Unanswered questions include whether genetic differences underlie these ethnic patterns, for which the evidence is slight so far. A study from Georgia, US of 702 twins, 40% AfAm, suggested heritability but could do no linkage.[86] GWAS studies in European-origin population samples suggest some effects on PWV, originally in 1480 Framingham participants of 817 pedigrees,[87] then meta-analyzed for 20,634, validated in a separate 5306, people of just European ancestry, and adjusted for BP.[88] Some of these variants were also replicated for cfPWV in a separate sample of 7669 Europeans from the LIFE-Adult study of Leipzig, Germany.[89] A small Korean study (n = 400) found no linkage,[90] perhaps illustrating how GWAS studies require very large samples but remain just associations.

It seems that the most likely external causal factors are social, economic, and their intergenerational and psychological effects, including reactions to racism[34,36] which may include obesity.

Summary and conclusions

Studies of ethnic-specific comparisons in physiology and disease provide a focus to understand and act on excess morbidity and mortality in particular groups. Most report that populations of African descent, and more recently also Hispanic populations, often living in western societies as ethnic "minorities," have greater arterial stiffness indices than white populations from very early life (e.g., 6 to 70 years of age). The South African context is interesting where populations and circumstances have changed rapidly in a generation. Yet AfCs and recently West Africans in the United Kingdom, both groups with long experience of excess stroke, have not yet experienced much obstructive coronary, but rather hypertensive heart disease. Raised BP often accompanies arterial stiffness in Black populations

but as above in Fig. 28.1A and B, for given BP levels some people have stiffer vessels than others, and those individuals have a poorer prognosis. Similarly, in analyses of normotensive or healthy subgroups, increased arterial stiffness may co-exist,[51] including in studies of children or young normotensive adults where African origin participants may already have elevated arterial stiffness but "normal," or BPs similar to, their comparison groups. When tracking arterial stiffness with increasing age, it becomes clear that early vascular aging already occurring in adolescence or young adulthood predisposes African origin individuals to excess CV risk throughout the life-course.

Identifying early vascular aging across all ethnic groups throughout the life-course by assessments of aortic PWV will add greater precision to BP alone to define those at risk for early onset of CVD and future events. Trials of specific treatments targeting blood vessel stiffening beyond BP are sorely needed, and some current vascular drugs may be excellent candidates.

There seems to be no doubt that once again continuing physical activity is the major opportunity for preventing early vascular aging, as shown in studies of individuals with differing, near life-long degrees of such activity.[91]

It is certainly clear that whatever the differences or similarities in arterial function by ethnic group and at any given ages and levels of peripheral or central BP, some individuals have stiffer vessels than others, and so are at higher CV risk.

Arterial stiffness and pulsatile hemodynamics in systemic hypertension

Stéphane Laurent[2,3,4,5] and Pierre Boutouyrie[1]

[1]Paris University, Assistance-Publique Hôpitaux de Paris, PARCC-INSERM U970, Department of Pharmacology and Hôpital Européen Georges Pompidou, Paris, France; [2]Department of Pharmacology and Hôpital Européen Georges Pompidou, Paris, France; [3]INSERM, U970, Paris Cardiovascular Research Center, PARCC, Paris, France; [4]Université de Paris, Paris, France; [5]Assistance Publique, Hopitaux de Paris, Paris, France

Introduction

Arterial stiffness refers to the loss of arterial compliance, i.e., its change if volume in response to changes in blood pressure (BP).[62] The major hemodynamic consequence of elevated arterial stiffness is illustrated by increased central systolic and pulse pressures. In systemic hypertension, arterial stiffening is a consequence of the aging of the large artery wall, which is accelerated by long-term high BP.[54,79] Pathophysiological studies have extensively investigated the structural factor in hypertension, including large and small artery remodeling and functional changes. Here, we review the recent literature on the alterations in large arteries in hypertension. We discuss the possible mechanisms underlying the relationship between arterial stiffness and increased central pressure pulsatility. We explain how hypertension is both a cause and a consequence of central arterial stiffening. Finally, we propose an integrated pathophysiological approach in order to better understand how the cross-talk between large and small artery changes interacts in the transmission of pressure pulsatility, exaggerates cardiac, brain, and kidney damage, and lead to cardiovascular and renal complications. We focus on patients with essential hypertension since this is the most prevalent form of hypertension.

Consequence of arterial stiffness on pressure pulsatility

The wording "arterial stiffness" is a general term that refers to the loss of arterial compliance and/or changes in vessel wall properties.[41,63] The classical view is that compliance of large arteries, including the thoracic aorta that has the major role, represents their ability to dampen the pulsatility of ventricular ejection and to transform a pulsatile pressure (and flow) at the site of the ascending aorta into a continuous pressure (and flow) downstream at the site of arterioles. This allows to lower the energy expenditure during organ perfusion and to protect small arteries of target organs (mainly the brain and the kidney) from the damaging effects of pressure pulsatility.[54] Indeed, during ventricular contraction, part of the stroke volume is forwarded directly to the peripheral tissues and part of it is momentarily stored in the aorta and central arteries stretching the arterial walls and raising local BP.[18]

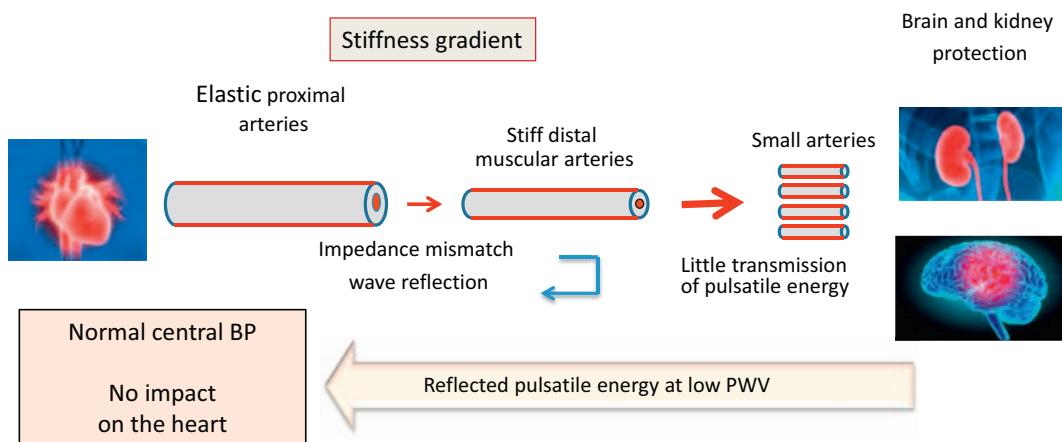
A more contemporary view is that arterial compliance is a key thermodynamic optimization of cardiovascular energetics. Part of the heart energy is reoriented to the distension of the arterial wall. This energy is thus "stored" in the vessel walls during systole, and recoils the aorta during diastole. This phenomenon squeezes the accumulated blood forward into the peripheral tissues, ensuring a subsequent diastolic flow. The stiffness and geometry of the arteries make this phenomenon effective in young, healthy subjects and less effective in older, hypertensive patients.[54,79]

When the stiffness is low (young healthy subject), a large amount of cardiac energy is redistributed during diastole and helps decreasing postload and improving organ perfusion during diastole (especially "torrential" circulations such as brain, kidney, and coronary arteries).[55] In hypertensives, arterial stiffness is higher[47] and a higher pressure is necessary to stretch a more rigid arterial system. Thus, this is mainly during systole that a larger proportion of the stroke volume flows through the arterial system and peripheral tissues. The main consequences are an intermittent flow and pressure, an exaggerated flow and pressure pulsatility at the site of distal small resistance, and a shorter

