edited by Julio A. Chirinos, MD, PhD, arrives to us at a time when the field of arterial stiffness has come full circle from experimental to clinical and therapeutic implications, including its potential applications to patients in the clinic. It is not an easy area of research and clinical understanding for most physicians, because of the physical and mathematical aspects that tend to be beyond their knowledge and typical clinical training curricula. Therefore, a text that fills the gap between biophysics, biology, physiology, clinical application, epidemiology, and therapeutics applied to a range of vessels throughout the body and different clinical conditions is certainly very welcome. In particular, it is important that the text is accessible to experts in different fields at all these levels, thanks to the ability to explain difficult concepts in detail but with clarity and some degree of simplicity, and that is what *Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease* does throughout its two volumes, with homogenous prose despite being multiauthored. Dr. Chirinos has managed to summon a group of writers for all chapters that comprises the "who's who" of the field of arterial stiffness and pulsatile hemodynamics from North America, Europe, Asia, and Australia.

The book is organized in sections that deal with successive aspects of vascular stiffness and its consequences. The first section addresses biophysical principles of pressure, flow, pulsatile hemodynamics, aortic structure, wall stiffness, and hemodynamic function. This is followed by a section on pulsatile hemodynamics of the arterial vasculature and its impact on the left ventricular function, and the microcirculation. The following section deals with the biology of arterial stiffening including associated effects on elastin, inflammation and calcification, and mechanisms of cellular aging, and dysfunction of smooth muscle and the endothelium. The clinical and epidemiological aspects of arterial stiffness and its role in cardiovascular prevention and different disease conditions, including hypertension, obesity, diabetes, heart failure, coronary artery disease, chronic kidney disease, cognitive decline, and pregnancy among others, follow in the next section. The primary aortopathies and conditions associated with low pulsatility such as use of left ventricular assist devices are described next. The following section addresses therapeutic implications of large artery stiffness and effects of exercise, weight control, and drugs, both presently in use and potential new drugs for the future. The last section addresses stiffening of the pulmonary circulation, including pulmonary hypertension.

Throughout this book the different authors manage to present complex concepts in a way that can be understood by the uninitiated, who could be expert in other aspects of this subject matter. Undoubtedly this is an authoritative textbook that will familiarize the biomedical community with the field, and facilitate the use of the knowledge acquired so far on arterial stiffness to improve patient outcomes.

This page intentionally left blank

Preface

The field of arterial stiffness and pulsatile hemodynamics has significantly expanded over the last few decades. Increasingly, epidemiologists, clinicians, engineers, and biologists recognize the importance of large artery stiffening in various disease states. The role of large artery stiffness and pulsatile hemodynamics in cardiovascular aging is also widely recognized. However, there remains a gap between the biophysical and theoretical concepts and clinical practice. The aim of this textbook is to provide a comprehensive reference on arterial stiffness and pulsatile hemodynamics, covering the intersection of clinical, biologic, epidemiologic, and biophysical concepts.

We intend for the audience of this book to be composed of clinical and basic science investigators interested in arterial stiffness, physicians and other healthcare providers, epidemiologists and biomedical engineers. Whereas excellent books are already available covering various aspects of this field, in many cases, these are highly specialized, are mathematically-oriented, are restricted to specific knowledge areas, or deal exclusively with clinical or biologic aspects without discussing hemodynamic mechanisms linking arterial stiffness and pulsatile hemodynamics with disease pathophysiology. Therefore, we intended to produce a book that introduces the interested reader to this field in relatively simple terms but at the same time covers, with reasonable depth, a broad range of relevant topics in biophysics, biology, epidemiology, and clinical medicine.

Despite the increasing recognition of this field, studies on arterial stiffness and pulsatile hemodynamics are often misinterpreted or underappreciated from a clinical standpoint. I believe that a proper interpretation of the field is nevertheless essential for a better understanding of multiple clinical conditions and disease states. One of the barriers to a better integration and data interpretation is that clinicians and biologists tend to be less familiar with the biophysical aspects of this field, whereas engineers naturally tend to be less familiar with the clinical and biologic aspects. Yet, a basic understanding of both is essential to drive the field forward and to adequately interpret available data. There is a need for a reference that: (a) presents complex engineering concepts in a readable format for individuals trained in clinical medicine, biology, or epidemiology rather than engineering; (b) clearly discusses the clinical implications of pulsatile hemodynamics

and arterial stiffness; and (c) provides a comprehensive review of key biologic pathways involved in arterial stiffening. This textbook intends to fill this gap.

Throughout the textbook, we utilize stand-alone basic concept boxes to deal with: (1) biophysics concepts that clinicians would be either be unlikely to be familiar with, but that would be very useful for understanding the topic; (2) clinical or biologic concepts that nonclinicians or non-biologists (i.e., bioengineers) are unlikely to be familiar but that are essential to understand the topic. We also utilize stand-alone "in-depth" boxes to develop more advanced concepts that clinicians or biologists are unlikely to be eager to study in depth due to relatively complex math or biophysics, even though a mathematically oriented person (such as a bioengineer) would find very useful. Stand-alone boxes are mentioned and are useful to understand the main text in the chapters, but should in general not be absolutely necessary to follow its flow. To the extent possible, mathematical principles are explained in the main text without complicated formulas, in a conceptual manner.

The book is organized into six sections. Section I deals with the biophysical and technical principles involved in the measurements and interpretation of pressure, flow, pulsatile hemodynamics, aortic structure, wall stiffness, and hemodynamic function, and is not considered optional but rather essential to better understand the rest of the book. Most of the content in this section deals with *in vivo* assessments, particularly in humans, but a dedicated chapter in this section deals with animal models and *ex vivo* methods to study arterial stiffness. Section II deals with basic anatomic and physiologic considerations, including the hemodynamic role of the aorta, pulsatile hemodynamics in the arterial tree, ventricular physiology, ventricular–arterial interactions (as they relate to both load and myocardial oxygen supply), and the microcirculation. Section III deals with the biologic pathways leading to arterial stiffening and dysfunctional pulsatile hemodynamics, including elastin breakdown and associated processes, inflammation, aortic wall calcification, smooth muscle dysfunction, endothelial dysfunction, autonomic dysfunction, and cellular mechanisms of aging. Section IV deals with clinical and epidemiologic aspects of arterial stiffness and pulsatile hemodynamics, including normal,

supernormal, and early vascular aging, ethnic differences, and the role of arterial stiffness in cardiovascular prevention strategies and in various disease states, such as hypertension, obesity, diabetes, exercise intolerance, heart failure, aortic valve disease, coronary artery disease, age-related cognitive dysfunction, chronic kidney disease, pregnancy related complications, congenital heart disease, and the cardiovascular complications of infectious diseases. Additional chapters deal with relevant aspects of primary arteriopathies and clinical situations associated with low arterial pulsatility (particularly, implanted left ventricular assist devices). Section V deals with therapeutic approaches to improve arterial stiffness and pulsatile hemodynamics, including discussions of standard vasoactive drugs in current use, as well as novel drugs, nonpharmacologic approaches (exercise training, diet), and personalized medicine strategies. Finally, Section VI deals with the pulmonary circulation, with an emphasis on pulmonary arterial stiffening, right ventricular—pulmonary arterial interactions, and pulmonary hypertension.

Throughout this book, we intend to discuss the relevant biophysics, presenting complex engineering concepts in a simplified format. Similarly, we intend to place the importance of arterial stiffness in the appropriate clinical context, ultimately keeping in mind how this field can aid in patient care and development of novel therapies. I have been extremely fortunate to have the support of a large number of internationally recognized experts, who have selflessly contributed their time, effort, and deep expertise to write the various chapters in this book, providing authoritative reviews about the state-of-the-art in their respective topics. I hope that this textbook will help advance the field, that it will be an aid to educators in this field, and that it will contribute to the training of the next generation of investigators dedicated to the study of arterial stiffness and pulsatile hemodynamics.

Acknowledgments

I want to thank the chapter authors for selflessly contributing their time and expertise for the success of this project. I am forever grateful to Melissa, Gabriella, and Daniel Chirinos for their support throughout this project, and to my parents, Julio Chirinos Pacheco and Josefina Medina, for being such inspirational role models. I also want to acknowledge my academic home, the Cardiovascular Medicine Division at the University of Pennsylvania, for strongly supporting my career and the various academic activities that led to the edition of this book. My very special thanks to my colleagues at the University of Ghent (particularly Ernst Rietzschel, Thierry Gillebert, Patrick Segers, and Marc De Buyzere) for many years of wonderful collaboration, and to the North American Artery, ARTERY, Pulse of Asia, and Latin American Artery societies for providing platforms for the advancement of this important field. I am also grateful to the National Institutes of Health (NIH) which supported my work through multiple awards throughout the years, particularly the National Institutes of Aging which provided me with a mid-career development award to study large artery stiffness and arterial aging (K24-AG070459). I am indebted to Dr. Patrick Segers for going above and beyond his chapter writing, providing critical feedback for several other sections of the book. I also want to acknowledge the essential contributions by the many senior investigators, who although did not participate in the book, inspired or motivated many of us, including but not limited to Wilmer Nichols, Nico Westerhof, Michael O'Rourke and Michel Safar, as well as John Cockcroft, who has worked relentlessly to promote the field in Europe and the US, and Alfonso Bryce, Pedro Forcada, Eduardo Barbosa and Enrique Melgarejo, who have done the same throughout Latin America. Last but not least, my gratitude goes to the editorial team at Elsevier for their guidance and help throughout this project.

Preamble

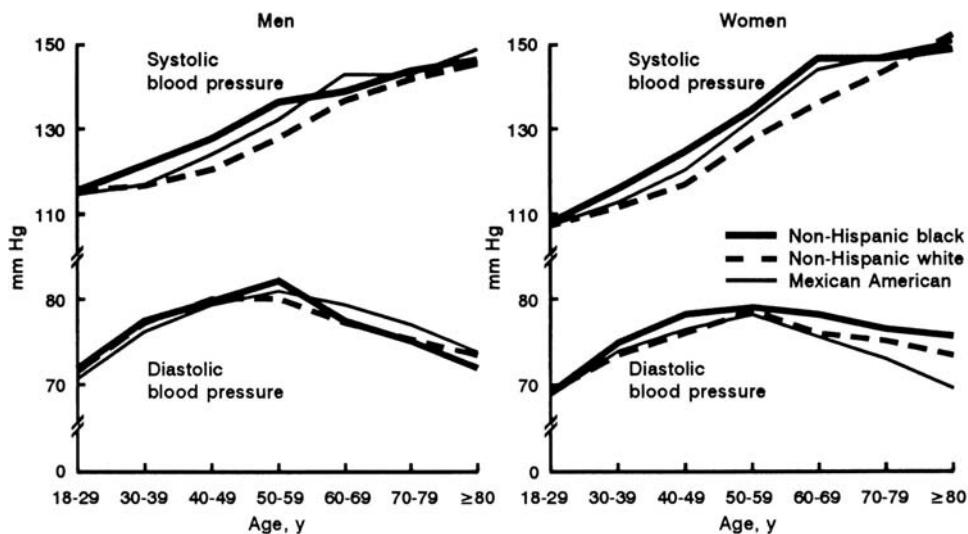
In the absence of a single "true and comprehensive" measure of this phenomenon, a plethora of parameters have been put forward, all very partially and incompletely describing different aspects of the underlying process of "arterial aging," While this chapter describes the insights gleaned from some of the more well-studied of these parameters, these limitations are best kept in mind to avoid the pitfall of reductionism of the aging process toward a single imperfect parameter.

Insights from cross-sectional epidemiological and cohort data

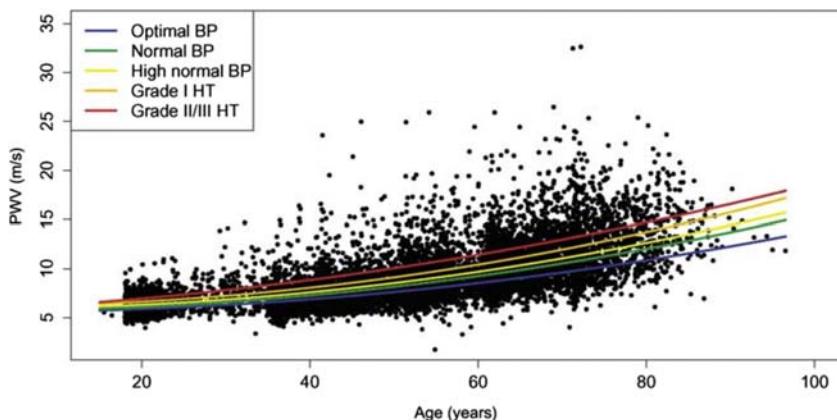
Blood pressure and pulse wave velocity

Aging is complex, and although many mechanisms are implicated, fragmentation of elastin, one of the most abundant extracellular matrix proteins in the arterial wall (representing 50% of its dry weight) is certainly a key process.[1] Elastogenesis is restricted to fetal life and infancy, and any damage—be it proteolytic, mechanical, or other—that does occur with age and disease is essentially irreparable. Elastin in the arterial wall has an estimated half-life of approximately 40 years.

Unsurprisingly, it is a common belief in physiology that from the fourth decade of human life, aging of the arterial tree takes a direction from which it does not recover anymore, neither in the apparently healthy individual nor in the diseased.

Aortic strain and distensibility sharply decline from the third to the fifth decade; a process mirrored by a rather steep increase in carotid-femoral pulse wave velocity (cf-PWV) which however lags by one or two decades (i.e., steep rise beyond age 50). In concert, albeit not necessarily causally linked, peripheral resistance and DBP increase.


Observations from the different cohorts of the Framingham Heart Study, which have been consistently confirmed in other settings, convincingly demonstrated that after the fifth decade an (increased) diastolic blood pressure (DBP) is no longer a leading blood pressure marker of arterial aging, but that systolic blood pressure (SBP) and pulse pressure (PP) rather aggressively take the lead, because DBP tends to decrease as aortic stiffness increases (Fig. 26.1).[2,3]

Pulse wave velocity (PWV) is—besides blood pressure—one of easiest to measure and most studied parameters for which data are available from early childhood until old age.


The Reference Values for Arterial Stiffness' Collaboration pooled data on 16,867 subjects from 13 different research samples across eight European countries.[4] Of these, some 11,000 subjects were free from overt cardiovascular disease (CVD), nondiabetic, and untreated either for hypertension or dyslipidemia. This collaboration was sufficiently powered to provide robust reference values for adults within the age range of below 30 years to above 70 years, and across blood pressure strata including subjects with optimal/normal blood pressures.