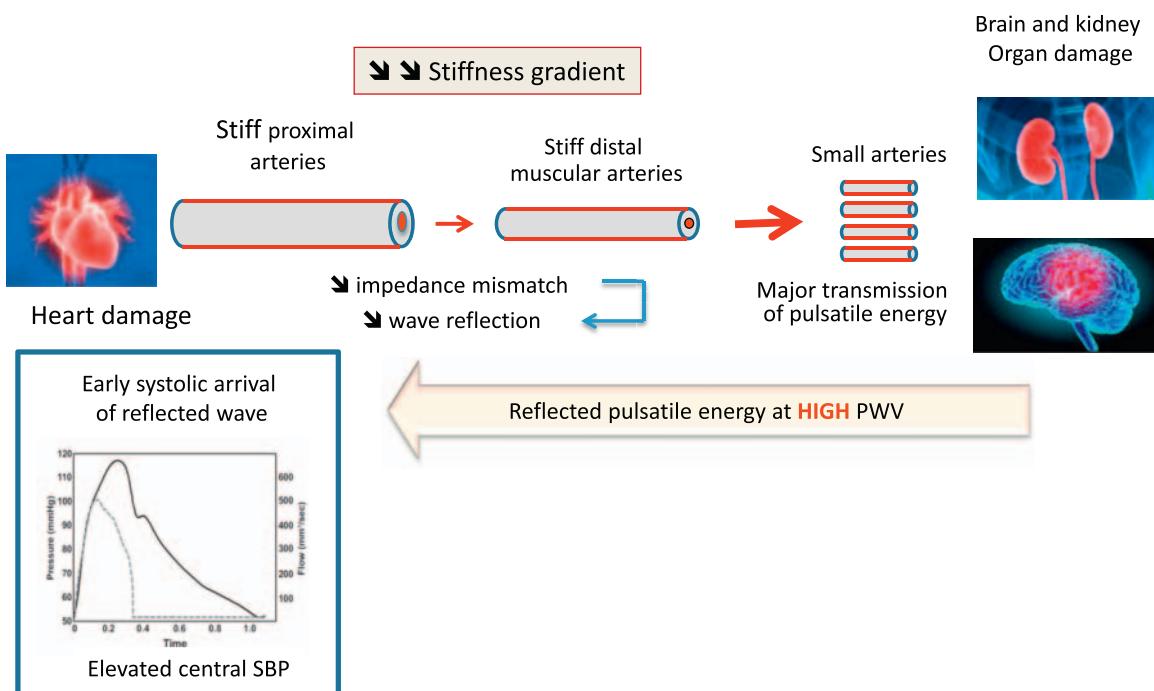
capillary transit time. The later reduces metabolic exchanges. Altogether, these mechanisms damage target organs.

Arterial stiffness and wave reflection in systemic hypertension

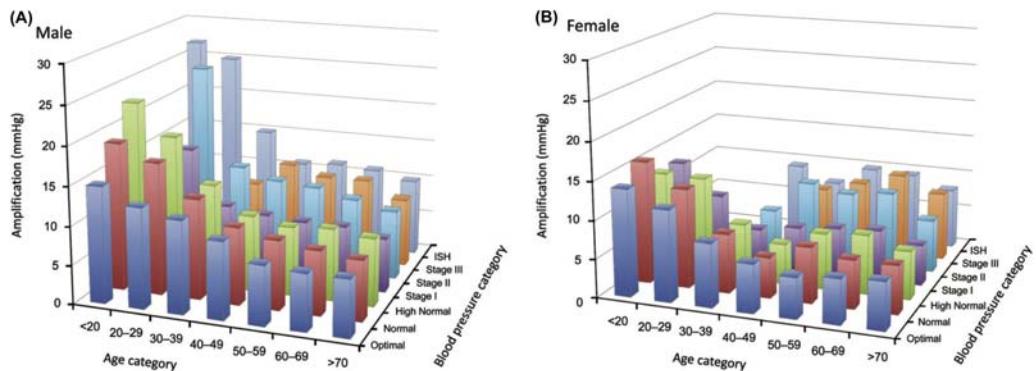
The pulsatility of BP is exaggerated in hypertensives by the phenomenon of wave reflection.[54,79] With hypertension, the large arteries stiffen and pulse pressure (PP = systolic *minus* diastolic) increases at the site of central and peripheral arteries. Because the arterial tree can be approximated to a viscoelastic tube with numerous branches and a high level of impedance (resistance in oscillatory conditions) of the tube end, retrograde waves, due to wave reflection, are generated. The higher the arterial stiffness, the higher the transmission velocity of both forward and reflected waves, thus the reflected wave arrives earlier in the central aorta and augments pressure in late systole, increasing central PP.[62,54]

To better understand the mechanisms leading to wave reflection and augmented central pulse pressure in systemic hypertension, it is important to take into account the heterogeneity of elastic properties along the arterial tree, resulting in a stiffness gradient or mismatch. In young normotensive subjects, the stiffness gradient is illustrated by the progressive increase in arterial stiffness from upstream proximal large arteries to downstream distal medium-size arteries (Fig. 29.1A). Although all of the large artery walls are constituted by three layers (intima, media, and adventitia), there is a difference between large proximal elastic arteries and medium-size distal muscular arteries regarding the relative amount of vascular smooth muscle cells (VSMCs) and extracellular matrix (especially elastin) in their media. In humans, pulse wave velocity increases from 4 to 5 m/s in the ascending aorta to 5−6 m/s in the abdominal aorta then 8−9 m/s in the iliac and femoral arteries.[35,54] In middle-aged normotensive subjects, the cross-sectional distensibility, assessed with echotracking systems, decreases from $40 \, kPa^{-1} \, 10^{-3}$ in the thoracic aorta[26] to $15-25 \, kPa^{-1} \, 10^{-3}$ in the carotid[37,28,5] and brachial[5,70] arteries, $10-15 \, kPa^{-1} \, 10^{-3}$ in the common femoral artery to $5 \, kPa^{-1} \, 10^{-3}$ in the radial artery.[36,38,5] Indeed, both VSMCs and many elastic lamellae are present in the media of large proximal artery, whereas VSMCs prevail in the media of medium-size distal artery.[54] In healthy subjects, the stiffness gradient between proximal elastic arteries and distal muscular arteries may lead to an impedance mismatch, generating pressure wave reflection upwards that limits the transmission of pressure pulsatility downward to the small arteries of target organs (Fig. 29.1A). The reflected pulsatile energy travels at low velocity along elastic arteries, thus do not superimpose on incident pressure wave and central systolic blood pressure (SBP) remains normal.


By contrasts, stiff elastic proximal arteries lose their ability to dampen the pulsatility of ventricular ejection. Thus, small arteries of target organ are damaged (Fig. 29.1B). Because distal muscular arteries do not stiffen with age,[43] the stiffness gradient between proximal elastic arteries and distal muscular arteries is reduced (and sometime inverted), and there is more transmission of pressure pulsatility toward small arteries of target organs. Most of the reflected pulsatile energy that return to the heart travels at high velocity along stiff arteries, and superimposes on incident pressure wave, thus increasing central SBP and PP. In parallel, the pulsatile pressure is not sufficiently attenuated and is transmitted downwards, damaging the microcirculation.

Whereas the paradigm described above takes into account the stiffness gradient, it should be noted that the main determinant of reflection at any given interface is the impedance gradient, rather than the stiffness gradient per se. As discussed in Chapters 1−3 and 11, impedance is more prominently influenced by size than stiffness. Therefore, the stiffness gradient does not equal impedance gradient, and indeed, the matching between the size of the aortic lumen and daughter vessels at bifurcations tends to match impedances even in young people with marked stiffness gradients. Conversely, in older people, aortic dilation may impact reflections at first order bifurcations, and may favor impedance mismatch despite stiffness matching (i.e., absence of a stiffness gradient). Clearly, more research is needed to better understand the role of stiffness and impedance matching at first order bifurcations as a determinant of target organ damage.


The wave reflection phenomenon also explains why the central systolic and pulse pressures are elevated in hypertensives. The main explanation resides in the "amplification phenomenon." The "central-to-peripheral amplification" means that central SBP increases from the central artery compartment to the peripheral arteries. Indeed, under resting conditions in healthy humans, brachial SBP is in average 10% higher than aortic SBP, sometimes up to 30%. In the presence of physiological arterial stiffness gradient (aortic PWV lower than peripheral PWV), reflection sites are closer to peripheral sites and reflection superimposes on forward wave, leading to amplification of pulse pressure. Because PWV is low, reflection comes late, in late systole or early diastole in central arteries, limiting pulse pressure. By contrast, when the stiffness gradient disappears or is inverted (aortic PWV higher than peripheral PWV), apparent reflection sites are much closer to central arteries, and pulsatile pressure is not sufficiently dampened at central level, and the central-to-peripheral pressure amplification is attenuated.[23]

The physiological amplification phenomenon is attenuated by aging because of arterial stiffening. Indeed, by favoring early wave reflections, arterial stiffening increases


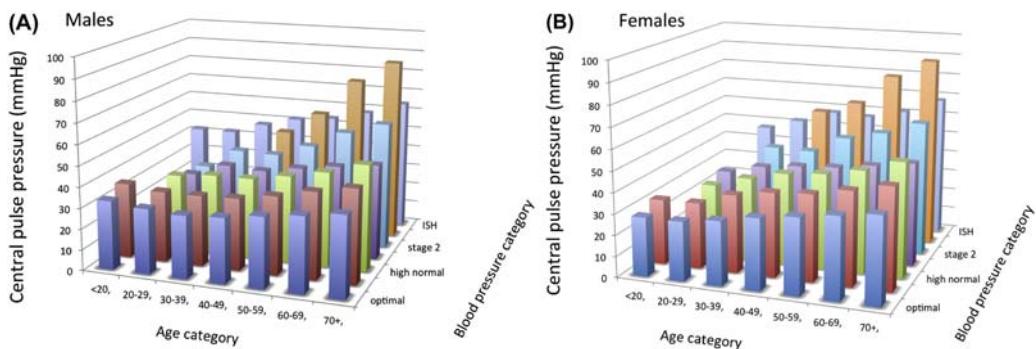


FIGURE 29.1 (A) Healthy aging is a means to retard brain, kidney, and heart damage. Indeed, in healthy subjects, an impedance mismatch occurs in response to the stiffness gradient between proximal elastic arteries and distal muscular arteries. This phenomenon generates pressure wave reflection, limiting the transmission of pressure pulsatility to target organs. The largest part of the reflected pulsatile energy that propagates backward, toward the heart, travels indeed at low velocity along elastic arteries, thus do not superimpose on incident pressure wave. Thus, central BP remains normal. (B) Wave reflections in elderly subjects and hypertensive patients. When the aorta stiffens with aging or hypertension, it loses its ability to dampen the pulsatility of ventricular ejection. Small arteries of the heart, brain, and kidney are damaged by the hyperpulsatility. Because the stiffness of distal muscular arteries does not change with age, there is a reduction of the stiffness gradient between proximal elastic arteries and distal muscular arteries. Thus, pressure pulsatility is transmitted to a larger extent toward small arteries of target organs. The largest part of the reflected pulsatile energy that propagates backward, toward the heart, travels at high velocity along stiff arteries. Thus, it superimposes on incident pressure wave and increase central systolic blood pressure. *(A) From Laurent S, Cunha P. Large vessels in hypertension: central blood pressure. peak- and end-systolic pressures in the ascending aorta. Thus, central systolic and pulse pressures are higher in elderly subjects than in young subjects and closer to the brachial SBP value, reducing the difference[23] (Figs. 29.2A,B and 29.3A,B). Excessive amplification leads to high SBP or PP in peripheral arteries, so called spurious systolic hypertension, often in young males, with various interpretations.[23]

Influence of lumen area on compliance, wave reflection, and pressure pulsatility

There is a bidirectional relationship between aortic root lumen area and pressure pulsatility.[49] The higher the central PP, the larger the aortic root diameter, suggesting a major role of pressure pulsatility on aortic root enlargement, through a fatigue phenomenon. Magnetic resonance imaging, which precisely investigates the geometry of aorta in hypertensives, showed that ascending aortic diameter and increased aortic arch length and width, as well as decreased aortic arch curvature were highly correlated with increased central PP.[57] Conversely the consequences of aortic remodeling on central BP remain less clear.[54,33,49] By contrast to studies in hypertensives, studies in normotensives[33,28] reported a negative relationship between central PP and aortic root diameter, i.e., the smaller the lumen diameter, the higher the central PP.[33] Thus suggested that the lack of aortic root dilatation, increasing characteristic impedance (Z_c) and wave reflection, would be the cause of high central PP and SBP. Altogether, these data suggest that excessive pulsatility favors aortic enlargement when the arterial wall is already damaged, for instance, by the hypertensive disease.[49] In turn, the enlargement of large proximal arteries can be viewed as a compensating phenomenon that enables to maintain a certain level of arterial compliance (expressed as $\Delta V/\Delta P$, i.e., the product of volumic distensibility $\Delta V/V.\Delta P$, and volume (V) despite aortic stiffening).[54] By contrast, when the aortic wall is healthy, a

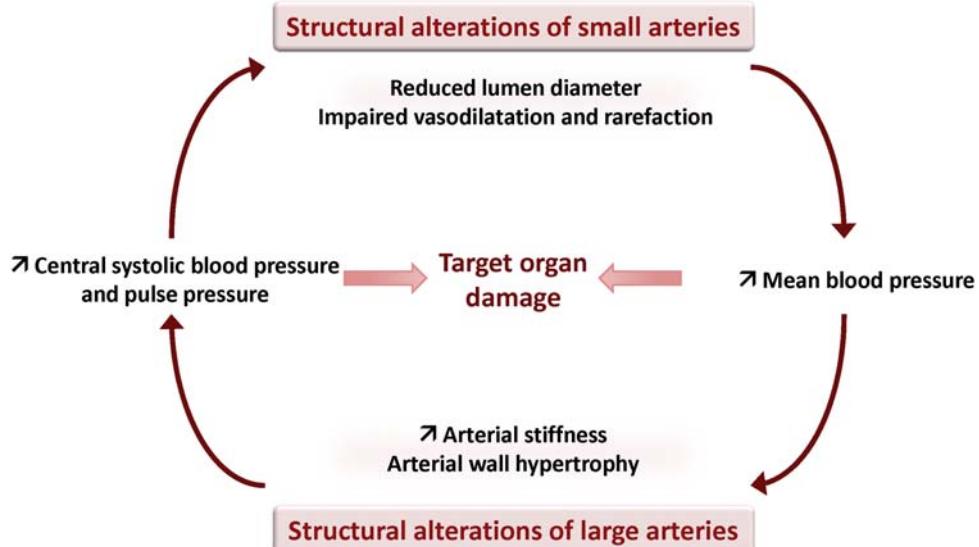
reduced volume of the aorta can increase characteristic impedance (Z_c) and generate wave reflection, and thus elevate central PP and SBP.

A second factor of complexity is represented by the changes in lumen area along the arterial pathway. Indeed, any change in lumen area (tapering or branching) can generate an impedance mismatch which may act in addition to the stiffness gradient between proximal elastic arteries and distal muscular arteries, as we have seen above. Points of arterial branching leading to changes in lumen area between daughter and parent vessels are sites of impedance mismatch.[13] Thus, given the innumerable sites of impedance mismatch throughout the arterial tree, individual reflection sites have little importance relative to the bulk of reflections originating elsewhere. In addition, all the reflected waves originating from thousands of reflection sites merge into a net reflected wave which appears discrete but is not due to a single reflection site, and can penetrate target organs as forward waves.[13]

Peripheral and central blood pressure in aging hypertensives

Cross-sectional and longitudinal population studies have shown that both peripheral SBP and DBP trajectories increase progressively between adolescence and adulthood.[12,21] Before 50 years of age, the increase in both brachial DBP and SBP can be explained by the increase in peripheral vascular resistance. DBP plateaus around age 50 years, and then decreases. By contrast, SBP continues to rise even after the age of 50 in response to the continuous age-induced increase in arterial stiffness, as explained above. After age 60, the divergent trajectories of SBP and DBP explains why PP begins to increase markedly after age 50. The rapid widening of PP is considered as caused by arterial stiffening.

For these reasons, isolated systolic hypertension, defined as SBP $\geq$140 and DBP <90 mmHg, represents the most frequent subtype of hypertension after age 60.[21] Men and women have different trajectories. The prevalence of hypertension in young women is lower than in men of the same age. And then, BP in women reaches men's values around the fourth decade of life. By the seventh decade, BP in women is higher than in men. Since hypertension is more frequent in the elderly, and elderly women have higher BP than men, it is not surprising that 60% of all hypertensive individuals now are women.[21]

Reference values for central SBP have been reported according to sex, age, and BP categories.[23] According to age, central SBP was higher in men than in women until age 50−59, after which the tendency was reversed. According to BP categories, central SBP was lower in men than in women within each peripheral BP category, except


"optimal." Amplification between central and peripheral BP, calculated as peripheral SBP minus central SBP, was higher in males than in females at any given age or BP value.[23] The difference between sexes becomes smaller with increasing age and values of BP. Amplification is very little influenced by BP categories. Amplification decreases gradually with aging without clearly reaching a plateau, except in those with optimal brachial BP.[23] (Figs. 29.2A,B and 29.3A,B).

Interaction between hypertension and arterial stiffness

Whether arterial stiffness is a cause or a consequence of hypertension, and whether large or small arteries are damaged first, have long been considered as major issues. The relationships between arterial stiffness, small artery damage, and BP are rendered more complex by two characteristics of hemodynamics and biomechanics.[63]

First, an insidious positive feedback loop between local mechanobiological responses and global hemodynamics may explain why central artery stiffening is at the same time a cause of hypertension and one of its consequences.[25] For instance, arterial stiffening in early phases of prehypertension may be a major determinant of elevated systolic BP on the long term.[44] Indeed, the longitudinal assessment of the temporal relationship between carotid and aortic stiffness[29] on the one side and incident hypertension on the other side suggests a precursor role of arterial stiffening in future altered systolic hemodynamic load. However, the reverse occurs when hypertension is installed, even at the lower grade of prehypertension. Indeed, arterial stiffening can be a consequence of the rise in mean BP. Early work, in the 1950s to 1970s, suggested that sustained increases in BP stimulate matrix synthesis and thus vascular thickness and structural stiffness. In addition, high BP loads the stiff components of the arterial wall and changes the spatial organization between smooth muscle cells and extracellular matrix[32] and eventually increases arterial stiffness.