The increase of cf-PWV with age could best be modeled by a quadratic function with the importance of the quadratic term increasing at higher age and at higher levels of operating blood pressure. To illustrate, the increase in average cf-PWV between the ages of 30 and 40 years was ∼0.3 m/s, while between the ages of 60 and 70 years, this was roughly double (∼0.6 m/s). PWV at any age is linearly related to BP and correspondingly at any BP level is dependent on the quadratic age. The slope of the relation between age (and MBP) and PWV increases by 1.5-fold between the younger/lower BP and the elderly/higher BP, a finding which was already previously well described (Fig. 26.2).[5,6]

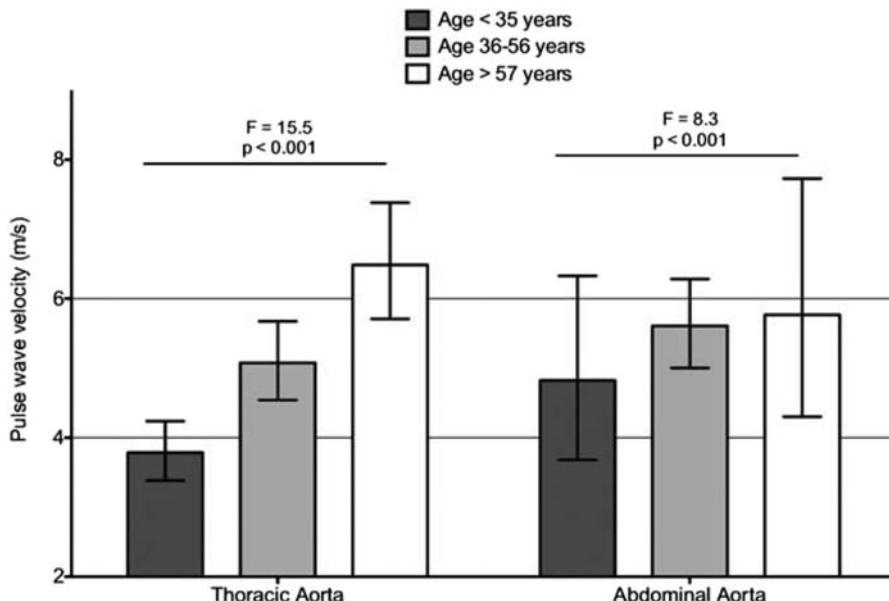
Modeling of the data could be greatly simplified because in the models there was no important residual influence of either smoking, dyslipidemia, or sex (a 0.1 m/s higher average in men) after correction for age, quadratic age, and mean blood pressure. This lack of a sex difference in cross-sectional data is in striking contrast to the longitudinal data (see below) (Fig. 26.3).[7,8]

There are some limitations to these reference data; a major limitation of this collaborative effort was the almost entirely Caucasian race of the subjects. Furthermore, data described above refer to carotid-femoral PWV, and might not be easily extrapolated to other PWV measures encompassing arterial path lengths substantially beyond the aorta (e.g., brachial-ankle PWV, cardiac-ankle vascular index, etc). Recent insights from magnetic resonance imaging (MRI) are highly informative in this regard, as MRI allows not only for precise calculation of arterial path lengths but also opens the possibility of measuring segmental PWV over various subsections of the aorta,

including sites less easily accessible by ultrasound. In a sample of healthy volunteers aged 20 to 80 years, thoracic aortic PWV (the more elastin-rich segment of the aorta from the heart to above the diaphragm) showed a far steeper age increase in PWV than the more muscular abdominal aorta (see Fig. 26.4).[9]

Cross-sectional wave reflection data


Mitchell et al. and Torjesen et al. have described cross-sectional sex-specific evolutions with aging of reflection-related parameters within the framework of the Framingham Heart Study.[10,11] In their 2004 data, with advancing age (>50) the forward wave amplitude increased in contrast to the reflected wave amplitude which remained rather stable. These cross-sectional observations may suggest (cave: see also longitudinal trajectory studies below) that the forward pressure wave drives the age-related increase in (central) SBP and PP. Moreover, with aging the role of

Table 5 Distribution of pulse wave velocity (PWV) values (m/s) in the reference value population (11 092 subjects) according to age and blood pressure category

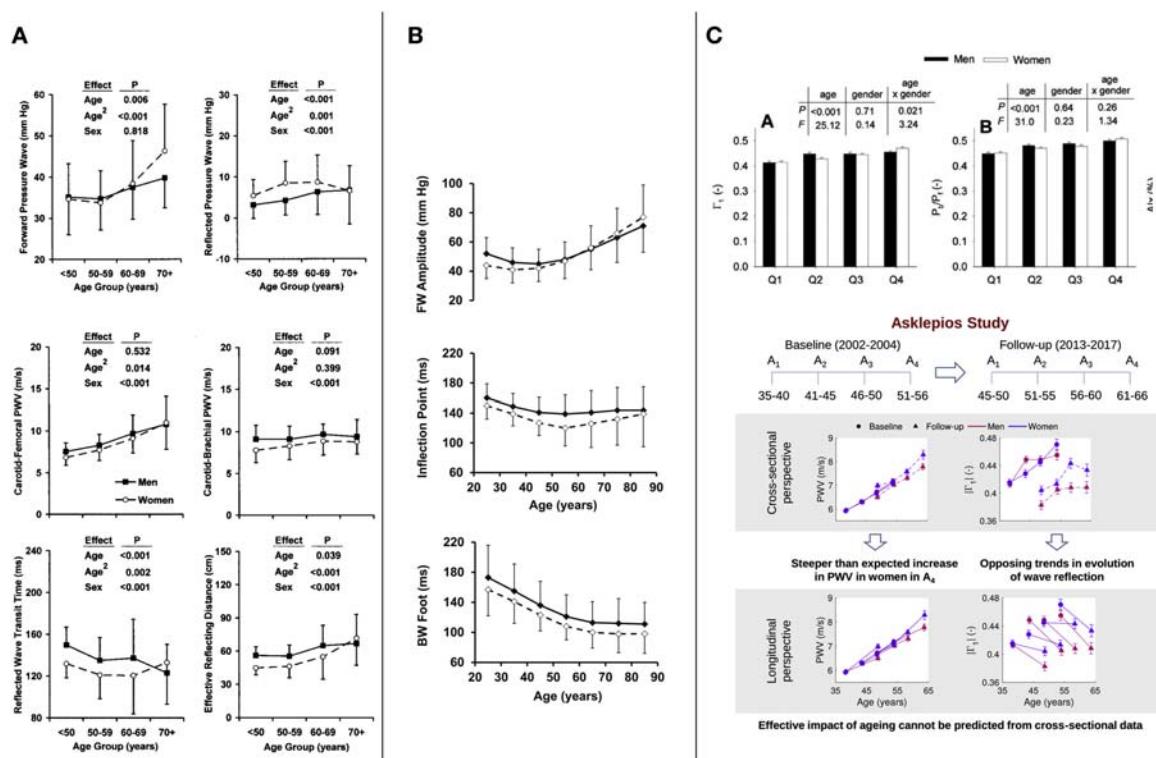
central arterial stiffness seems to be more prominent (no steep rise in carotid-brachial PWV with aging). Reasoning with the concept of a "theoretical single effective reflecting site," effective reflective distance increased with aging in both sexes but was minimally determined by height in women. This is however a controversial issue (see studies by Phan et al.[12,13]) which is further complicated by their sex-specific evolution of reflected wave transit time (RWTT) (increasing in women after age 50 and decreasing in men).

In the 2014 cross-sectional Framingham data, after age 50, the increase of the forward wave amplitude has been confirmed with relatively small variations in the timing of the inflection point and a sharp decline of the timing for the backward wave foot. As a consequence, after

midlife, the timing of the inflection point was later than that of the backward wave foot. Sex differences could be partially explained by the characteristics of the LV ejection phase and morphology of the backward wave (cave: see studies by Phan et al. for a different interpretation of the data, below).

In the framework of the ASKLEPIOS Study, Segers et al.[14] described the cross-sectional effects of sex and age on wave reflection parameters. Both the wave reflection coefficient derived from impedance analysis and the ratio of backward to forward pressure wave amplitude increased from age 35 to 55 with little or no sex differences. However, evolution of the reflection parameters over a 10-y trajectory (Round 2 ASKLEPIOS) revealed more accentuated sex differences with even opposing trends in the evolution of wave reflection! (see below).[15] Thus, the effective impact of aging on arterial system properties, in a middle-aged population, might not be well reflected by cross-sectional studies, which implies a compelling need for longitudinal studies and for reasoning in early and adult life trajectories (Fig. 26.5).


Insights from longitudinal cohort data: the early life trajectory

There is a substantial wealth of epidemiological data studying children which are subsequently reexamined in (young) adulthood suggesting that genetics, the fetal phase, and childhood risk factor burden jointly determine a blood pressure/arterial stiffening trajectory that persists later in life above and beyond the adult risk factor burden.

Beyond the impact of birth weight, gestational diabetes and hypertensive disorders of pregnancy have been implicated in programming higher offspring blood pressure trajectories.[16] The differences in blood pressure between offspring of hypertensive pregnancies and offspring of normotensive pregnancies persisted across childhood and through adolescence. Importantly, higher maternal blood pressure early in the pregnancy was found to have a larger impact than pregnancy related blood pressure changes.[17] Furthermore, higher offspring blood pressure in childhood was present in the absence of other vascular alterations or metabolic derangements, suggesting shared mother-offspring risk factors for higher blood pressure rather than the additional cardiometabolic abnormalities of hypertensive pregnancies being causal for the long-term consequences for the offspring.[18]

Tantalizing trajectory evidence also comes from genetic data looking at the fundamental question whether "blood pressure begets (increasing) blood pressure," i.e., whether higher blood pressure is associated with the higher *rate of change* of blood pressure over time. Ference at al. evaluated the effect of 12 polymorphisms associated with lower SBP on the age-related rate of rise in SBP in a series of

FIGURE 26.5   Panel A and B depict Framingham data adapted, respectively, from Mitchell et al.[10] and from Torjesen et al.[11] Panel C depicts Asklepios data from Segers et al. (upper part)[14] and Campos-Arias et al. meta-regression analyses involving 199,477 participants in 63 studies.[19] Evaluating the effect of higher or lower SBP mediated by polymorphisms provided a naturally randomized (Mendelian) and therefore unconfounded estimate of the causal effect of SBP on the usual age-related rise in SBP. The authors found that randomly receiving polymorphisms associated with lower SBP was also independently associated with a slower rise in SBP over time, suggesting that SBP is causally related to the rate of rise in SBP with age. Fig. 26.6 illustrates that the blood pressure lowering effect increases with age at which the cohort is investigated. These findings are quite distinct from the genetics of other cardiovascular risk factors such as, for example, low-density lipoprotein (LDL) cholesterol where genetics provide a "set point" which does not evolve over time. The findings by Ference at al. suggest that we are inherently genetically programmed to be on a blood pressure (and very likely arterial aging/stiffening) trajectory by default.

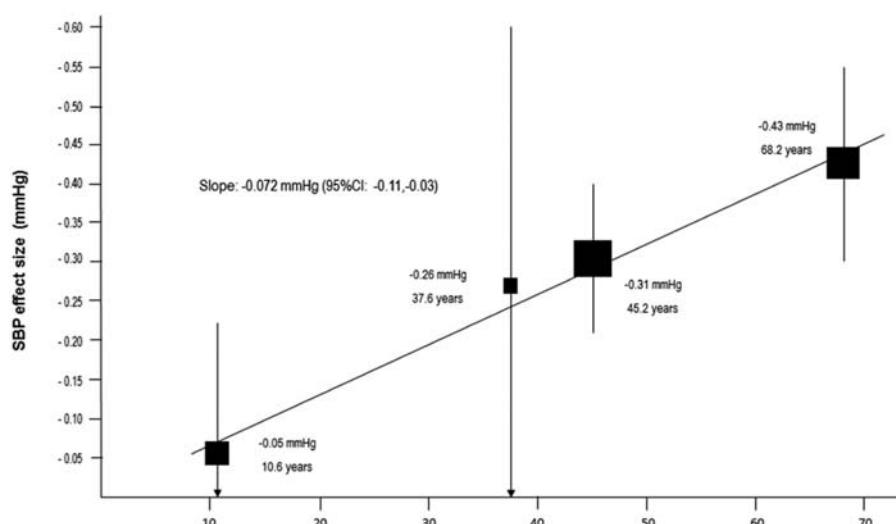
A number of pivotal studies, among which (but not limited to) the Bogalusa Heart Study, the Atherosclerosis Risk in Young Adults (ARYA) Study, Childhood Determinants of Adult Health, Muscatine Study, and the Cardiovascular Risk in Young Finns Study provided major insights between childhood exposure to risk factors an adult arterial status.


The Cardiovascular Risk in Young Finns Study investigated the cohort of 3696 children, initially investigated in 1980 when they were between the ages of 3 and 18 years. Follow-up studies were conducted in childhood in 1983 and 1986 and in adulthood in 2001 and 2007, respectively, 21 and 27 years after the initial examination. This pivotal cohort was phenotyped in depth and comprised a broad spectrum of markers of arterial aging comprising (but not limited to) intima-media thickness, cf-PWV, and carotid

distensibility, thereby often linking, confirming, and extending results from other cohorts.

Childhood risk factor burden, defined by exceeding the age- and sex-specific 80th percentiles of, respectively, LDL cholesterol, blood pressure, or BMI, or cigarette smoking, was associated with adult intima-media thickness 21 years later even after adjustment for adult risk factors.[22] Subsequently this finding was extended using a broader childhood risk factor construct, adding low HDL cholesterol, diabetes, low physical activity, and infrequent food consumption to the previous four risk factors. Juonala et al. demonstrated a persisting accelerated IMT progression in adulthood related to the childhood risk factor burden, independent of the adult risk factor burden.[23]

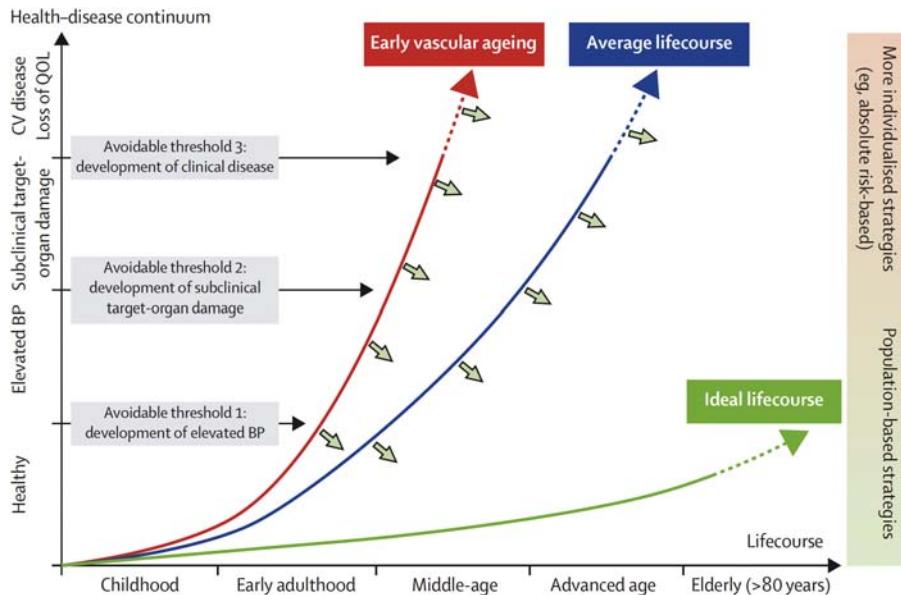
Interestingly, a more in-depth analysis of the impact of the age at which the childhood risk factors were measured on adult IMT was conducted by pooling data from the Cardiovascular Risk in Young Finns, Childhood Determinants of Adult Health, Bogalusa Heart Study, and Muscatine Study. In these pooled analyses on 4380 subjects, adjusted odds ratios for elevated intima-media thickness progressively increased with the childhood age at which the risk factor burden was measured, becoming significant from the age of 9 years onwards and failing to reach statistical significance for risk factor burden measured at ages six or below.[24]