Second, arterial stiffening may be paralleled by a remodeling of small resistance arteries. Small and large artery alterations are indeed closely interdependent in sustained grade I hypertension, and likely during the early phases of prehypertension. A temporal relationship is difficult to establish, and we previously suggested that a cross-talk, by which small artery alterations influence larger artery phenotype, and conversely large artery alterations influence small artery phenotype, is more likely than a linear sequence.[42] Both small and large artery damages contribute to the rise in central BP, by favoring the generation of wave reflections and their propagation, respectively. This is exemplified by the fact that, in hypertensive

FIGURE 29.4 Schematic representation of the large/small artery cross-talk: a vicious circle of aggravation between large and small artery alterations in essential hypertension. *From Safar ME, Asmar R, Benetos A, et al. French study group on arterial stiffness. Interaction between hypertension and arterial stiffness.* **Hypertension**. *2018; 72:796−805 with permission.*

patients, media-to-lumen ratio of subcutaneous small resistance arteries and carotid-femoral PWV are both independent determinants of central SBP. The cross-talk between the micro- and the macrocirculation[42] promotes a vicious circle which can be described by starting at the site of small arteries (Fig. 29.4). An increased resistance in small arteries increases mean BP, and then increases arterial stiffness in the large elastic arteries, which in parallel with more pressure wave reflections increases central systolic BP, variability of 24-h ambulatory brachial BP, and ultimately damages target organs.[42,43] The increased central BP pulsatility in turn is a factor of small resistance artery damage, i.e., increased media-to-lumen ratio of subcutaneous small resistance arteries. This has initially been reported in hypertensive animals,[14] and then in hypertensive patients with brachial pulse pressure[27] and more recently with central systolic and pulse pressures measured with applanation tonometry.[53] Interestingly, the wall-to-lumen ratio of retinal arteries is significantly correlated with 24-h systolic BP, and retinal microcirculation changes can already be found in prehypertensive subjects.[64] Eventually, increased media-to-lumen ratio of subcutaneous small resistance arteries, which is associated with reduced lumen diameter, represents the largest part of the structural part of increased total peripheral resistance, leading to a rise in mean BP, and thus continuing the vicious circle (Fig. 29.4). This may also apply to the interactions between diabetes and hypertension.[15]

Thus, whether hypertension causes or is caused by central arterial stiffening and whether large or small arteries are damaged first, can be considered irrelevant. The main issue is that a progressive worsening can ensue in either case, thus any onset of large artery stiffening or small artery remodeling merits early intervention.

High central blood pressure, hypertension-mediated organ damage, and cardiovascular complication

The small/large artery cross-talk has a synergistic effect on the heart, brain, and kidney, in large part through a high pulsatile energy that is delivered as central systolic or pulse pressure. There is a large amount of evidence that central systolic and pulse pressures are the most deleterious elements of the BP load on the heart, brain, and kidney in hypertensives. Their increase is better correlated with hypertension-mediated organ damage (HMOD) than either brachial systolic and pulse pressures or mean BP.[62,42,59] Because the effects of pulsatile hemodynamics on the heart, brain, and kidney are described in details in other chapters of this book, we only address here the main mechanisms and consequences related to systemic hypertension.

Cardiac damage

A higher correlation has been observed with central SBP and PP than with brachial SBP and PP for left ventricular hypertrophy (LVH),[6,56,78] systolic dysfunction,[34] and diastolic dysfunction[77] that can be considered as characteristics of cardiac damage in hypertensive patients. This is also the case for new onset of atrial fibrillation and left atria enlargement.[50] Central SBP increases the load on the left ventricle thus the myocardial oxygen demand. In addition, arterial stiffness is correlated to LVH,[6] a known risk factor

for coronary events.[31] High central PP and low diastolic BP can cause subendocardial ischemia. Indeed, a high central pulsatility reduces large epicardial coronary vascular tree perfusion during diastole, thus decreases coronary flow reserve because of lesser BP during early diastole.[19] Rarefaction and remodeling of intramyocardial coronary artery, as well as LVH and left ventricular diastolic dysfunction also contribute to a reduction in microcirculatory flow reserve, an impairment of tissue perfusion and a higher susceptibility to ischemia during high levels of metabolic and oxygen demand.[19] Atherosclerosis at the site of epicardial coronary arteries increases the damaging effects of above damages and the risk of ischemic heart disease.

Brain damage

The damage of large and small arteries can increase the risk of ischemic stroke, and, likely in parallel, white matter lesions, lacunar infarcts, and cognitive decline.[11,67] High pulse pressure can be transmitted into cerebral arteries, thus leading to an inward remodeling reducing lumen diameter aiming at protecting the microcirculation from pulsatile stress. The cerebral (as well as renal) circulation is particularly susceptible to pressure damage, since this is a high flow/low resistance circulation. Under such condition, mean and pulse pressures are easily transmitted from the aorta to small cerebral (and renal) arteries.[55] An increased arterial pulsatility due to large artery stiffening can thus be transmitted to cerebral small vessels and associated with white matter lesions.[76,52] Indeed, the pulsatility of the carotid flow, measured with Doppler, and pressure, and the carotid-femoral pulse wave velocity (cfPWV), are related with silent subcortical infarcts or white matter lesions,[76,52] and lower scores in various cognitive domains.[52] There is also a relationship between carotid stiffness and large white matter hyperintensity volume, independently of vascular risk factors and carotid plaque,[11] and with stroke.[71]

Several mechanisms can explain why an increased arterial stiffness can increase the risk of stroke: an elevated central PP, remodeling extracranial and intracranial arteries, in association with an increased carotid wall thickness and the development of stenosis and plaques[43] and the prevalence and severity of cerebral white matter lesions.[11,66] Aortic stiffening may also express damages at the site of the cerebral vasculature. Thus, it is not surprising that aortic stiffness can to predict not only incident stroke,[40] but also the functional outcome after stroke, independently of classical cardiovascular risk factors.[22] Another explanation is given by the differential physiological behavior of brain small arteries compared with other systemic vascular beds.[62] In elderly hypertensives, the inward remodeling of small cerebral arteries and associated increased myogenic

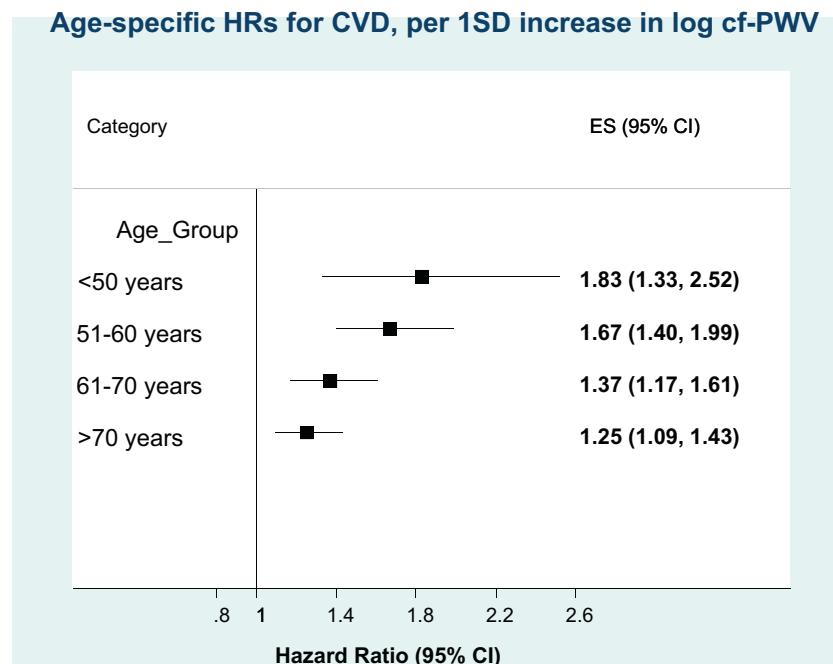
tone impairs vasomotor reactivity, limits the autoregulation of cerebral blood flow, and increases susceptibility to focal ischemia when BP is transiently and/or acutely low. Patients with exaggerated visit-to-visit variability of BP, namely SBP, are at increased risk of stroke,[60] which suggests that repeated episodes of hypoperfusion and microvascular ischemia resulting from excessive variability coupled with reduced autoregulation, could favor tissue damage and stroke. Similar findings can result from exaggerated short-term BP variability, detected with ambulatory BP monitoring, that is associated with arterial stiffness.[65] Finally, a high central PP may remodel the arterial system not only at the site of the intracranial arteries, but also in extracranial arteries, thickening the carotid wall, leading to the development of atherosclerotic plaques.[7,82]

Renal damage

Myogenic tone in the renal circulation is impaired in the elderly hypertensive. The consequence is a loss of the autoregulation capacity and an increase in barotrauma due to high systolic BP, leading to glomerular injury. Because of its torrential nature (very low resistances), even small increases in peripheral BP are transformed into high pulsatile energy that is transmitted to the kidney and dissipated in the microcirculation, leading to hyperfiltration and glomerulosclerosis. Clinical data are consistent with this pathophysiological approach. Significant relationships have been demonstrated between brachial pulse pressure and either glomerular filtration rate (GFR) or microalbuminuria[20]; between arterial stiffness and either GFR[9,24] or urinary albumin[24]; between carotid stiffness and GFR[24]; and between central PP and incident end-stage renal disease.[10] Although confounding factors may not be fully excluded, there is a large amount of evidence for linking the pulsatility of BP to renal damage.