Childhood risk factor burden (such as high LDL cholesterol, low HDL cholesterol, elevated blood pressure, skinfold thickness or BMI, high triglycerides, smoking, and glucose levels) and lifestyle factors such as lower childhood fruit and vegetable intake and lower levels of childhood physical activity have been linked to higher adult cf-PWV[25−27] and carotid stiffness measures.[28,29] However, these findings were not universally replicated, e.g., in the ARYA Study, no association between adolescent blood

FIGURE 26.6 Association between effect of exposure alleles and systolic blood pressure (SBP) measured at different ages. Boxes represent the combined weighted mean effect of 10 exposure alleles on SBP (mm Hg) measured at four different ages: 10.7 and 38.7 years in the Young Finns Cohort[20] and 45 and 68 years in the Malmö Preventive Project.[21] Vertical lines represent 95% confidence interval (CI). The line represents the absolute increase in the combined effect of these 10 polymorphisms on SBP per year of increasing age. *From Ference BA, Julius S, Mahajan N, Levy PD, Williams KA, Flack JM. Clinical effect of naturally random allocation to lower systolic blood pressure beginning before the development of hypertension.* **Hypertension**. *2014; 63:1182−1188.*

pressure and adult PWV was observed. This controversial result could be at least partly explained by differences in blood pressure measurement methods as they used only single measurement from school health records rather than measured blood pressure using the same protocol in the entire cohort.[30]

Beyond traditional cardiovascular risk factors, and lifestyle, socioeconomic status and adverse childhood experiences (ACEs), have also shown to have a long-term deleterious impact. In the Georgia Stress and Heart Study, ACEs such as emotional, physical or sexual abuse, physical or emotional neglect, household dysfunction (substance abuse, mental illness, domestic violence, presence of a criminal household member, and parental marital discord) before the age of 18 years were collected in a cohort where blood pressures were measured 13 times on average over a 23 year period.[31] Individual growth curve modeling within a multilevel framework was used to examine the relation between exposure to ACEs and BP development. The authors observed that participants who were exposed to multiple ACEs displayed a graded and greater increase in BP levels in young adulthood compared with their counterparts without ACEs. Interestingly, Kivimäki et al. suggested that early socioeconomic disadvantage influences later blood pressure in part through an effect on blood pressure in early life, which tracks into adulthood, but also in part through an effect on BMI.[32]

Finally, in the Cardiovascular Risk in Young Finns Study, better childhood socioeconomic status was linked to lower arterial stiffness (lower cf-PWV and higher carotid distensibility) in adulthood independent from childhood cardiometabolic risk factor burden[33]


All in all, the long-term follow-up of these childhood cohorts produced a remarkably broad and consistent set of findings which show a persistent and *ongoing* effect of a broad spectrum of childhood risk factors in (early) adulthood above and beyond the risk factor burden in adulthood.

In summary, exposure to risk factors, major life stresses or an unhealthy lifestyle in childhood results in a clear, persistent, and likely progressive adverse effects on vascular health in adulthood. Similarly, a lifelong striving to achieve and maintain the lowest possible cardiovascular risk factor burden (ideal cardiovascular health) is likely to translate into a substantially "better" arterial aging trajectory.

These concepts form part of the underpinnings of the vision from the Lancet Commission on hypertension which envisages a life course strategy to address the global burden of raised blood pressure.[34] Focusing on the life course of an individual, the sum of preventive measures is to try to shift an individual toward an ideal life course, starting with population-based strategies (public health approaches) from birth (e.g., every child should ideally leave school as a health literate adult). Based on the life course of the individual crossing a number of avoidable thresholds such as the development of elevated blood pressure, development of subclinical target organ damage, or the development of clinical disease, these population-based strategies are then augmented by individualized strategies tailored to the individual's needs and risk (Fig. 26.7).

A call to action and a lifecourse strategy to address the global burden of raised blood pressure on current and future generations: the Lancet Commission on hypertension.* **Lancet**. *2016; 388:2665–2712.*

Insights from longitudinal cohort data: the adult life trajectory

Manifestations in middle-aged and aged individuals

One of the many merits of BLSA Study is that it drew the attention of the Hypertension Society that a prediction model of incident hypertension by a greater aging-induced cf-PWV and an increased SBP is a far too simple a model.[7] The BLSA authors' linear-mixed models and also those from the SardiNIA Study based on trajectories of repeated measurements of cf-PWV and SBP clearly revealed sex-specific diverging trajectories over time of rates of SBP (PP) versus rates of PWV.[8] In women the rate of change of SBP with age is merely constant, whereas the rate of change of PWV is steadily increasing. Men show a completely different course; an initially increasing rate of change of SBP which rapidly slows down during the fourth decade. The inversed U-shaped form for the rate of change of SBP is not mirrored by the trajectory for the rate of change of PWV. The latter showing little or no sex dependency.[35]

Whether or not the sex differences in rates of change of SBP have long-term consequences on the development of heart failure and hard CV events is a matter of debate. Nonetheless preliminary data from BLSA suggest that there is a progressive arterial–ventricular uncoupling (ratio of arterial elastance and end-systolic LV elastance) with aging that is more pronounced in women. More specifically, over time the rate of change (increase) of the arterial component was faster than the rate of increase of the ventricular component.[36] The trajectory of change of the arterial component was largely sex-independent whereas in women the trajectory of change of the ventricular component was at a slower pace. AlGhatrif et al. (BLSA data) further concluded that loss of arterial compliance (TAC) was the main determinant of subject-specific rate of change of AV uncoupling.[36] Moreover, progressive AV uncoupling occurred with aging and was more pronounced in women and was inversely associated with rates of changes of end-diastolic volume and stroke volume and directly associated with rate of change of end-systolic volume. As the ratio of the elastances can be approximated by ESV/SV, maintained coupling is mostly associated with a longitudinal increase of SV and a smaller increase of LV end-systolic volume. However, the smaller increase of end-diastolic volume over time is all but intuitive as one could expect commensurate increases with end-systolic volume to maintain a favorable position on the Frank–Starling curve (maintenance of cardiac output).[37] AlGhatrif et al. considered failure of end-diastolic volume to sufficiently increase a pivotal early consequence of AV uncoupling.[36] Thus, the uncoupling might be a sign of deviation from normal physiology preceding (diastolic) heart failure.

Ejection fraction

E_a/E_{es} can* also be written as (EDV-SV)/SV or (1/EF)-1, from which

$$EF = \frac{1}{1 + \dfrac{E_a}{E_{es}}}$$

Most energy-efficient coupling happens when $E_a/E_{es} = 0.5$ giving an $EF = 0.67$; with progressive uncoupling and increase of E_a/E_{es}, EF declines. Many clinicians usually misinterpret ejection fraction (EF) as a cardiac function parameter while it rather reflects coupling.

* with the assumption of the intercept of end-systolic pressure-volume relationship being zero.

Obviously, the ventricle can no longer match the increase in arterial elastance at a certain stage of aging.[38] Of interest, conflicting results have been published with even a longitudinal decline of the arterial component.[39] The physiology underlying arterial and ventricular aging might be counteracted by pharmacological interventions. As a consequence, analysis of cross-sectional data might not be the best way to get insights into the natural history of arterial stiffness, and longitudinal studies might come up with different results (See also below, insights from the second round in the ASKLEPIOS Study).[14,15,40] In BLSA, this is nicely illustrated by sex differences in baseline coupling (ratio usually lower in women) but a higher rate of increase in the ratio, mainly driven by smaller increase of ventricular component, among women.

Data from the first round[14] and recent novel insights from the second round[15] of the Belgian ASKLEPIOS Study may reconcile those apparently diverging sex-specific trajectories. Characteristic impedance (Zc) expressing "impedance to flow" and integrating the concepts of proximal aortic stiffness (PWV) and aortic diameter (dilatation) might be the key to the enigma. Given the comparable rates of change of PWV between the sexes and lower Zc in men versus women, sex-specific changes in aortic diameters with age are very likely involved (in concert with the water hammer principle; please refer to Chapters 1 and 3 for a discussion of this principle). The lower Zc in men has been confirmed in the first round of the ASKLEPIOS Study whereas BLSA has documented steeper increases of aortic diameters with age in men.

Effects of aging on wave reflections

In the Framingham Heart Study, increased forward wave (Pf) amplitude has been incriminated as a major determinant of increasing PP with aging whereas wave reflections were supposed to play a less prominent role. An expert group headed by Mitchell[10,41,42] have introduced mismatch

between peak aortic flow and proximal aortic root properties (geometry and function) as one of the possible explanations for those findings (impedance matching and mismatching).[43,44] Their concept started with observations in systolic hypertension: elevated PP independent of mean arterial pressure and attributable primarily to elevated Zc and reduced effective diameter of the proximal aorta. In the Framingham cohort, an age-related increase in aortic stiffness, as compared with peripheral arterial stiffness, was associated with increasing forward wave amplitude and PP and reversal of the arterial stiffness gradient. Subsequently higher forward pressure wave amplitude (a measure of proximal aortic geometry and stiffness) was associated with increased risk for incident CVD, whereas mean arterial pressure and relative wave reflection (correlates of resistance vessel structure and function) were not associated with increased risk for incident CVD. Also in the multiracial population-based Dallas Heart Study, evidence for a mismatch between proximal aortic stiffness and diameter in young and middle-aged adults with isolated systolic hypertension could be documented.[45]

An important limitation of using the "stiffness gradient" as to support the concept of impedance matching with aging is that vessel impedance is dependent more prominently on vessel size rather than vessel stiffness (as discussed in Chapters 1, 3 and 11). Moreover, the impedance matching at bifurcations is highly influenced by the area of the parent vessel versus the summed area of the daughter branches, which tends to minimize wave reflections in first order (aortic) bifurcations even before age-related aortic stiffening ensues.[46,47]

However, in 2016 Phan et al. revisited some of the prevailing hypotheses.[12,13]

First, they started from earlier literature data of earlier return of reflected waves contributing to elevated PPs.[14] They emphasized the uttermost importance of the so-called rectified wave reflections defined as backward waves that re-reflect at cardiac structures and thereafter will propagate as forward waves. They demonstrated that with increasing arterial stiffness (in essence a higher PWV) rectified reflections should play a more dominant role. Thus, in the natural history of aging, rectified waves may contribute beyond and above the concept of classically defined forward waves. However, one should bear in mind that in reality forward waves should comprise part of the rectified propagating waves. In their experiments at low amounts of reflections in humans, indeed Pf nearly approximates the product of aortic flow and Zc. At more realistic and higher amounts of reflections, the divergence between Pf and this

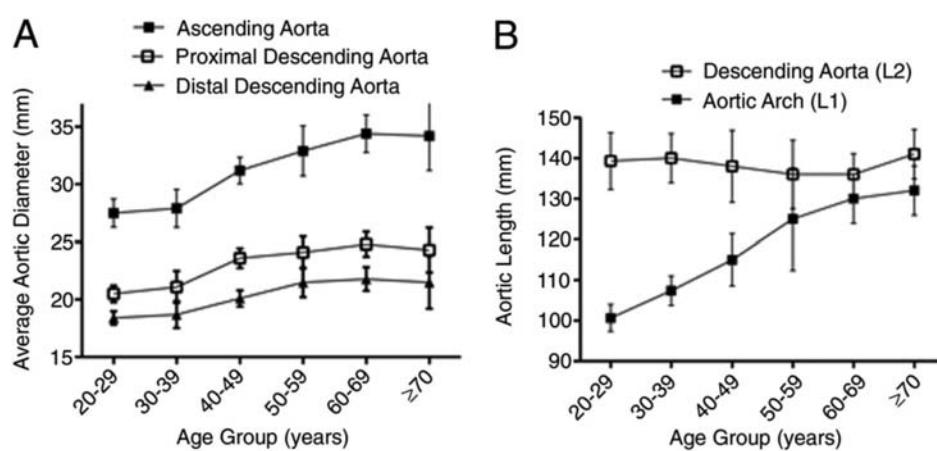
product becomes larger and larger. Moreover, the backward traveling waves also harbor both impedance matches and mismatches. Phan et al. concluded that elevated (and even earlier, see below) wave reflections contribute to increase of PP with aging without the compelling need to introduce the concept of altered proximal aortic properties. In addition, with increasing stiffness (PWV) even repeated re-reflection will occur resulting in a wider and more peaked forward wave. Thus, one should not overestimate the role of proximal aortic morphology and function in the natural history of aging of the arterial tree and more particularly one should not underestimate the role of rectified waves.

The major limitation for the validation of the work of Phan et al. is the absence of sex-specific results and experiments. Do the observed sex-specific interactions between changes of PWV and SBP (PP) with aging in the linear-mixed modeling of the SardiNIA and BLSA trajectories invalidate the experiments by Phan et al.?[12,13] (Data from the second round of the ASKLEPIOS Study might be key to reconcile available data, as discussed below).

Second, the same authors (Phan et al.[12,13]) further extended their insights into the physiology behind reflected waves in the natural history of aging. They demonstrated that the aging process is characterized by an earlier arrival of reflected waves without a distal shift in reflection sites. It is at odds with a common belief[48] and some observations in the Framingham Study of a shift of the reflection sites to more distal locations at advanced age. Those researchers further assumed an impedance matching of central and muscular peripheral arteries allowing swift albeit deleterious energy transfers to the smaller arteries and the microcirculation. The distal shift hypothesis has arisen from an unproven assumption (suspicion) that the RWTT should remain closely associated with the timing of the inflection point (Tinf) during the natural history of aging. However, there is little evidence from the point-of-view of physiology that the assumption would hold true.[49,50]

Phan et al. studying unselected adults and some elderly CVD patients reported on a remarkable expanding dissociation with both age and stiffening of arteries (increasing PWV) between Tinf (nearly constant over time) and RWTT (dramatic decrease).[12,13] Further application of basic rules of physiology infers that effective reflection distance (ERD = 0.5 × RWTT × PWV) should not increase. On the contrary there was a tendency that in both healthy and unhealthy individuals, the apparent ERD was moving into the direction of the heart with aging! It should be noted, however, that the ERD is a purely theoretical construct (a single reflection site), and not anatomically valid, given the

prominent phase shifts at reflection sites, as reviewed in Chapters 1, 3 and 11.

What are the consequences?


-   Wave reflections will increase the pulsatile load with aging, which might translate into diastolic dysfunction, left ventricular hypertrophy/remodeling, and new-onset (diastolic) heart failure. Thus, earlier arrival of wave reflections at the proximal aorta might be deleterious for the heart and the brain.
-   From an epidemiological point-of-view, the earlier return of reflected waves is in line with earlier described characteristics of input impedance with increasing age: (i) shift of the modulus minimum, (ii) shift of the phase zero-crossings to increasing frequency, and (iii) impedance modulus setting around Zc with increasing frequency.

Is there agreement or disagreement between the ASKLEPIOS Study data and trajectories of PWV and SBP (PP) in BLSA and SardiNIA? In the second round of the ASKLEPIOS Study, overall, the effective 10-year increase in cf-PWV was less than expected from first round cross-sectional data, and cf-PWV was found to accelerate more in women than in men.[15] Interestingly, the increase in PWV was not paralleled by a decrease in arterial volume compliance, particularly in younger males. Aortic root characteristic impedance decreased with age in younger subjects while it increased for the older subjects in the study. These changes suggest that aortic dilation and elongation may play an important role determining the longitudinal age-related changes in impedance parameters in middle-age. Wave reflection decreased with aging, whereas resistance increased in women and decreased in men (Fig. 26.8).

Conclusions

One of largest paradigm shifts over the last decades in epidemiology and preventive medicine is that unsuccessful aging does not start in middle-aged individuals with an already accumulated risk factor burden heralding "the eve of destruction": prevalent target organ damage and incident hard cardiovascular events. Unsuccessful aging starts earlier, much earlier. Accumulation of risk starts intra-uterine and progressively continues during childhood and adulthood. Therefore, the Lancet Commission on hypertension has launched the idea of a lifelong striving to achieve and maintain the lowest possible cardiovascular risk burden. A considerable part of the evidence comes from early life trajectories obtained in childhood cohorts (e.g., Young Finns, Bogalusa Heart Study, Muscatine, and CDAH) all pointing into the same direction that childhood risk factors add up over and above the risk factor burden accumulated in adulthood.

Separate population-based studies (e.g., NHANES III) and adult life trajectories (e.g., BLSA, SardiNIA) over decades allowed for mixed linear modeling and identified some sex-specific longitudinal changes of SBP and PWV (two parameters of particular interest for the description of normal aging and with well-documented reference values). In this chapter, from physiology point-of-view, we discussed the contributions of ventriculo-arterial coupling, characteristic impedance and wave reflection parameters (forward, backward, and rectified waves) in some large population-based cohorts (e.g., Framingham, Dallas Heart, Asklepios). Moreover, we tried to understand and rectify two misunderstandings in the field of aortic stiffness: (i) the overestimated role of the geometry and function of

FIGURE 26.8 Panel A depicts average aortic diameters (ascending, proximal descending, distal descending) for age groups by decade. Panel B depicts estimated aortic lengths for age groups by decade. *L1*, length of the aortic arch; *L2*, length of the descending aorta. *From Redheuil A, Yu W-C, Mousseaux E, et al. Age-Related Changes in Aortic Arch Geometry. **J Am College Cardiol.** 2011; 58:1262–1270.*

the proximal aorta in the process of normal aging and (ii) the unrealistic shift away from the heart of reflection sites during normal aging. Finally, we tried to reconcile the apparently conflicting data from observational studies by more unifying suggestions derived from recently published novel insights from round two of the Asklepios Study.

Chapter 27

Early vascular aging and supernormal vascular aging: genetics, epigenetics, and the environment

Peter M. Nilsson[1] and Stéphane Laurent[2,3,4,5]

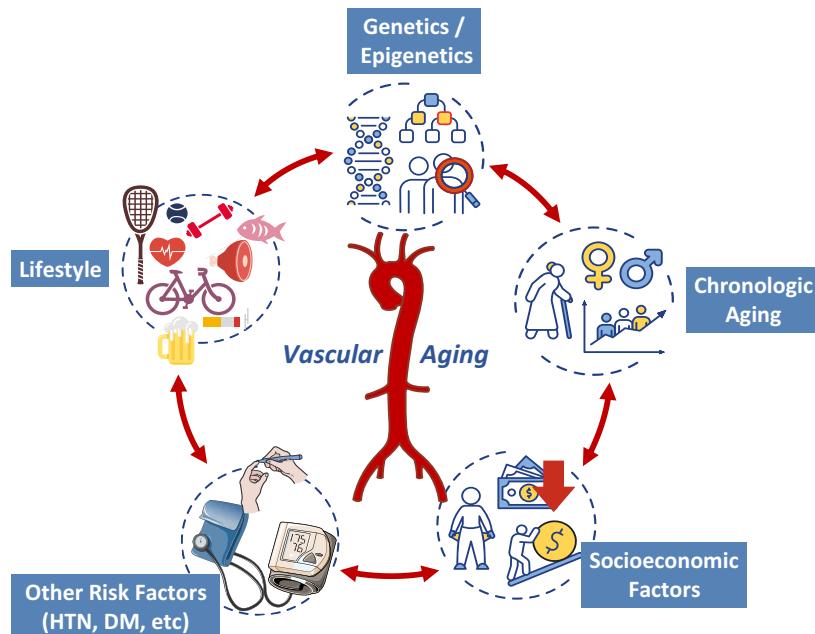
The background and characteristics of early vascular aging

The vascular tree, its morphology and function, is shaped by evolution and subject to different positive or negative influences during the life course of an individual reaching senescence.[1] Factors acting early in life, even before birth, are of importance for the development and structure of the vascular system, most notably for the wall of the large elastic arteries,[2] but also for smaller arteries and the capillary density, both influencing central hemodynamics.[3] This programming effect, that involves postnatal growth patterns,[4] may also be relevant for metabolic function and the risk of insulin resistance and later on type 2 diabetes, factors that are often linked to vascular changes and increased cardiovascular disease (CVD) risk. As this risk in general is clearly age-related, it is of interest to understand if these factors acting early in life could also be instrumental, or mirror, processes that regulate the aging of organs and the body as a whole. One argument to support this is that the increasing longevity of people in western populations are influenced not only by habits, economy, and social factors but also to a large extent by improved conditions for pregnant women, better birth outcomes, and lower perinatal mortality during the 20th century. In fact, fatal cardiovascular events are now becoming less prevalent. The burden on nonfatal events has increased and thus the prevalence rate of CVD as more patients survive into old age. Still, however, some individuals suffer from early onset cardiovascular events and early biological versus chronological aging,[5] a process that is relevant to the early vascular aging (EVA) concept.[6] Of special relevance is the postnatal catch up growth[4] when small babies grow to become overweight or obese adults when the risk of vascular aging (VA) is increased.[7]


Atherosclerosis versus arteriosclerosis

Genetic factors affect the development of the arterial system and the regulation of blood pressure that is a driving force behind hypertension, and this may in turn interact with vascular remodeling, i.e., functional and structural changes of the large and small arteries. Later on *atherosclerosis* may develop, starting in the arterial intima and leading to plaque formation and risk of thromboembolism and cardiovascular events, a well-described pathophysiological process.[10] This process is enhanced by lipid accumulation, hyperglycemia, oxidative stress, and chronic inflammation besides the influence of hypertension. Another process is the age-dependent stiffening of large elastic arteries caused by changes starting in the arterial media but later on involving also other layers of the arterial wall (endothelium, adventitia), a process named arterial stiffening or *arteriosclerosis*.[11,12] For some individuals the combination of genetic susceptibility, early life programming, unhealthy lifestyle, adverse social conditions, and the burden of cardiovascular risk factors (Fig. 27.1) will lead to earlier than expected, i.e. early vascular aging (EVA), for which arteriosclerosis is the hallmark. This is an effect that is measurable through the stiffness of large elastic arteries, for example, via the measurement of carotid-femoral pulse wave velocity (c-f PWV), the gold standard for large artery wall stiffness.[13,14]

The EVA concept was first developed in 2008,[15,16] but several earlier researchers have discussed arterial aging in general with a focus on endothelial dysfunction and

morphological changes.[17,18] However, following the introduction of new technical devices for a more accurate measurement of PWV, be it c-f PWV or brachial-ankle (b-a) PWV, or in other ways, the interest in arterial stiffness (arteriosclerosis) has rapidly increased. This interest has been sparked by two consensus documents published in 2006[13] and 2012,[14] as well as several longitudinal studies in populations[19−24] that have repeatedly documented that increased PWV, the hallmark of EVA, is independently predictive of cardiovascular events (nonfatal and fatal) as well as total mortality. Two meta-analyses,[25,26] including one on individual data,[26] clearly demonstrated the predictive value of c-f PWV for cardiovascular (CV) events. In parallel, several observational studies linked arterial stiffness with CV risk factors.[27−29] These data were summarized in another consensus document published by the European Society of Cardiology and the ARTERY society in 2015, endorsing the concept of EVA and guiding on how to measure arterial stiffness, an integrated biomarker of cardiovascular risk.[30] The Lancet Commission on Hypertension also supported the EVA concept in 2016 and applied it in a life course perspective for prevention and treatment of vascular changes associated with hypertension.[31] It was suggested that early intervention for prevention had greater opportunities to reverse EVA as compared to prevention starting in mid or later life.

Further studies have looked into other characteristics of EVA, such as hyperglycemia, insulin resistance, chronic inflammation, impaired renal function, or other features.[32−34] Still it has been difficult to fully define the process of EVA and its contributing factors, as discussed in several previous publications.[35,36]

Structural components of arterial wall aging

Aortic stiffening accompanying age and cardiovascular risk factors is caused by common mechanisms including reduced elastin/collagen ratio, production of elastin cross-linking, reactive oxygen species (ROS)-induced inflammation, calcification, vascular smooth muscle cell stiffness, and endothelial dysfunction.[11,12]

It is important to highlight the link between energy balance, metabolic function, and regulatory systems of longevity. A lower calorie intake, for example, has been linked to increased survival in mammals such as rodents and monkeys. Mitochondria and transmembrane nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOXs) are involved in the energy metabolism of the cell and represent the two main sources of ROS that may enhance the aging process, also linked to chronic inflammation. Increased NOX4 expression/activity in vascular smooth muscle cells (VSMC) mitochondria results in increased mitochondrial oxidative stress inducing an accelerated VA characterized by increased aortic pulse wave velocity (PWV) and VSMC stiffening.[37] Several novel data suggest a role for the mitochondria in the process of VA and therefore a potential future drug target.[38]

Cross-talk between the micro- and macrocirculation

Small and large artery alterations are closely interdependent in response to aging and CV risk factors, particularly hypertension and type 2 diabetes. Thus, any pathophysiological approach of aortic stiffening should be paralleled by considering the remodeling of small resistance arteries. We previously suggested the existence of a cross-talk (as opposed to a linear sequence) whereby changes in small arteries affect the phenotype of larger arteries, and changes in large arteries affect the phenotype of small arteries.[8] Indeed, it is difficult to establish a temporal relationship between small and large artery changes. The cross-talk between the micro- and the macrocirculation[8] promotes a vicious circle, which can begin either from large vessels or at the site of small arteries. This is well illustrated by the effects of VA in hypertensive patients. Increased resistance in small arteries increases mean BP, and then increases arterial stiffness in the large elastic arteries, which concomitantly with more pressure wave reflections increases central SBP and 24-hour ambulatory brachial BP variability, ultimately leading to target organ damage.[8,9] The increased central BP pulsatility is in turn a factor of small resistance artery damage, i.e., increased media-to-lumen ratio of small resistance arteries and concomitant reduction in lumen diameter, leading to a rise in mean BP, and thus prolonging the vicious circle.

Vascular aging and target organ damage

The small/large artery cross-talk has a synergistic effect on the heart, brain, and kidney, in large part through a high pulsatile energy that is delivered as central systolic or pulse pressure. This aspect, which is well illustrated by hypertension, is detailed in other chapters of this book. Briefly, there is a large amount of evidence that central systolic and pulse pressures are the most deleterious elements of the BP load on the heart, brain, and kidney in hypertensives. Their increase is better correlated with hypertension-mediated organ damage than either brachial systolic and pulse pressures or mean BP.[9,39,40]

Particularly, an interesting line of research has linked arterial stiffness and VA to brain aging and the risk of cognitive decline and dementia, at least for vascular dementia.[41] Several studies have shown that hypertension in poor control is a risk factor not only for stroke but also for white matter intensities and microbleeds,[42] factors that may further impair cognition. It may well be that a neurocognitive reserve protects the brain from the effects of VA (arterial stiffness) until it reaches high levels of c-f PWV when cognitive impairment may become more visible.[43]

Poor sleep, for example, linked to obstructive sleep apnea, is another aspect of brain function that may impact on VA in a bidirectional way.[44]

Genetics and epigenetics

There are some rare genetic syndromes associated with premature aging including vascular changes such as Hutchinson−Gilford Progeria in children[45] and Werner's syndrome in middle-aged subjects,[46] caused by dominant genetic mutations. Another genetic syndrome affecting large arteries is the vascular Ehlers−Danlos syndrome[47] presenting with very lax joints, arterial changes, and increased risk of stroke.

From a genetic perspective, a few studies have specifically focused on genetic markers of arterial stiffness as such.[48−55] For example, Fibrillin-1 genetic deficiency leads to pathological aging of arteries in mice[49] and the Wnt pathway gene expression is associated with arterial stiffness.[53] In one study from Sweden, it was reported that a genetic risk score for hyperglycemia as a trait in a nondiabetic elderly population was independently associated with increased c-f PWV, and thus of VA.[56] This proves a causal link that opens up for interventions on hyperglycemia to counteract VA. Other studies have investigated the role of epigenetics.[57]

Recently a new focus has been to describe the profile of metabolomics associated with VA as one way to deepen our understanding of the metabolic fingerprint that is supposed to influence EVA and its consequences.[58,59] This is part of an approach to develop "personalized medicine" with tailored therapy id data from genomics and other omics can be used to map a certain pathophysiological process and pave the way to find new treatment opportunities.

Finally, a well-known marker associated with biological aging, i.e., telomere length, has also been investigated in relation to VA.[60,61] Telomere length is regulated by genetic factors but also influenced according to telomere attrition rate by factors in early life as well as adverse lifestyle and cardiovascular risk factors in adult life. However, telomere length has not developed into a useful tool for clinical practice to estimate biological aging and more research is needed.