Cardiovascular and renal outcome

Because the small/large artery cross-talk exerts a synergistic damaging effect on the heart, brain, and kidney, it is not surprising that arterial stiffness[39,8]; Vlachopoulos et al. 2010,[30,51] central systolic and pulse pressures[10]; Vlachopoulos et al. 2010,[61] and media-to-lumen ratio of small resistance arteries,[58] have independent predictive value for CV events and renal complications in hypertensive patients.

Predictive value of arterial stiffness and wave reflection in hypertensives


The measurement of arterial stiffness and wave reflections in clinical practice in hypertensives is comforted by the repeated demonstration that arterial stiffness has an independent predictive value for CV events.[41,69]

Several longitudinal epidemiological studies have demonstrated the predictive value of arterial stiffness for CV events. The largest amount of evidence has been given for aortic stiffness, measured through carotid-femoral PWV. Aortic stiffness has independent predictive value for all-cause and CV mortality, fatal and nonfatal coronary events, and fatal strokes not only in patients with uncomplicated essential hypertension,[39,8,40] but also in patients with type 2 diabetes,[17] end-stage renal disease,[4] in elderly subjects[48] and in the general population.[46,51]

Two meta-analyses[72,3] consistently showed the independent predictive value of aortic stiffness, measured by carotid-femoral PWV, for fatal and nonfatal CV events in various populations, as well as two meta-analyses on carotid stiffness.[71,81] Brachial-ankle PWV has also demonstrated a predictive value for CV events.[73] This amount of evidence led the European Society of Hypertension and the European Society of Cardiology, in their 2013[45] and 2018[80] common guidelines for the management of hypertension, to include carotid-femoral PWV in the list of measurements in order to assess HMOD. The measurement of brachial-ankle PWV is recommended by the 2019 Japanese Society of Hypertension guidelines for the management of hypertension.[68] A 2015 position statement from the European Society of Cardiology working group on peripheral circulation ranked the carotid-femoral PWV and the brachial-ankle PWV as top biomarkers for assessing the CV risk in clinical practice.[74]

Aortic stiffness has demonstrated an independent predictive value for CV events after adjustment to classical CV risk factors, including brachial pulse pressure. These data show that aortic stiffness predicts CV events to a larger extent than each of classical risk factors. In addition, aortic stiffness retains its predictive value for CHD events after adjustment to the Framingham risk score, demonstrating an added value to a combination of CV risk factors.[8] Aortic and carotid stiffness have additive predictive value.[71] As discussed above, one reason may be that aortic stiffness is an integrator of the cumulative damage of CV risk factors on the aortic wall over a long period of time, whereas the classical CV risk factors, such as BP, glycemia, and lipids can fluctuate over time. Thus, their values, measured at the time of risk assessment, may not reflect the true values damaging the arterial wall.

An important issue is whether arterial stiffness retains its independent predictive value in elderly hypertensives[3] undertook a systematic review and obtained individual participant data from 16 studies gathering 17,635 participants. cfPWV demonstrated predictive value for coronary heart disease, stroke, and CVD. Associations stratified according to sex, diabetes, and hypertension were similar but decreased in intensity with age: 1.89, 1.77, 1.36, and 1.23 for age <50, 51–60, 61 to 70, and >70 years, respectively, for one standard deviation, with a significant interaction (Fig. 29.5). Thus, although the predictive value of arterial stiffness for CV events is higher in adults less than 50 years, it is still significant in elderly.

Age-specific HRs for CVD, per 1SD increase in log cf-PWV

The particular case of very elderly hypertensives

Subjects older than 80 years represent a particular population since they are often frail, with several comorbidities. Very few studies have been done in very elderly hypertensives. The HYVET study,[1] one of the rare large randomized clinical trial performed so far in very old hypertensives (average 84 years), showed that antihypertensive treatment with indapamide, with or without perindopril, can be beneficial. This was confirmed by Corrao et al.,[16] in a nested case-control study on a cohort of patients aged 85 years or older (average 88 years). These patients were newly treated with antihypertensive drugs and the level of drug adherence was available. Compared with patients with very low adherence, patients with high adherence[16] showed a significant risk reduction for death and all the outcomes combined. The risk of heart failure and stroke was also reduced, whereas the risk of MI was not affected by adherence with antihypertensive drugs. Interestingly, similar findings were obtained in the cohort of patients aged 70–84 years.

Very few studies addressed the particular case of very elderly individuals. The PARTAGE study is an observational one[2,75] that followed 682 individuals aged older than 80 during 2 years, and showed that arterial stiffness as evaluated by cfPWV was associated with a more pronounced cognitive decline over a one-year period in very old frail institutionalized individuals. These data suggest that even in very old, frail individuals, arterial stiffness remains a determinant of cognitive decline, morbidity, and mortality.[63]

Conclusion

In this chapter, we have discussed the various mechanisms underlying the relationship between arterial stiffness and increased central pressure pulsatility. We addressed the issue that hypertension is both a cause and a consequence of central arterial stiffening. Finally, we suggested an integrated pathophysiological approach through which the cross-talk between large and small artery changes interacts in the transmission of pressure pulsatility, exaggerates cardiac, brain and kidney damage, and lead to cardiovascular and renal complications in hypertensive patients.

Chapter 30

Arterial stiffness and pulsatile hemodynamics in diabetes and obesity

Introduction

Increased large artery stiffness (LAS) contributes to isolated systolic hypertension, increases cardiac afterload, and promotes increased pressure and flow pulsatility in the arterial tree.[1-3] Diabetes mellitus (DM), hypertension, obesity, and chronic kidney disease accelerate vascular aging, promoting LAS.[4,5] Furthermore, as the aorta stiffens over time, the increased pressure pulsatility is preferentially transferred to low-resistance microvascular beds such as the brain, kidney, liver, and pancreatic islets.[6-8] The resulting microvascular dysfunction may contribute to the development of insulin resistance and DM,[9-12] suggesting a bidirectional relationship between arterial stiffness and metabolic diseases (Fig. 30.1). There is a strong association of elevated carotid-femoral pulse wave velocity (CF-PWV; the reference standard measurement of arterial stiffness)[13-16] and measures of adverse pulsatile hemodynamics (e.g., increase and/or premature wave reflection)[17,18] with adverse cardiovascular outcomes. The bidirectional relationship of arterial stiffness with DM likely plays a distinctive role in mediating adverse cardiovascular outcomes in this patient population.

The goal of this chapter is to provide a translational overview of the pathophysiology and epidemiology of the relationship arterial stiffness with DM and obesity, and to identify important areas for future investigation.

Diabetes Mellitus

142

FIGURE 30.1 **Bidirectional relationship between large artery stiffening and diabetes mellitus**. On one hand, large artery stiffening may contribute to the pathogenesis of diabetes mellitus. On the other hand, established diabetes mellitus may contribute to accelerated large artery stiffening. Some potential mechanisms are listed.

Pathophysiologic role of diabetes mellitus in the development of increased arterial stiffness

Multiple mechanisms contribute to accelerated vascular aging and arterial wall stiffening in patients with type 2 DM, including (1) excess collagen deposition and cross-linking due to advanced glycation end-products (AGEs)[19]; (2) nitric oxide dysregulation resulting in oxidative stress and endothelial dysfunction[20]; (3) large artery calcification and atherosclerosis[21]; (4) chronic inflammation[22]; and (5) increased sympathetic tone.[22] In this section, we will highlight proposed pathophysiologic mechanisms of vascular stiffness particularly as they relate to AGEs and nitric oxide dysregulation (Fig. 30.2).

The role of advanced glycation end-products in the development of arterial stiffness

AGEs are proteins or lipids that develop in hyperglycemic environments and during aging.[23] AGEs are glycated and oxidized after exposure to sugars, and are commonly found in the vasculature of patients with diabetes.[19] AGEs have been demonstrated to contribute to the development of several microvascular and macrovascular complications in both diabetic and nondiabetic populations.[24] The main mechanism of arterial stiffness due to AGEs is attributed to the accumulation of AGEs in the arterial vessel wall, resulting in changes to structure and function of the blood vessel.