Low socioeconomic status and vascular aging

People live different lives and this translates into resilience to or susceptibility for health problems as influenced by unhealthy lifestyle and adverse background factors such as poor income, low educational level, unemployment, poor housing or lack of social support and networks. This has

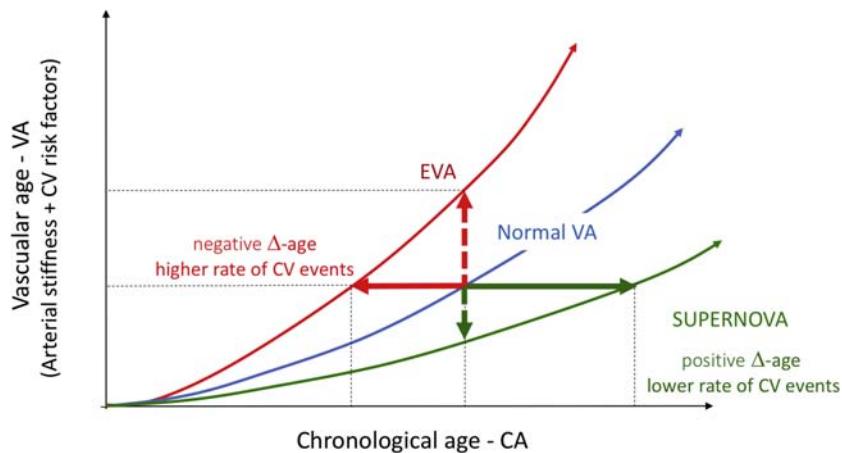
been shown to influence the development of VA as mirrored by time-trends in c-f PWV, shown in the Whitehall II study of civil servants in London[62] as well as in a cohort of young Finnish men[63] and with carotid stiffness in the PPS3 study.[64] One consequence of these adverse factors could be the development of depression, a mental state that is also associated with increased arterial stiffness and thus VA.[65,66]

Intervention studies on vascular aging and early vascular aging

Several studies have tried to use improvement of lifestyle as a way to favorably influence VA [by aggressive decrease of arteriosclerosis modifiers (ADAM)], as discussed in a review on EVA and ADAM,[67] and even more are underway, even in the young.[68] One problem is to disentangle the more general effects on cardiovascular risk factor levels from that more specific effect on arterial stiffness that was aimed for. A Mediterranean diet is believed to be protective of the cardiovascular system in general and also used for treatment of hyperglycemia.[69] This could be one feasible way to counteract VA as the ultimate consequence of that is prevention of cardiovascular events, as shown in the randomized, controlled PREDIMED trial based on Mediterranean diet for primary prevention of CVD in more than 9000 Spanish subjects.[70]

The control of hypertension and other cardiovascular risk factors is a cornerstone in cardiovascular prevention and documented in several national and international guidelines from the United States[71] and from Europe.[72] It has been shown that some classes of antihypertensive drugs, i.e., renin-angiotensin-aldosterone system blockers exert beneficial effects on reduction of markers of arterial stiffness beyond the impact of blood pressure lowering per se.[73] Even some of the newer antidiabetes drugs for treatment of type 2 diabetes, so called sodium-glucose cotransporter 2 inhibitors, have been shown to improve markers of arterial stiffness such as augmentation index or c-f PWV.[74] It remains, however, an open question whether this is a specific effect or if it depends on the concomitant lowering of body weight, blood pressure, and HbA$_{1c}$, or the diuretic effect with volume depletion induced by these drugs.[75]

A new treatment option on the horizon is to positively influence the receptor of adiponectin, a biomarker associated with better insulin sensitivity and lower cardiovascular risk, developed by Japanese colleagues.[76]

In the randomized intervention study on c-f PWV (SPARTE study) that has been conducted in France, the goal was to compare a guidelines-based strategy to control cardiovascular risk in hypertensive patients versus a strategy based on repeated measurement of c-f PWV followed by adjustment of drug therapy based on the results.[77] The SPARTE study has recruited 544 patients from 25 centers and was published in 2021.[78]


The concept and usefulness of supernormal vascular aging

Some studies have focused on people at the lower end of the distribution of PWV to find out more about vascular protection and healthy vascular aging (HVA) phenotype.[79−81] However, this approach is suboptimal as it does not fully account for the fact that some people seem to be protected from VA in spite of a similar cardiovascular risk factor burden as seen in other subjects with higher PWV.

In fact, the search-light is now directed to patients who seem to survive chronic disease and risk factors for a long duration with no or few complications, the true extremes of phenotypes linked to disease.[82] For instance, as we reported in our concept paper in 2019,[82] a minority of patients with long-standing type-1 diabetes of more than 40 to 50 years duration and daily insulin regimen, seem to escape major cardiovascular complications. In addition, patients with metabolically healthy obesity, a disputed condition normally defined by absence of variables linked to the metabolic syndrome, can remain hospitalization-free during long periods of midlife. Finally, a minority of patients with end-stage renal disease on peritoneal dialysis for a number of years may not exhibit cardiovascular complications.

We thus suggested the concept of SUPERNOVA that stands for Supernormal Vascular Aging.[82] Using arterial stiffness as the best proxy for the cumulative effect of known and unknown risk factors damaging the arterial wall throughout life, i.e., a measure of VA as discussed above, it was possible to suggest that subjects who present very low values of c-f PWV, whatever the level of CV risk factors, define a protective phenotype and we proposed to call this phenotype SUPERNOVA (Fig. 27.2). The difference between SUPERNOVA and HVA is that CV risk factors are generally absent in HVA. SUPERNOVA subjects are protected against the influence of CV risk factors, despite being exposed to them, i.e., CV risk factors are not translated into subclinical organ damage and CV complications.

To make proof of concept, we had to show in a longitudinal study that SUPERNOVA individuals underwent less CV complications than EVA subjects, despite a similar amount of CV risk factors.[83] For this purpose, we had first to identify SUPERNOVA individuals exhibiting a similar level of CV risk factors as EVA subjects.[83] We chose to compare chronological age with vascular age, and defined vascular age as the predicted age in the best fitting

FIGURE 27.2 **Early vascular aging and supernormal vascular aging.** For a substantially similar vascular age and cardiovascular (CV) risk profile (solid arrows), early vascular aging (EVA) individuals are significantly younger, and SUPERNOVA individuals are significantly older than the normal VA aging group. As a consequence, SUPERNOVA subjects have the largest difference (Δ-age, VA < CA) between chronological and vascular age; conversely, EVA subjects have negative difference (Δ-age, CA < VA) between chronological and vascular age. This translates into a lower rate of CV events in SUPERNOVA subjects, and a higher rate in EVA subjects; in other words, Δ-age is inversely associated with CV events. *From Bruno RM, Nilsson PM, Engström G, et al. Early and supernormal vascular aging: clinical characteristics and association with incident cardiovascular events. Hypertension. 2020. https://doi.org/10.1161/HYPERTENSIONAHA.120.14971. [published online ahead of print, 2020 Sep 8], with permission.*

multivariable regression model including classical CV risk factors and treatment and PWV. A large difference between chronological aging and VA means that, despite being "older," subjects have "younger" arteries. These are SUPERNOVA individuals. By contrast, when the difference is negative, it means that chronological aging is well below VA, in other words, that subjects have much "older" arteries than expected from their chronological age. These are EVA subjects. The multivariate analysis was performed in a subset of the cross-sectional Reference Values for Arterial stiffness Collaboration Database.[84] We used the 10th and 90th percentiles of the distribution of the difference between chronological age and vascular age, as cut-offs to define three categories of VA categories: EVA (below the 10th percentile), normal VA (between the 10th and the 90th percentiles), and SUPERNOVA (above the 90th percentile). The first part of the proof of concept was obtained by the following finding: while mean age significantly increased from EVA to normal VA and then to SUPERNOVA, the distribution of CV factors, PWV, and vascular age was similar among the three groups. The second part of the proof of concept was to show that SUPERNOVA individuals would undergo the lowest rate of CV events. For that purpose, the risk of fatal and nonfatal CV events in EVA and SUPERNOVA groups as compared to normal VA was investigated by Cox proportional hazard models in the longitudinal Malmö Diet and Cancer Study Cardiovascular Arm cohort that included 2642 subjects with a 6.6-year follow-up and 286 events.[85] The main finding was that the difference between chronological age and vascular age was significantly and inversely associated with CV events.

Compared to subjects with normal VA, SUPERNOVA individuals had half the risk of CV events, whereas EVA individuals had a 2.7 higher risk, in particular coronary events.

Conclusion

The EVA and SUPERNOVA concepts have led to the search of new models to understand protection from VA. In addition to a large number of studies testing drugs that may favorably influence EVA, a major issue is whether a treatment strategy based on targeting the normalization of arterial stiffness could be more beneficial than conventional treatment based on the normalization of blood pressure levels. Another therapeutic promising approach may use data from genomics and other omics to map specific pathophysiological processes through "personalized medicine." Finally, in clinical practice, it may be useful to detect SUPERNOVA subjects since they do not represent a clinical problem and should not necessarily be followed with the same intensity as EVA patients or even subjects with average VA. They represent, on the contrary, a challenge for academic research to better understand pathways for vascular protection, and if any identified, consider it as a potential therapeutic target in the future.

Chapter 28

Ethnic differences in arterial stiffness and central aortic hemodynamics

J.K. Cruickshank[1], S.G. Anderson[2,3,4], M. Strauss-Kruger[5], L. Gafane-Matemane[5], R. Kruger[5], Y. Breet[5] and A.E. Schutte[5,6]

[1]Cardiovascular Medicine Group, Division of Life-course/ Nutritional Sciences, Kings College London, United Kingdom; [2]George Alleyne Chronic Disease Research Centre, University of the West Indies Cave Hill Campus, Barbados; [3]Division of Cardiovascular Sciences, School of Medical Sciences, University of Manchester, United Kingdom; [4]College of Medical, Veterinary and Life Sciences, University of Glasgow, United Kingdom; [5]Hypertension in Africa Research Team; MRC Unit for Hypertension and Cardiovascular Disease, North-West University, South Africa; [6]School of Population Health, University of New South Wales, The George Institute for Global Health, Sydney, Australia

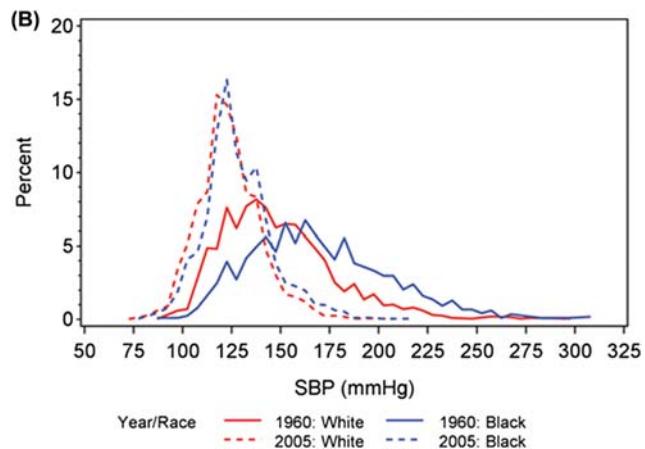
This chapter introduces why ethnic influences on arterial function are relevant, what questions related to ethnicity may be useful and do apparent effects indicate ways to improve vascular outcomes in particular ethnic groups.

Is studying ethnic differences in vascular or any physiological feature or disease useful?

We naturally answer "yes" for three major reasons:

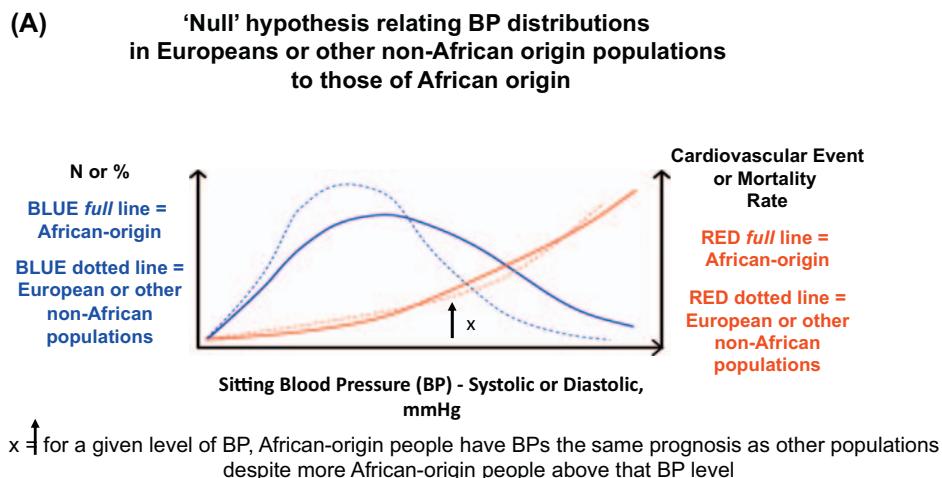
i. If one population group compared with another develops excess rates of cardiovascular events or death, it seems reasonable to examine how and why.
ii. Uncovering general causes of such differences calls into doubt frequent tendencies to consider genetic polymorphic or "inherent" variations as "causes." That is until gene variants, or more likely their products, when expressed by adverse influences, are shown to drive these conditions.
iii. Discovering specific environmental or life-course factors between one group and another offers both preventive and therapeutic opportunity.

Reduced access to diagnosis, intervention, and health care leads to persistent, intergenerational social inequalities in health and plays a major role of in the health status of African-Americans (AfAms) and other minority populations in the United States. Some 150 years since the end of slavery in the United States and less than a century since the same for peonage (the practice of holding persons in servitude or partial slavery, to work off a "debt"[1]) is short phylogenetic (the evolutionary history of a species) and epigenetic time. Similar issues hold for African-Caribbean (AfC) populations. We try here to avoid skin color designation as it is the basis of major discrimination, also preferring ethnicity to "race" which has no biological definition.[2–4] Yet that historical or political perspective seems inadequate in some instances, for example, to account for excess coronary heart disease (CHD) in South Asian people, in the Indian subcontinent itself, in those who migrated, or whose forebears were settled elsewhere under "indentured labor" schemes.[5] The emergence of obvious excess type 2 diabetes in South Asian people, and higher blood pressure (BP) in the last ±30 years, shows these to be dynamic issues which science struggles to keep up with. More recently CHD and diabetes have become epidemic in the subcontinent itself. Less recognized are similar excess rates among indigenous peoples worldwide, especially in their migrants to cities (e.g., in Brazil).

How is this relevant to arterial function and particularly stiffness, still mainly measured as carotid-femoral pulse wave velocity (cfPWV)? We use examples of available data to illustrate how and why cfPWV in particular helps to pinpoint not only risk/prognosis but should become the focus of preventive and therapeutic effort in randomized clinical trials (RCTs). Several studies and meta-analyses demonstrate the value of cfPWV for prognosis independently of ambient BP.[6]


Relationships to blood pressure

A key component for examining ethnic issues in (cardio) vascular function is how much morbidity/mortality apparently

due to (high) BP is in part related to greater arterial stiffening *independently of BP* in one group compared with another.


A hypothesis one of us promoted 40 years ago, based on pre-1980s data then, was that for *given levels of BP* in "Black" AfAm or AfC populations, prognosis was not "worse" or "more severe" than in European origin people, just that high BP *prevalence* was greater; so *at given levels of BP*, complications from high BP were no different from those in Europeans[7]—see Fig. 28.1A.

Fig. 28.1B shows how considerably BP distributions improved in the "stroke" belt of the South-East USA over a period of 50 years, greatly diminishing AfAm-white differences, so these can be at least partially reversed.[9] The challenge is to detect how much of any residual difference is due to the pathology of stiffening (medial replacement by collagen, etc., thought to be reversible) independently of BP. Can it be measured better by change in underlying large artery stiffening than by BP—whether true aortic (to bifurcation), as cfPWV, or local carotid PWV or carotid dynamics? Earlier outcome data from the "REasons for Geographic And Racial Differences in Stroke" (REGARDS) study included a much larger area of the south-east US "stroke belt" beyond those in.[9] Stroke risk was three times greater in AfAm than white adults—for a 10mmHg difference in systolic BP (SBP), risk increased 24% for AfAm but 8% for whites. However, adjusting for the two- to threefold excess diabetes nearly eliminated the excess.[8] Could that excess be due to large and small arterial stiffening in type 2 diabetes?

FIGURE 28.1B From: "40-Year Shifting Distribution of Systolic BP with Population Hypertension Treatment and Control." Lackland DT et al.: Circulation 2020; 142, 16: 1524—1531, DOI: (10.1161/CIRCULATION AHA.120.048,063).[8]

Our earlier work had shown the change in aortic PWV across the glucose tolerance (GT) spectrum. Between 1987 and 90 we had measured aortic PWV with a simple Doppler method decoded on a spectrum analyzer, (Fig. 28.2) as developed by Gosling (photo).[10] (He had taken the famous "photo 51" of DNA, as a PhD student with Rosalind Franklin, published beside Watson, Crick, and Wilkins' Nature paper, 1953. After her death from leukemia, Gosling moved into ultrasound). Note this was real "descending aortic" PWV from the aortic arch at the left brachial artery junction to just above the bifurcation. Participants were a

FIGURE 28.1A The "null hypothesis": more (High) blood pressure in African-Americans, African-Caribbeans, and west Africans than Europeans but for given BP levels, no difference in outcomes. *Redrawn and adapted from Cruickshank JK. Natural History of Blood Pressure in Blacks and Whites, Ch.31, pt D, p274 in: Ethnic Factors in Health and Disease, Ed JK Cruickshank, DG Beevers, publ.Wright, Butterworth-Heinemann, 1989/1994.*

Pulse-Wave Velocity Signals

PWV = separation distance/ pulse transit time

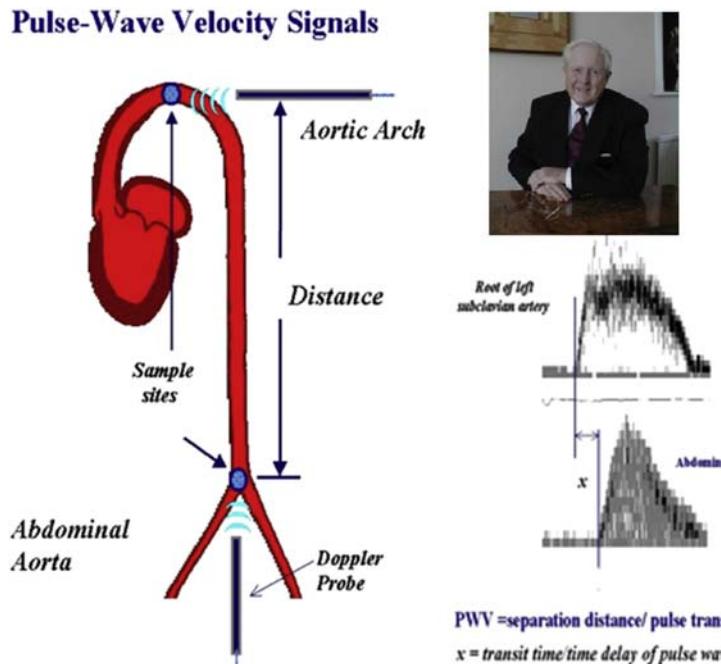
x = transit time/time delay of pulse wave


FIGURE 28.2 Doppler measurement of PWV, with length.

cohort of three specific ethnic groups, people of AfC, Gujarati Indian, and European white residents in North West London, England, defined by three of four grandparents in the same ethnic group, all of whom underwent glucose tolerance testing. We followed them for vital status for a mean of 11 years (Table 28.1).[11]

People there with diabetes had an adjusted hazard ratio (HR) of mortality 2.3 greater than those in the "normoglycemic" group, with a similar twofold excess in the intermediate glucose (in)tolerance group. To our surprise at that time, baseline aortic PWV displaced any index of BP, systolic, diastolic, mean or pulse, as a mortality predictor, and risk was *lower* for AfCs or Gujeratis than Europeans (Table). For those still alive 11 years later, intriguingly mean (95% CI) baseline PWV was no different across those 3 GT categories at 9.7 (9.2−10.2), 9.8 (9.1−10.5), and 10.4 (10−10.8) m/s. While BP treatment then was not started until >160 or 95 mmHg, which changed to 140/90 during follow-up, a key point was that between 140 and 160 mmHg, 17% of those with diabetes had baseline PWV >15 m/s compared with only 2% of controls.[11]

The role of early blood vessel pathology underlying and developing earlier than the hyperglycemia currently used to define "Type 2 diabetes" is beyond the scope of the review here.

Other British data continue to show clear differences in stroke rates in AfCs compared with "whites," partly related to less CHD allowing by competing cause more people to be at risk of stroke.[12,13] However, earlier, better BP control is vital.

Arterial stiffness through the life-course across different ethnic/geographic groups

What follows is a summary of data presented by the authors in a review article,[14] with its extensive Tables. Detailed accounts of molecular and mechanical mechanisms of arterial wall stiffening were published by Lacolley et al.[15] and Shadwick,[16] as was an excellent detailed review of aortic microstructure, collagen and elastin content or concentration by Tsamis et al.[17]

We cover studies comparing arterial stiffness, the main evidence-based component of early vascular aging,[18] between ethnic groups over the life-course, but the examples are neither exhaustive nor systematic reviews, which are referenced if available. For instance, only recent reports are quoted from the major US multiethnic cohorts (e.g., ARIC, Dallas, Multiethnic Study of Atherosclerosis [MESA], etc—see the Life-course section below). Their reports which incorporated, generally latterly, a range of arterial stiffness-related indices are cited. For a detailed review of the various metrics of arterial stiffness and pulsatile hemodynamics, the reader is referred to Chapters 3, 4, 7 and 8.

Fetal life, infancy, childhood, and adolescence (see Table 1)[14]

The onset of arterial stiffening starts even in-utero due to continuous adaptations in molecular structure and

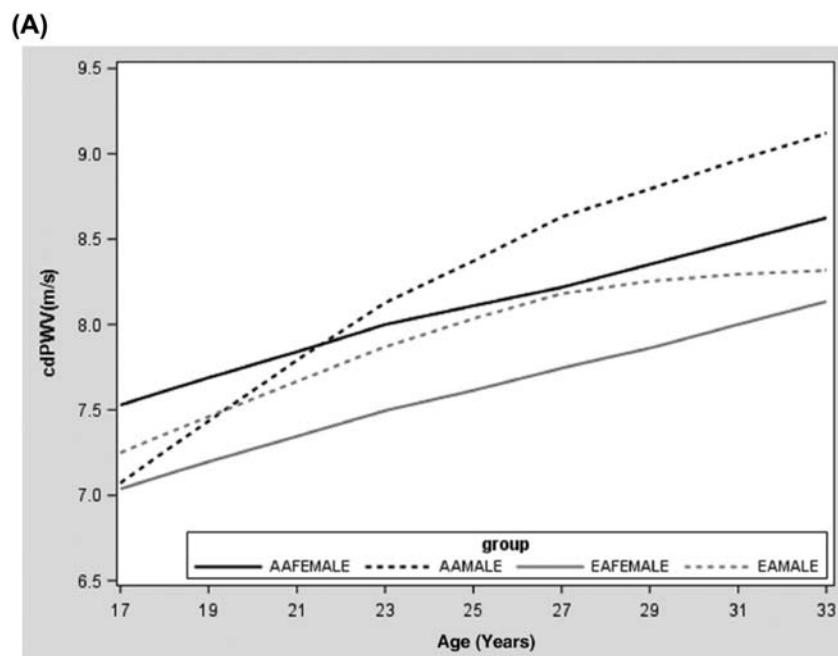
biomechanical responsiveness of blood vessels. Perhaps the best example is in monozygotic twins with varying degrees of twin-twin transfusion syndrome, where the donor twin shows increased aortic stiffening postnatally which may subside by 10 years of follow-up, while the recipient twin also develops higher BP.[19,20] Increased aortic stiffness occurs in premature infants as measured by aortic wall thickness and vasomotor function.[21] Together with excess systemic hypertension in preterm infants,[22] low birth weight and other complications such as bronchopulmonary dysplasia[21] all contribute to the early onset of arterial stiffening. Explanations for higher large artery stiffness in preterm infants include impaired elastin synthesis in the aortic wall[23] which alter mechanical properties, reduce arterial compliance,[24] and create higher or premature pulse wave reflections.[25]

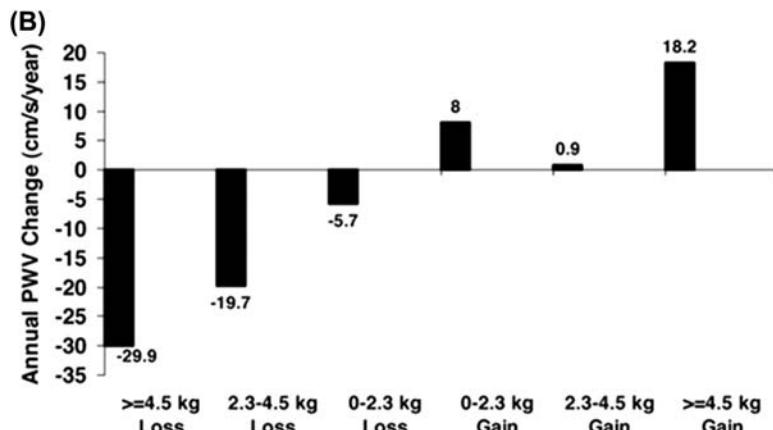
As shown in Table 1 of our review,[14] several studies investigated the impact of maternal risk factor. In UK infants, mainly European and Pakistani origin, we reported an inverse possibly adaptive link between maternal BP and neonatal aortic PWV.[26] Another could find no such association[27] although it used routinely measured antenatal BPs taken by clinic staff rather than by specifically trained personnel. That UK study suggested a weaker link between infant PWV and maternal anemia/iron status.[27] The

youngest South African children studied to date (mean age 7.3 years)[28] were boys aged 6−8 years, with regional PWV, arterial PP, as well as carotid ultrasound indices of local vascular stiffness measured. PWV (in all regions) and intima media thickness (IMT) were highest in African compared with white boys. Carotid stiffness indices were similar between groups.

In slightly older children, cfPWV was also higher in African compared with white Brazilian adolescents (mean age, 11.9 years; n = 771),[29] as also found in the United States. In Syracuse, New York state, cfPWV measured using arterial tonometry was higher in AfAm than white adolescents (mean age 10.7 years; n = 107), with no differences in PP, carotid IMT, and central SBP after adjustment for confounders.[30] A study in Memphis, Tennessee of white, AfAm and Hispanic adolescents (age 13.7 years) measured the cardiac-ankle vascular index (CAVI), with higher values indicating stiffer arteries.[31] Despite no univariate differences in CAVI, after adjusting for body mass index (BMI), AfAm boys had higher CAVI than both white and Hispanic boys with normal weight but CAVI was lowest in obese AfAm boys suggesting early vascular adaptations to obesity. Another study indicated higher brachial-ankle PWV in older AfAm than white US adolescents (n = 205, mean age, 15.9 years), with no

difference in PP.[32] In other American studies, socioeconomic disparities and carotid-femoral[33,34] as well as aorto-radial and aorto-dorsalis pedis PWV were higher in AfAm than white adolescents. Augmentation index corrected for heart rate (AI_{75}), which predicts mortality and CVD events,[35] was also higher among young type 2 diabetic AfAm than white American patients,[33] likely indicating more prominent pulse wave reflections.


Young adults (see Table 2)[14]

Even within age bands, age and BP, and hypertensive status/treatment, need to be accounted for as major contributors to stiffening when investigating ethnic differences. Here, cross-sectional or longitudinal studies again generally compared AfAm and white populations, with some studies including Hispanics and other minority ethnic groups (Table 2).[14] Most were from the United States, but also Brazil, South Africa, and the United Kingdom, as below. African origin samples, particularly men, had greater arterial stiffness compared with African (origin) women, and men or women of other ethnicities. In one UK study, only augmentation index (AIx) and not PWV was higher.[36] In the South African "Predict" study, neither PWV nor AIx were greater in African participants.[37] Increased PWV in African-origin samples has been related to sociodemographic and psychosocial factors in the United Kingdom and the United States.[36,38]


US studies are generally consistent: healthy AfAm men had higher central BP, AI_{75}, augmentation pressure, cfPWV, carotid β-stiffness index, carotid IMT, and lower pulse pressure amplification (PPA) despite younger mean age than whites, 21.7 versus 23.6 years, and after adjustments for heart rate, body fat, and cardiorespiratory fitness.[39] Group differences were not significant comparing brachial structure and function,[40] where routine BP is taken, confirming that early arterial alterations occur in central elastic vessels. Another mechanistic US study compared just 26 AfAm adults (mean age 32 years) who had higher AI_{75} than 10 Hispanics (28 years) and 26 white adults (28 years). cfPWV was also higher in the AfAm versus white group after post hoc analysis.[41]

In important longitudinal work, Liang et al. reported higher carotid-dorsalis pedis PWV over seven years in apparently healthy, normotensive African than white Americans from late childhood to early adulthood (Fig. 28.3A).[38] AfAm men had higher PWV with aging than AfAm women or white men and women.