The AGE formation process begins when the carbonyl group of a reducing sugar moiety (glucose, fructose, glycolytic adductions) interacts with proteins, lipids, and nucleic acid amino groups in a reaction first described by Louis Maillard in the early 20th century. This reaction leads to the formation of two intermediate products, Schiff bases and Amadori products. Over the course of several months, Amadori products accumulate and react with amino, sulfhydryl, and guanidine groups of targeted proteins, promoting the denaturation, fragmentation, and cross-linking of these proteins which ultimately leads to the irreversible formation of AGEs.[24-27] These reactions are enhanced in carbonyl-enriched states such as DM (which increases AGE formation) and end stage kidney disease (which reduces AGE degradation).[3,28] They are also promoted via other intermediates, such as glyoxal and methylglyoxal, through lipid oxidation, inflammation, and environmental pollutant exposure, such as cigarette smoke.[29] Glycated hemoglobin (HbA1c) is an example of a clinically familiar and relevant Amadori product that is used for the diagnosis of diabetes and reflects blood glucose levels over an approximate 90-day period.[30-32]

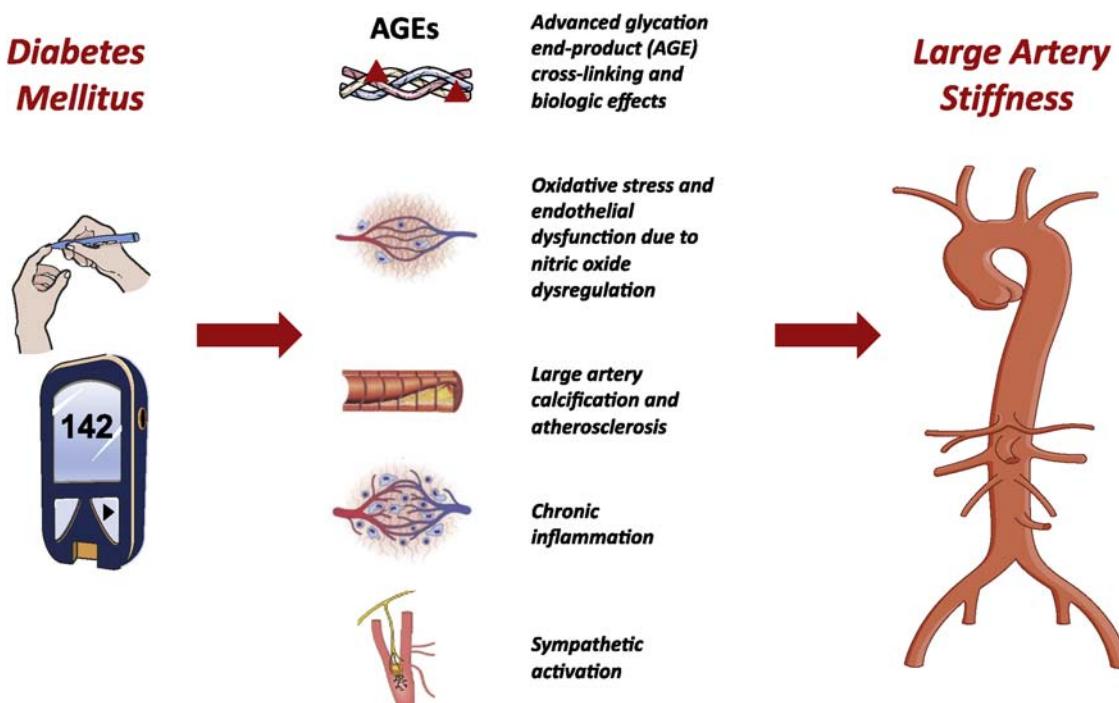
AGEs can accumulate in arterial walls, where they disrupt normal vascular structure and function. Arterial walls are largely composed of collagen, which provides structural support, and elastin, which provides distensibility.[33] Fragmentation of elastin fibers in the arterial wall occurs during aging. In large arteries, fragmentation and loss of elastin fibers can also be associated with increased collagen deposition.[34,35] AGEs preferentially cross-link


FIGURE 30.2   Pathophysiologic relationship between diabetes mellitus (DM) and large artery stiffness. Mechanistic factors that promote large artery stiffness in patients with DM are shown.

collagen over elastin, potentially due to a relatively higher content of lysine residues on collagen compared with elastin.[34] Normally, cross-links occur at two discrete sites at the N-terminal and C-terminal ends of collagen. However, AGEs can form cross-links at any site on collagen.[36] AGE-mediated cross-links confer increased resistance to enzymatic proteolysis of collagen and decreased rate of collagen degradation, promoting accumulation of collagen in large artery walls.[37] In contrast, glycated elastin is more susceptible to degradation.

In addition to collagen and elastin cross-linking, AGEs may promote vascular stiffness via several alternative mechanisms, including (1) activation of transcription factor NF-κB, which alters cellular adhesion molecule expression and promotes cytokine activation[38,39]; (2) glycosylation and oxidation of lipoproteins and increased foam cell formation[40]; and (3) glycosylation of reactive intermediates that inactivate nitric oxide and mediate endothelial dysfunction.[41] AGEs can activate the receptor of AGEs (RAGEs), inducing inflammation, oxidative stress, and calcification pathways (via sodium phosphate co-transporter PiT-1 expression). However, the functional significance of AGE-RAGE interactions in vivo is unclear.[3]

Several human studies have demonstrated a relationship between collagen cross-linking, AGE accumulation, and elevated CF-PWV. In a study of 41 subjects with long-standing type 1 DM compared with 25 controls, Monnier et al. observed that collagen-linked fluorescence was positively correlated with CF-PWV (r = 0.41, $P < .01$).[42] Subsequently, accumulation of specific AGEs in aortic tissue, such as pentosidine and glyoxal/methylglyoxal hydroimidazolones, has been correlated with aortic stiffness in subjects both with and without DM.[43]

Serum levels of AGE have also been cross-sectionally associated with markers of LAS, though this is not consistent across all studies. In a nested case-control study of 543 type 1 diabetic participants of the EURODIAB Prospective Complications Study, Schram et al. demonstrated that serum levels of two AGEs, Nε-(carboxymethyl)lysine and Nε-(carboxyethyl)lysine, were significantly associated with wider pulse pressure in models adjusted for several demographic, anthropomorphic, and clinical characteristics.[44] Similarly, in 423 diabetic and nondiabetic adult participants of the Baltimore Longitudinal Study of Aging, Semba et al. observed that every standard deviation higher serum level of Nε-(carboxymethyl)lysine was associated with a 0.16 m/s higher CF-PWV in multivariable-adjusted models.[45] Alternatively, in a cohort of 145 patients referred for coronary angiography for assessment of suspected coronary artery disease, Won et al. observed an association of serum levels of AGE with obstructive coronary artery disease, but not with brachial-ankle PWV.[46] The lack of association

may be due to the limitations of brachial-ankle PWV as a metric of LAS.

A number of longitudinal studies have also demonstrated a relationship between AGEs and the development and progression of microvascular complications of DM.[47] In a prospective study of 211 participants of the Diabetes Control and Complications Trial who underwent skin biopsy, skin AGEs independently predicted the 10-year risk of diabetic retinopathy and nephropathy.[48,49] Similarly, in a study of 30 patients with type 1 or type 2 DM and age- and sex-matched controls, skin pentosidine and fluorescence were associated with the six-year risk of progression of retinopathy and nephropathy.[50] In a case-control study of subgroup of 134 participants of the Collaborative Study Group's Trial of captopril in type 1 diabetic nephropathy, Weiss et al. observed that individuals who experienced doubling of serum creatinine during follow-up had higher serum levels of pentosidine compared with those who did not experience progressive nephropathy.[51]

Elevated serum AGE levels have also been linked to all-cause mortality and cardiovascular mortality in several cohorts. For example, in a longitudinal cohort study of 974 Finnish patients with type 2 DM followed for 18 years, the highest sex-specific quartile of serum AGE levels was associated with a 51% higher risk of all-cause mortality [hazard ratio (HR) 1.51, 95% confidence interval (CI) 1.14−1.99] and a 68% higher risk of cardiovascular mortality compared with the lowest quartile (HR 1.68, 95% CI 1.11−2.52) among women, which persisted after robust adjustment for multiple demographic and physiologic parameters.[52] However, the relationship of AGEs with mortality was not significant among men in the cohort. In a cohort of 339 men and women with type 1 DM followed for a median of 12.3 years, every standard deviation increase in serum levels of AGEs was associated with a 30% increased risk of incident fatal and nonfatal cardiovascular disease (adjusted HR 1.30, 95% CI 1.03−1.66) and a 34% increased risk of all-cause mortality (adjusted HR 1.28, 95% CI 1.01−1.64).[53] In the same cohort, higher plasma levels of soluble receptor for AGEs were also strongly and independently associated with increased risk of incident fatal and nonfatal cardiovascular disease and all-cause mortality.[54]