Further longitudinal work came from follow-up in Allegheny County, Pennsylvania, if in a small sample of 67 AfAm and 85 white Americans there. These carefully measured and analyzed data clearly showed the continuing impact of weight gain on BP-adjusted PWV across ethnic groups in these 20−40 years old participants followed for a period of two years (Fig. 28.3B).[42] A 2019 meta-analysis compared cfPWV in AfAm and white samples aged 18−49 years

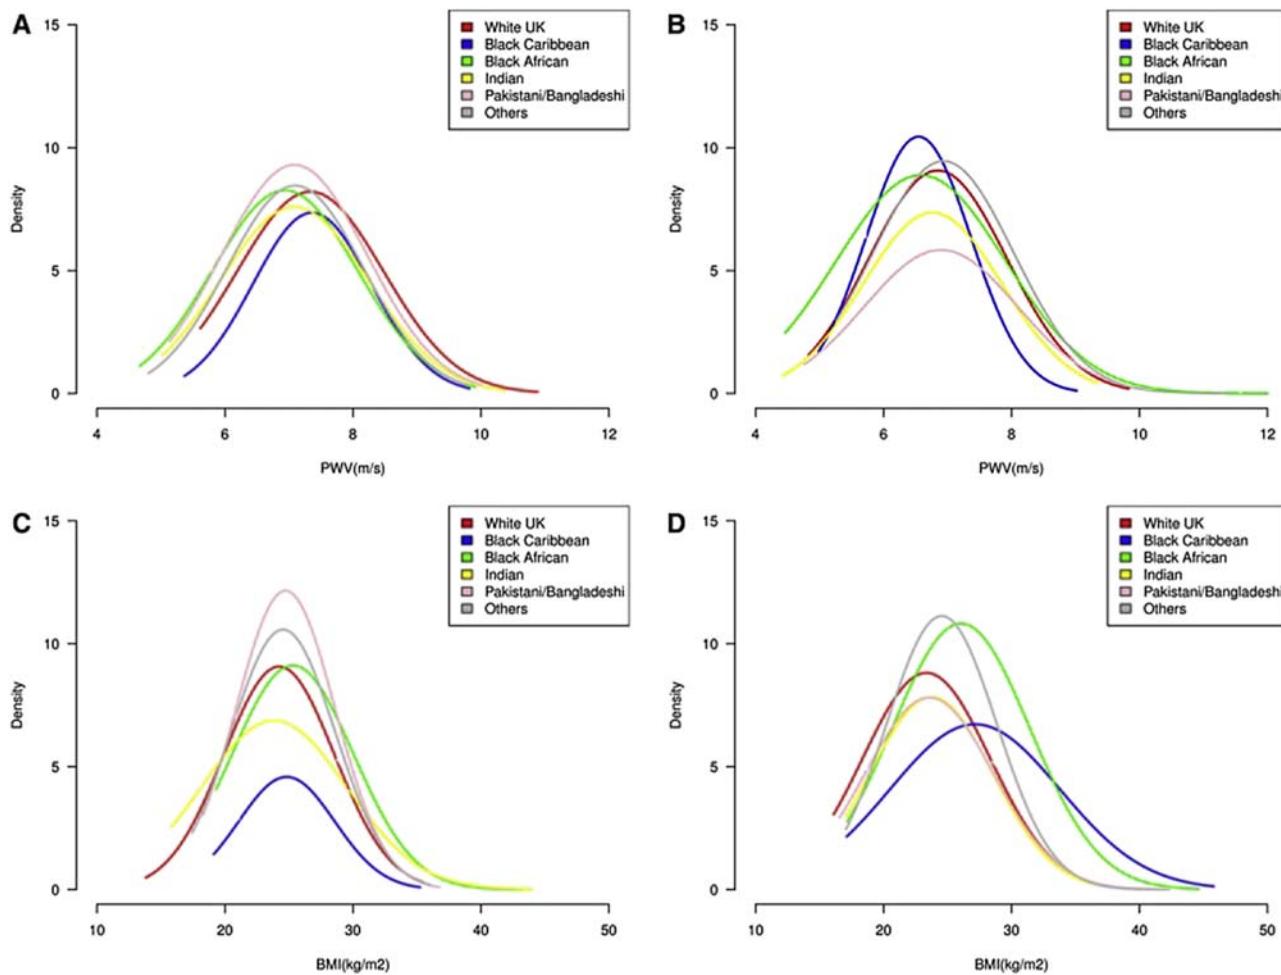
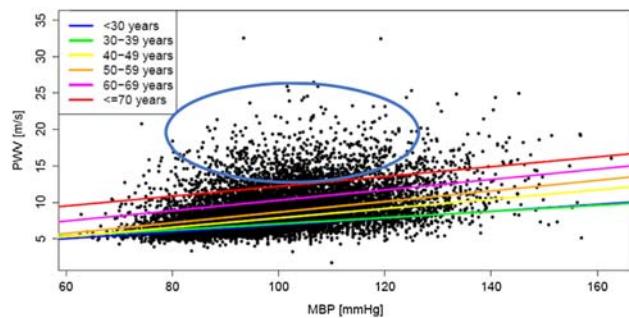
Weight change is associated with change in arterial stiffness among healthy young adults.* **Hypertension**. *2005; 45:187−192.* https://doi.org/10.1161/01.HYP.0000152200.10578.5d.

with apparent excess rates among AfAm men and women; however, that analysis was not adjusted for BP.[43]

Outside the United States, in our Determinants of Adolescent, now Young Adult, Social Wellbeing, and Health (DASH) study in London, the United Kingdom, unadjusted aortic PWVs were similar in young (21−23 years) Black Caribbean and white men, but higher than in other groups (Black African, Pakistani/Bangladeshi, and others).[36] Models were then adjusted for age, BP, current and adolescent SES indices (employment, education, and perceived racism). Women had lower stiffness than men, as did Black African, Black Caribbean, and Indian origin young people than white youth, with current BP, current and adolescent waist/height ratio, and perceived racism effects increasing arterial stiffness.[36] In slightly smaller samples of participants who wore five-day physical activity monitors, both number of steps/day and time walking >100steps/min were negative determinants of aortic PWV (i.e., more exercise, lower aortic PWV), independently of all other factors (Fig. 28.4).[36]

In the same study population, unadjusted AI was higher in Caribbean, West African, Indian and Pakistani/Bangladeshi groups compared with white young adults (with some borderline significant). In multivariate models including SBP, AI was marginally but not significantly higher in West Africans and Caribbeans than in whites.[44]


The key issue from all these data is that for given levels of BP, some people have stiffer blood vessels than others—as shown in the large middle-older aged European dataset, Fig. 28.5A,[45] p2338, and the same dataset of the London "DASH" cohort above, Fig. 28.5B (Reference 36, p1055).

Effects of age and BP on PWV were examined in African origin and white, Brazilian-born young men (mean age 26 years). In normotensives, white men had higher PWV than African, but in hypertensives, African men had higher PWV than white. The slope of the age-adjusted PWV-SBP regression was steeper in Black than white men.[46] A cross-sectional study in urban Vitoria, Brazil, included 2015 people (aged 36−47 years) from four different ethnic groups: Amerindians (29.2%), white (26.7%), Mulatto (38.3%), and Black (5.8%). (Note still the color-based classification, as in the more "detailed" UK 2011 census list, or the simplistic Black/white/(Hispanic) US list). cfPWV was higher in the Black group after adjustment for traditional covariates including age, sex, and mean BP.[47]


The African-PREDICT study in South Africa included only normotensive young healthy African and white adults (mean 24.4 years, range 20−30 y), reporting no ethnic differences in cfPWV, AI_{75}, or PPA, *adjusted for mean arterial pressure*. Although there were no ethnic differences in stiffness indices between normotensives, African adults showed a steeper decline in PPA between ages 20−30 years, similar to findings in African American men.[37] A subgroup of these young people in African-PREDICT had metabolomic analyses done on two groups either in the lower or higher halves of the PWV range. No associations were found with PWV but several urinary nonessential amino acids with roles in collagen metabolism were independently and inversely related to the 3 mmHg higher central SBP in the African origin young adults.[48]

In summary, cross-sectional US and South African studies report higher cfPWV in African origin men than women and in both, higher cfPWV than other ethnic groups. In younger adults (20−40 years) in England and in Brazil, at lower BP levels and to the surprise of some, European-origin ("white") people had higher cfPWV in fully adjusted analyses as above. Data on women were fewer. However, the slope of the PWV-BP relationship was

steeper in African Brazilians. In the London data, Af-Caribbean-origin young men had slighter higher aortic PWV than directly West African origin men. BMI had direct elevating effects on aortic cfPWV in all the studies above, as did waist/height ratios in the London cohort in adolescence and in youth, with additional effects from perceived racism.

Middle-aged and elderly populations

Arterial stiffness in middle-older ages has been extensively investigated. Large population-based, cross-sectional studies in different world regions consistently found that "Black" African origin participants had increased arterial stiffness than the comparison group(s) (Table 3).[14]

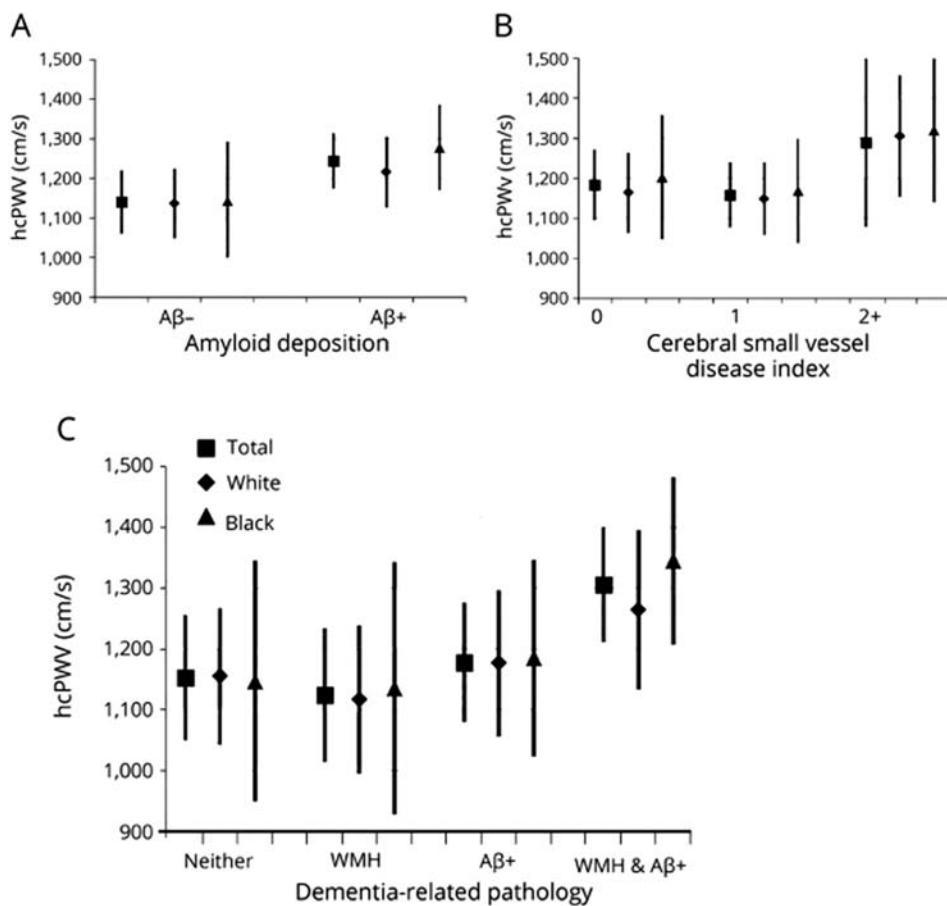
Another South African study of African and white adults (40.7 years; n = 750) showed carotid-radial (cr) and carotid-dorsalis-pedis (cdp) PWVs were elevated in Black adults, with normal or elevated BP.[49] Using the cr/cdp PWV ratio could at least estimate its BP independence.[50]

In our study of a multiethnic sample of older middle-aged men (in Manchester, England,[51] mean [SE] aPWV in South Asians [n = 68; age 55 ± 10 years]), at known higher coronary disease risk than other groups, was 0.5 (±0.2) m/s higher than in AfCs (n = 67; 55 ± 10 years), at lowest coronary disease risk here, and than in Europeans (n = 63; 57 ± 8 years), adjusted for age, SBP, and diabetes (P = .01). By magnetic resonance in a subsample of these men balanced by ethnicity, PWV over the descending aorta in South Asians was 0.7 m/s (0.3 m/s) and 0.8 m/s (0.3 m/s) higher than in AfCs and Europeans, respectively; PWV over the aortic arch was not different. We found close approximation of transit times between MR and the aortic measure, and using more precise, MR-measured length for the aortic PWV greatly improved its precision.[52]

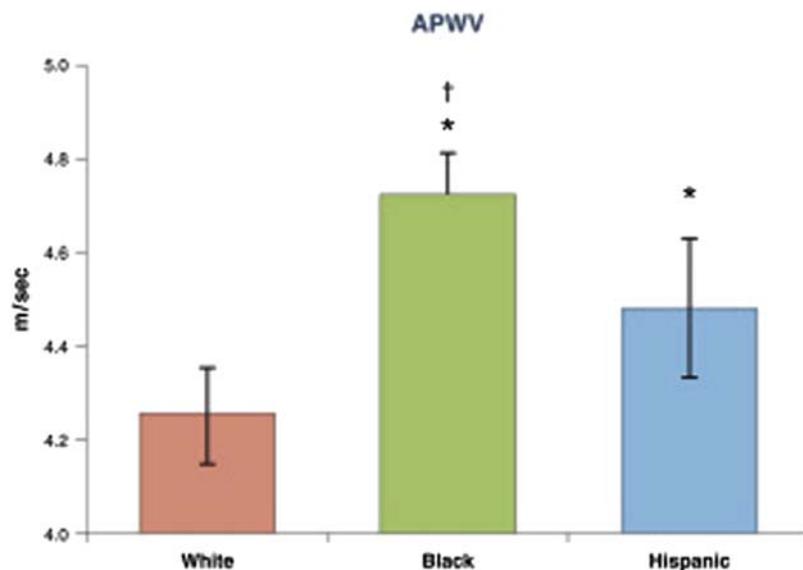
In a US community sample from metropolitan Atlanta (48 years; n = 855), cfPWV, central and peripheral AI were higher in the AfAm group compared to white counterparts, after adjustment for traditional risk factors. These differences persisted in a subgroup free of conventional risk factors.[53]

In the large US cohorts, ethnic factors are becoming clearer. In a subsample of ARIC from North Carolina (in the "stroke belt" as above, Fig.28.1B), 268 AfAm and 2459 white men and women aged 45−64 years with no history of CHD or stroke were studied.[54] The size of the AfAm sample is only ±10% of the white sample, but remains sizable compared with other studies (Table 3).[14] After adjustment for CV risk factors, mean β *carotid* stiffness was 9% higher for Black adults (mean ± SE: 11.3 ± 0.3) than for whites (10.3 ± 0.1).

These carotid measures are important because *carotid arterial function* plays a key role in stroke,[55] cerebral white matter lesions (WMLs)[56,57] and cognitive decline,[58]

independent of both ambient BP but also *aortic PWV*. Of those three studies, only in the 303 people in the Healthy Brain subcohort of the Health ABC study,[57] by then elderly at 83 years, was there an AfAm group (41%, N-±124). cfPWV was independently associated with incident WML, together with only sysBP and prevalent stroke in the model adjusted for demographic, cardiovascular risk factors, and diseases over 10 years. Age and ethnicity were not significant predictors of WML, but the study had inadequate power to do so in such survivors. In those with specific MRI brain lesions, AfAm had somewhat higher cfPWV than whites.[57]


The only sub-Saharan study of carotid features compared 351 hypertensives known for >5 years, aged 59 years, with 241 normotensives, aged 53 years, among HIV-free African South Africans, 63% women in both samples.[59] Any index of carotid distensibility was reduced as expected, but these all remained significantly more so after adjusting for mean BP, but not central sysBP. However, the central SysBP was measured by a radial tonometry device, which probably underestimates SBP.[60]

The value of detailed PET-scan data for showing the impact of heart-*carotid* (hc)PWV in ethnic comparisons came from the recent small ARIC "PET" scan substudy. This substudy included 141 older AfAm and 180 white participants, with a mean age of 76 years, and without dementia.[61] The analysis related "central" heart-carotid PWV to cerebral small vessel disease and to ±30% excess fibrillar amyloid-beta (Aβ) deposition via a fluoride marker and white matter hyperintensities.[61] Oddly, at least by that age, SBP was not related to hcPWV. No ethnic effects were apparent on these cortical brain indices, adjusted for central BP or not, shown in Fig. 28.6 below:


While finding cerebral vessel disease was not associated with Aβ, especially adjusted for usual risk factors, presence of Aβ was somewhat if not significantly greater in white than in AfAM people, who carry a higher ApoEe4 allele frequency.[62] Small sample sizes in these substudies (due to the high cost of PET) and survivor bias may be relevant.