Nitric oxide, oxidative stress, and arterial stiffness

Nitric oxide (NO) has vasodilatory, antiplatelet, anti-inflammatory, and antioxidant properties, impaired nitric oxide synthesis and bioavailability promotes endothelial dysfunction and arterial stiffness.[20] Reduced NO production by the endothelium may play a role in regulating VSMC stiffness/tone in distal aortic segments like the

abdominal aorta.[3] Hyperglycemia and insulin resistance contribute to endothelial dysfunction and arterial stiffness by interfering with NO-mediated vasodilatation. In patients with insulin resistance, impaired NO synthase activation and increased superoxide production lead to increased NO inactivation and decreased endothelial NO production, reducing its overall bioavailability.[55,56] Chronically elevated blood glucose is associated with enhanced polyol, protein kinase C, and pentose phosphate pathways, further contributing to increased oxidative stress and endothelial apoptosis.[57,58]

Abnormalities in the NO pathway in type 2 DM contribute to endothelial progenitor cell dysregulation.[55] Circulating levels of endothelial progenitor cells, which are responsible for the normal development of new endothelial cells, are lower in patients with type 2 DM compared with normal controls.[59] In a cross-sectional study of 234 patient with type 2 DM and 121 age- and sex-matched nondiabetic controls, Yue et al. observed that circulating levels of endothelial progenitor cells were inversely proportional to glycemic control as well as brachial-ankle PWV[60]; patients with DM and better glycemic control, measured using HbA1c, exhibited lower arterial stiffness and higher circulating levels of endothelial progenitor cells than those with poorer glycemic control. However, these associations may represent epiphenomena related to the multiple biologic changes associated with poor glycemic control, and the causal relationship between endothelial progenitor cells and arterial stiffening was not established.

Epidemiologic association of diabetes mellitus with the development of increased arterial stiffness

DM is a well-established risk factor for accelerated large artery stiffening, as measured by pulse pressure, CF-PWV, and aortic characteristic impedance (Zc). The breadth of studies demonstrating cross-sectional and longitudinal associations of DM with LAS and pulsatile hemodynamics has grown substantially over time with ongoing improvements in the techniques used to noninvasively measure these parameters. The aim of this section is to highlight key studies that have evaluated arterial stiffness and pulsatile hemodynamics in patients with DM.

Risk of increased arterial stiffness and adverse cardiovascular events in patients with diabetes mellitus type 2

Cross-sectional data consistently demonstrate a strong association of DM with elevated PWV.[61−69] For example, in a cross-sectional study of 169 patients with type 2 DM (n = 57) and nondiabetic controls (n = 112), Cameron et al. observed that patients with type 2 DM exhibited

CF-PWV, carotid-radial PWV, and aortic-finger PWV values that were similar, on average, to those among nondiabetic patients who were 15 year older.[61] In a population-based study of 571 patients in London, United Kingdom, Cruickshank et al. showed that at any level of systolic blood pressure, aortic PWV was higher in patients with type 2 DM compared with nondiabetic controls.[62,63] Kimoto et al. measured four arterial segments of PWV in 434 patients with type 2 DM and 192 nondiabetic controls. The authors observed that patients with diabetes had greater PWV in all four arterial segments compared with nondiabetic controls. However, after multivariable adjustment, diabetes was significantly associated with higher PWV in larger-sized arterial segments representing aortic PWV, but not in medium-sized arterial segments (heart-brachial and femoral-ankle).[64]

Although most data are cross-sectional, prospective data support that type 2 DM is a risk factor for the development of arterial stiffening over time. For example, in a prospective analysis of 508 community-dwelling participants of the Maine−Syracuse Longitudinal Study, Elias et al. observed that prior type 2 DM was associated with higher subsequent CF-PWV and that uncontrolled DM was associated with a ninefold higher risk of elevated PWV (defined by the authors as $\geq$12 m/s).[70]

There is a strong relationship between arterial stiffness and the risk of cardiovascular events and mortality that is particularly robust in patients with type 2 DM.[71,72] In the Hoorn Study, a population-based cohort study of 2484 Dutch patients including 208 patients with type 2 DM, pulse pressure was associated with cardiovascular mortality among diabetic, but not nondiabetic patients.[73] In a longitudinal, population-based cohort study of 140 patients with impaired fasting glucose, van Dijk et al. showed that every standard deviation increase in brachial artery pulse pressure was associated with a 70% increase in all-cause mortality, with similar results after multivariable adjustment for several demographic, anthropomorphic, and clinical parameters.[74] In a prospective cohort study of 2308 patients with type 2 DM followed for a median of 8.6 years, Kim et al. observed that the highest quartile of brachial-ankle PWV was associated with a 2.5-fold increased risk of all-cause mortality (adjusted HR 2.55, 95% CI 1.49−4.35) and a 5.6-fold increased risk of cardiovascular mortality (adjusted HR 5.57, 95% CI 1.19−26.18) compared with the lowest quartile.

Risk of increased arterial stiffness and adverse cardiovascular events in patients with diabetes mellitus type 1

The relationship between PWV and type 1 DM is less consistently demonstrated than in type 2 DM, which may be due to smaller sample sizes in studies of patients with

type 1 DM as well as generally lower rates of other metabolic diseases and obesity. In a study of 17 patients with type 1 DM compared with age- and sex-matched nondiabetic controls, Sweitzer et al. observed that patients with type 1 DM exhibited wider central and peripheral pulse pressure, despite similar mean blood pressure, compared with nondiabetic controls. Although CF-PWV was similar between diabetics and nondiabetics, aortic characteristic impedance (Zc) was higher in type 1 diabetics compared with diabetics, and was particularly elevated among those with albuminuria.[75] Similarly, in a study of 35 patients with type 1 DM compared with 35 nondiabetic matched controls, Wilkinson et al. observed that aortic augmentation index, a metric of pulse wave reflection, and estimated PWV, were significantly higher in patients with diabetes compared with controls using peripheral pulse waveforms.[76] In contrast, in a cross-sectional study of 89 subjects with type 1 DM compared with 95 nondiabetic controls, Brooks observed that aortic augmentation index was increased in men, but not women, with type 1 DM compared with controls.[77]

Limited evidence exists regarding the association between hyperglycemia and measures of arterial stiffness and pulsatile hemodynamics in type 1 DM. In a mechanistic study of 22 men with type 1 DM and 13 nondiabetic men, Gordin et al. evaluated the effect of acute hyperglycemia on arterial stiffness by measuring carotid-radial PWV, CF-PWV, and aortic augmentation index before and after a 2-h hyperglycemic clamp.[78] At baseline, the authors observed that patients with diabetes had higher aortic augmentation index, but similar carotid-radial and CF-PWV, compared with nondiabetic controls. After the 2-h clamp, acute hyperglycemia increased the carotid-radial PWV in patients with but not those without diabetes, and increased the aortic augmentation index similarly in patients both with and without diabetes.

Risk of increased arterial stiffness and adverse cardiovascular events in patients with prediabetes

Several studies have evaluated the cross-sectional association between prediabetes and vascular stiffness to better understand the temporal relationship between arterial stiffness, impaired glucose tolerance, and DM. In the Hoorn Study, a population-based cohort study of 2484 Dutch patients, Schram et al. observed a dose-response relationship of normal blood glucose, impaired fasting glucose, and DM with regard to carotid-femoral transit time.[79] A number of studies have demonstrated that levels of plasma glucose at the upper limit of normal are associated with increased arterial stiffness,[80–83] but these observations are not consistent across all studies. For example, in the Asklepios Study, a population-based study of 1927 middle-aged

middle-aged adults, after adjustment for age, sex, and mean arterial pressure, impaired fasting glucose was not associated with elevated arterial stiffness.[65] Thus, the temporal relationship between prediabetes and arterial stiffness requires further investigation, particularly in studies that evaluate PWV and changes in glucose tolerance and diabetes status longitudinally.

The role of arterial stiffness in the promotion of diabetic microvascular disease

In the Asklepios Study, after adjustment for age, sex, and mean arterial pressure, type 2 DM was associated with higher CF-PWV, lower total arterial compliance and decreased reflection magnitude.[65] The reduced reflection magnitude arriving at the proximal aorta suggests increased penetration of pulsatile energy to distal vascular beds in patients with type 2 diabetes, as also suggested by previous studies.[84–86] This selective aortic stiffening without stiffening of more distal arteries may facilitate increased penetration of potentially harmful pulsatile energy into the microvasculature of target organs, promoting the microvascular damage observed in patients with DM including retinopathy, nephropathy, peripheral neuropathy, autonomic dysfunction, and cognitive dysfunction. Microvascular damage in DM is consistently associated with elevated mortality risk.[87–90] Thus, more research is needed to identify ways to prevent and slow the progression of microvascular disease in this population.