Retinal vessels

A vital additional small vessel site is the eye, particularly for diabetes and risk of retinopathy, perhaps in sickle cell disease but also to indicate smaller cerebral vessel status. In a middle-aged Flemish population sample, cfPWV and estimated *forward and backward pressure waves* are related to retinal arteriolar and venular diameter and their ratios.[64] Further, cfPWV was also found related to mean retinal capillary blood flow, independently of age, sex, SBP, and BMI in a Polish study of hypertensive patients and controls.[65]There were also borderline effects on retinal vessels in the older ARIC study using the Omron VP

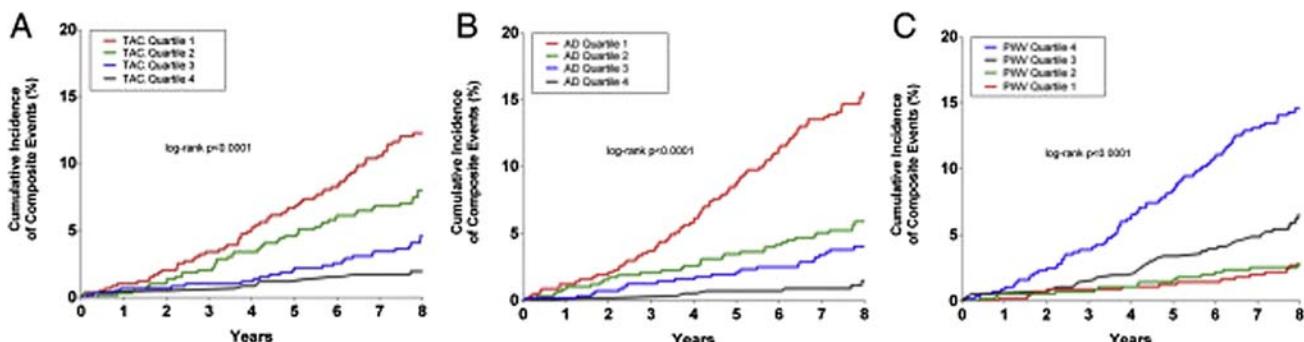
FIGURE 28.6 From ref.57 Hughes TM et al. Arterial stiffness and Dementia pathology. ARIC-PET study. Neurology 2018; 90(14):e1248−56 (hcPWV = heart-carotid)[61].

FIGURE 28.7A Proximal Aortic pulse wave velocity adjusted for all major cardiovascular risk factors including mean blood pressure—*from the Dallas Heart Study*[63].

1000+ device: none on arterioles but of cfPWV in relation to wider retinal *venules*, greater in those without high BP and independent of BP.[66] These relationships are clearly worth exploring further across ethnic groups, especially in T2 diabetes.

Pulse wave velocity measures in AORTIC segments by Magnetic Resonance Imaging (MRI)

In the multiethnic, population-based *Dallas Heart Study* (43.7 years; n = 2544)[63] Black and Hispanic compared with white participants had greater *proximal* aortic stiffness, measured either as aortic arch PWV or as characteristic impedance, in fully adjusted models. Although AfAm had a higher prevalence of numerous CV risk factors, none accounted for ethnic differences in aortic arch PWV and characteristic impedance. Different regional aortic components of stiffness each predicted cardiovascular outcomes, but as yet with insufficient events to examine those ethnic differences (Fig. 28.7).[67]

The MESA, another major US multiethnic study with modern imaging, also provides novel results on regional aortic stiffening.[68] Its CVD outcomes distinguished effects of aortic arch stiffening between middle-aged and older adults. A 1SD increase in log arch PWV was associated with incident CVD events in younger middle-age, but not in older people, with a multivariate CVD risk factor-adjusted HR of 1.47 (1.1−1.97) $P < .009$, at 45−54 years. That adjustment included ethnic group (*not independently significant*) and SBP. Arch PWV remained separately significant at 45−54 years after also including left ventricular (LV) mass, carotid IMT (both NS) and coronary artery calcium score ($P = .098$). Only ankle-brachial index (ABI) remained a significant predictor of events ($P = .026$), suggesting that general PWV was adding to prediction by arch PWV.[68] Whether with more events ethnic group will be separately significant is awaited. An important limitation of aortic arch PWV measurements in MESA is the very low temporal resolution achieved by the phase contrast sequences used in this study, which is unlikely to resolve fast PWV ranges as seen in older participants.


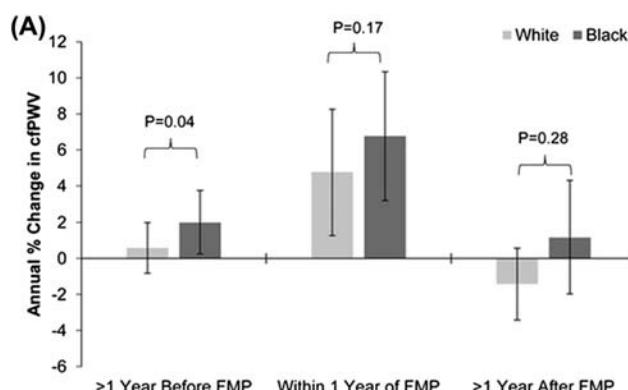
In South Africa, among 309 randomly sampled, untreated people of African ancestry, there was a marked gender divergence in the cross-sectional cfPWV−LV relationships, being found only in women.[69] cfPWV measured with arterial tonometry was closely related in simple correlation to LV mass index at r = 0.67, but rather oddly not at all in men. In multivariate analysis, adjusting for either standard brachial systolic or mean BP, independent relations between LV mass and cfPWV persisted, more strongly so with 24hr systolic ambulatory BP. Including other standard confounders also, with 63% overweight or obese and 17% with poor GT, the partial r, 0.37, for cfPWV was exactly equivalent to, but again independent of, that from SBP. These were cross-sectional data but clearly illustrate the potential impact of ventricular-arterial coupling, which generally we continue to ignore. Longitudinal data and perhaps explanations for the major gender difference so far will be invaluable in this at-risk population.

HIV

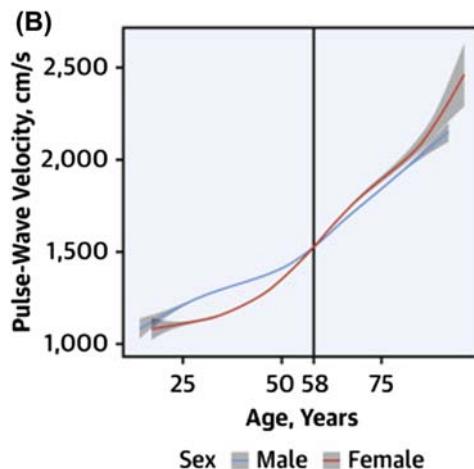
Finally, now in a relatively controlled epidemic, the world has near forgotten, a case-control cohort study in South Africa has started, comparing 278 HIV-infected, aged 43 years, and 104 HIV-negative people, aged 39 years, only some 28% men in each.[70] Some 80% were taking their ART, 47 had been for >5 years. Intriguingly in an apparently inflammatory disease, PWV was no different nor was forearm vasodilatation at baseline, with follow-up monitoring ongoing.

Ethnicity and the menopausal transition

A key part of women's life-course is the apparent perimenopausal change in cardiovascular function and risk.

FIGURE 28.7B   Cumulative incidence of cardiovascular events by quartile of: (A) Total Arterial Compliance; (B) Ascending aorta distensibility; (C) Arch pulse wave velocity. *Maroules CD, Khera A, Ayers C, et al. Cardiovascular outcome associations among cardiovascular magnetic resonance measures of arterial stiffness: the Dallas heart study.* **J Cardiovasc Magn Reson**. *2014; 16(1):33.* PMC4031496.


Two studies compared between the United States and China illustrate potential ethnic or geographic issues for arterial stiffening as an end point for standard risk factor impact during this phase. The US "Swan" Heart Study, a sub-study of the full Swan study, enrolled 554 women at baseline,[71] on whom a further analysis was reported recently of 123 AfAm, 216 white women—Fig. 28.8A.[72]

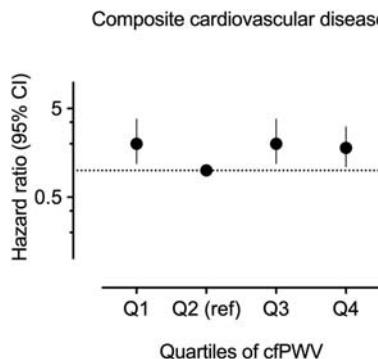
AfAm women had greater progression in cfPWV than did white US women but in the baseline-follow-up, that greater progression was not independent of SBP.[71] However, in the recent report, where the regression "time-oriented" modeling was more complex and the final model included SBP, annual change in cfPWV was significantly greater in AfAm women at 6.8%, and highly so comparing segments during and after the menopause.[72] Only AfAm women had a statistically significant increase in cfPWV up to the menopause (Fig. 28.8A). Adjusting for blood levels of reproductive hormones FSH, estradiol, or CRP, did not alter the analyses.


The study from Changsha, central China, combined two large cross-sectional studies (n = 66,058) with a smaller longitudinal one (n = 1724) and included measurements of brachial-ankle PWV (baPWV).[73] The crossover age, ±58 years, where women have equal or higher PWV to men thereafter is very close to that obtained by using MRI-based aortic regional PWV and distensibility in 777 Europeans, 408 women, in Britain.[74]

The elderly

Much less data are available for ethnic effects on arterial stiffness in, and especially from younger ages to, older age. An early example is the Northern Manhattan Study (NOMAS)[75] which compared carotid artery diameter and stiffness in 1536 Black, white, and Hispanic participants at

FIGURE 28.8A Ethnic difference between African and white American Women in carotid-femoral pulse wave velocity before, during, and after the menopause at ±53 years. *From Samargandy S, Matthews KA, Brooks MM, et al. Arterial stiffness accelerates within 1 year of the final menstrual period.* **Arterioscler Thromb Vasc Biol**. 2020; 40:1001−1008.

FIGURE 28.8B Cross-sectional + longitudinal data in China; brachial-ankle pulse wave velocity in women = or > men at ± age 58 years. *From Lu Y, Pechlaner R, Cai J, et al. Trajectories of age-related arterial stiffness in Chinese men and women.* **J Am Coll Cardiol**. 2020; 75: 870−880.


age 70 years, and showed greater carotid stiffness among the AfAm and Hispanic groups compared to whites.[75]

Further comparisons by ethnic group for cfPWV across different arterial paths again come from ARIC in a large sample all aged ∼75 years at their visit 5.[76] Unadjusted mean ± SD cfPWVs were 1163 ± 297 (n = 1694 white men), 1247 ± 344 (363 AfAm men), 1120 ± 282 (2208 white women), and 1222 ± 332 (708 AfAm women) cm/s (note this population sample has a relatively high mean value at this age of ±12 m/s, the usual units for carotid-aortic-femoral PWV). Those "significant" cfPWV differences were accompanied by respective mean arterial pressure values of 86.5 ± 11, 90.9 ± 12, and 86.9 ± 11, 91.5 ± 11 mmHg, but cfPWV adjusted for mean pressure was not presented.[77] baPWV however did not differ by ethnic group because femoral-ankle PWV, which is not prognostic of major outcomes, was *higher* in white groups. At this age in this cohort, prognosis was "J-shaped" for cfPWV, with the lowest quartile at twofold higher risk than quartile 2 as reference, with twofold excess risk also present in quartiles 3 and 4 (see Fig. 28.9).[77]

Renal impairment/failure (end-stage renal disease)

Ethnicity is highly relevant for renal disease because decline into and overt chronic renal disease/end-stage renal disease (ESRD) is much commoner among AfAms, driven by inadequately treated or managed high BP.

Townsend recently reviewed the powerful role of cfPWV in renal disease progression, based on follow-up of 2795 participants in the CRIC study.[78] The 1088 AfAms had a 45(14−84)% excess progression to ESRD. The

FIGURE 28.9 J-shaped relationship of carotid-femoral pulse wave velocity to composite of CHD, stroke and heart failure events in the older ARIC cohort. *From HHS version of Kim ED, Ballew SH, Tanaka H, Heiss G, Coresh J, Matsushita K. Short-term prognostic impact of arterial stiffness in older adults without prevalent cardiovascular disease.* **Hypertension**. *2019; 74(6):1373−1382 open access.*

adjusted risk for halving eGFR or ESRD itself was only "significant" with cfPWVs >10.3 m/s, with mean BP still significant for ESRD or eGFR decline, while mortality risk with cfPWV was continuous and independent of mean BP which no longer predicted mortality.[79] A similar pattern was found for heart failure risk. CRIC investigators also examined relationships between eGFR decline and retinal vessel changes,[80] but the likely role of cfPWV is not yet analyzed.

In the full older ARIC cohort (n = 3424, mean age 75 years), an increase in cfPWV of ±17 cm/s or more (∼0.17 m/s) was associated with a fall in eGFR of 15 mL/min/1.73m,[2] adjusted for age, sex, and ethnicity ("Black" v "white").[81] That reduced to 10 cm/s, (0.1 m/s) additionally adjusted for major risk factors and ABI. So, the 72 people with fully adjusted cfPWV higher by 0.7 m/s had eGFRs down to <30 ml/min/1.73m[2]; vice versa, those in that lowest eGFR group had ±twofold risk of being in the highest quartile of cfPWV.[81] Intriguingly, the effect was most prominent in European rather than in African-Americans (see their Fig. 28.2A). As perhaps expected, much of the impact was on the amount of albumin/creatinine excreted. Other measures of PWV (Ba, heart-carotid, femoral-ankle) had no effect.

Other ethnic differences in arterial function, excepting AfAm populations highlighted above in detail, are evident in middle age, specifically among South Asians, who have a high prevalence/incidence of coronary, stroke, and small vessel disease.[82] These populations have been greatly under-represented in studies on arterial function. A small Canadian study[83] recruited just 22 South Asian 71 years old participants and compared them with age-/sex-matched European-origin participants. South Asians had higher carotid PP and lower compliance, therefore exhibiting stiffer vessels. Similarly, central PP and AI were elevated in an older South Asian sample (69 ± 6.1 years) compared with

AfC and European-origin population samples in the UK Southall and Brent REvisited (SABRE) study.[84] Despite being uniquely valuable to date in Britain, note the study shares the limitation of all long-term adult cohorts of "survivor bias" affecting conclusions. We had found both these groups to have similar central aortic PWV relative to Europeans 25 years earlier, and PWV higher in those with T2 diabetes, despite some differences in BP and outcomes (Table and Fig. 28.2 above Reference 12). The Healthy Life in an Urban Setting (HELIUS) study,[85] a large prospective cohort in Amsterdam, had similar findings. Dutch European (n = 1797), South Asian Surinamese (n = 1846), African-Surinamese (n = 1840), and Ghanaian origin (n = 1673) participants were included in this study. Unadjusted aortic PWV was higher in African and South Asian groups compared with those of European Dutch descent, but these differences disappeared after adjusting for BP. The authors concluded that increased PWV in some groups was driven mainly by conventional risk factors.