Arterial stiffness and diabetic retinopathy

Several studies have demonstrated a consistent correlation of arterial stiffness with diabetic retinopathy.[89,91–95] In a cross-sectional analysis of 600 randomly selected subjects with type 2 DM from the Chennai Urban Rural Epidemiology Study, Rema et al. observed that aortic augmentation index was significantly higher in subjects with retinopathy compared with those without retinopathy (27.9 vs. 25.8 mm, $P = .031$), which persisted after multivariable adjustment for age, duration of diabetes, HbA1c, serum cholesterol, serum triglycerides, and microalbuminuria.[91] Similarly, in a cross-sectional study of 494 participants of the Seoul Metro-City Diabetes Prevention Program with type 2 DM, Kim et al. showed that the highest quartile of heart-femoral PWV was independently associated with a fivefold higher odds of diabetic retinopathy than the lowest quartile (adjusted odds ratio 5.02, 95% CI 1.69–14.91).[92] A number of studies have demonstrated similar cross-sectional associations between LAS and pulsatile hemodynamics with diabetic retinopathy.[93–95] Moreover, in a cross-sectional analysis of 689 patients with type 2 DM in Japan, Tanaka et al. observed a positive association between the stages of diabetic retinopathy and higher brachial-ankle PWV.[89]

Arterial stiffness and diabetic nephropathy

DM is the foremost cause of chronic kidney disease and end-stage kidney disease.[96,97] Correspondingly, the development of microvascular disease in the kidney, as evidenced by, albuminuria, is strongly associated with increased risk of progression to end stage kidney disease, cardiovascular disease, and all-cause mortality.[98] Mild albuminuria often precedes the development of clinically evident renal dysfunction, or reduction in glomerular filtration rate, in patients with DM by several years.[99]

Several studies have investigated the relationship between arterial stiffness and diabetic nephropathy.[5,90,100−105] In a cross-sectional analysis of 2564 participants of the Chronic Renal Insufficiency Cohort (CRIC) Study with mild to moderate chronic kidney disease, Townsend et al. observed that DM (β coefficient 1.51, standard error 0.13) and fasting blood glucose (β coefficient 0.04 per 10 mg/dL, standard error 0.01) were independently associated with increased CF-PWV.[5] In multivariable models stratified by diabetes status, carotid-femoral PWV explained a significant portion of the variation in urinary protein excretion among diabetic, but not among nondiabetic, participants.[100] In longitudinal analyses of the full 2795 CRIC Study participants who ultimately underwent CF-PWV measurements and were followed for a mean of 5.4 years, those in the highest tertile of CF-PWV exhibited a 37% higher risk of end stage kidney disease (adjusted HR 1.37, 95% CI 1.05−1.80) and 72% higher risk of all-cause mortality (adjusted HR 1.72, 95% CI 1.24−2.38) compared with those in the lowest tertile.[90]

Smith et al. measured CF-PWV in 134 patients with type 2 DM, normal serum creatinine, and varying severity of albuminuria,[104] and demonstrated that an elevated albumin to creatinine ratio (defined by the authors as ≥3 mg/mmol) was associated with higher CF-PWV and that PWV was higher in patients with lower glomerular filtration rate. Additionally, the authors estimated that a 10-year period of longer duration of DM was associated with PWV to the same extent as 10 mmHg higher pulse pressure or 6.5-year older age.[104] In a case-control study of 122 patients with type 2 DM compared with 122 matched controls, a decline in glomerular filtration rate over time was associated with increased aortic stiffness, independent of baseline level of kidney function.[106] Moreover, in a longitudinal cohort study of 461 patients with type 2 DM followed over a median of 5.9 years, Bouchi et al. demonstrated that CF-PWV was associated with incident albuminuria (HR 1.23, 95% CI 1.13−1.33) and rate of decline in estimated glomerular filtration rate.[107]

In their study measuring four arterial segments of PWV in 434 patients with type 2 DM and 192 nondiabetic controls, Kimoto et al. observed that increased PWV in each segment was associated with advancing stage of chronic

kidney disease, respectively.[64] However, after multivariable adjustment, lower GFR was only independently associated with higher heart-femoral PWV.[64] The authors' findings suggest an association between LAS, but not medium-sized (muscular) artery stiffness, with poorer kidney function,[64] which has also been supported by other studies.[106] Furthermore, aortic PWV, but not brachial or femorotibial PWV, predict all-cause mortality in patients with end stage kidney disease.[67] For an extensive discussion regarding the relationship between arterial stiffness and renal disease, the reader is referred to Chapter 40.

Arterial stiffness and diabetic neuropathy and autonomic dysfunction

Longstanding DM is associated with a high incidence of neuropathy, which can manifest as peripheral neuropathy or autonomic dysfunction. Arterial stiffness and adverse pulsatile hemodynamics have been associated with both peripheral neuropathy and autonomic dysfunction in patients with DM.

In a cross-sectional analysis of 692 patients with type 2 DM, patients with brachial-ankle PWV ≥16 m/s were more likely to have abnormal monofilament testing (14.9% vs. 6.6%) and elevated peripheral neuropathy total symptom score (36.8% vs. 28.3%) compared with those with brachial-ankle PWV <1.6 m/s.[108] A study of 100 patients with DM who underwent nerve conduction studies demonstrated a significant negative correlation between brachial-ankle PWV and superficial peroneal and sural sensory nerve action potential and nerve conduction velocity.[109] Similarly, in 294 patients with type 2 diabetes, Yokoyama et al. observed that brachial-ankle PWV (odds ratio 1.002, 95% CI 1.001−1.003 per cm/s increase) and pulse pressure (odds ratio 1.05, 95% CI 1.02−1.08 per mmHg increase) were independently associated with neuropathy determined by symptoms, absence of ankle tendon reflexes, vibratory perception, and heart rate variability.[110]

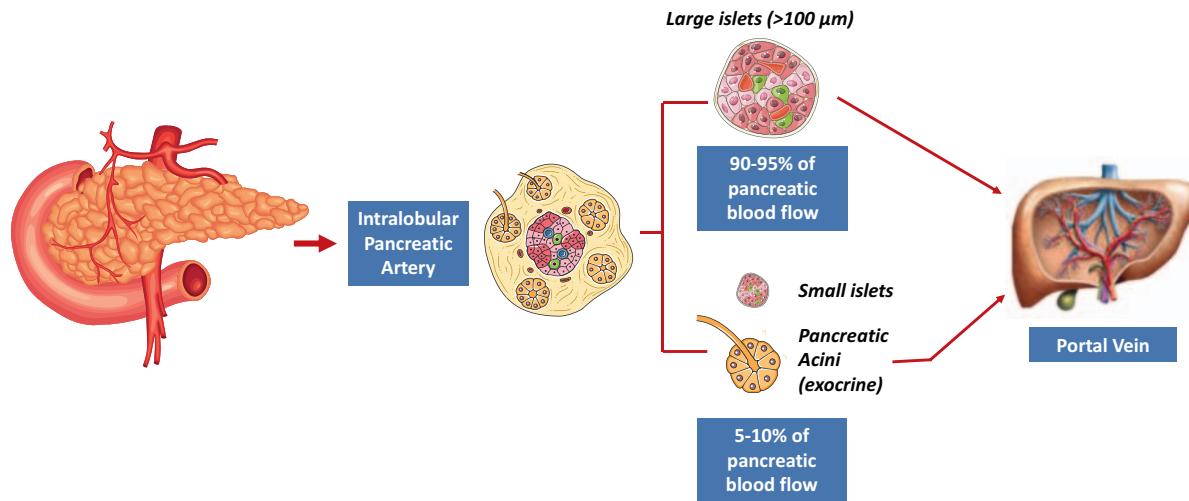
Several studies have demonstrated a correlation between elevated PWV and autonomic dysfunction.[111,112] For example, in 2004, Meyer et al. assessed autonomic function in 45 patients with type 2 diabetes and 45 age-, sex-, and BMI-matched nondiabetic controls by assessing heart rate variability during breathing, Valsalva, and postural maneuvers. The authors showed that CF-PWV and femoral-dorsalis pedis PWV were positively correlated with autonomic dysfunction.[112]

Arterial stiffness and cognitive dysfunction in patients with diabetes mellitus

Similar to other markers of microvascular disease in patients with DM, several studies have demonstrated an

independent association of arterial stiffness with cognitive dysfunction and white matter lesions. For example, in a study of 89 patients with recently diagnosed type 2 DM and 89 age- and sex-matched nondiabetic controls, Laugesen et al. observed that CF-PWV was higher in patients with diabetes compared with controls, and that higher PWV was associated with higher volume of white matter lesions.[113] In patients with type 2 DM, LAS is associated with poorer cognitive function on neuropsychiatric testing.[114] Brachial-ankle PWV is higher among patients with type 2 DM with a prior history of ischemic stroke compared to those without stroke.[115] For an extensive discussion regarding the relationship between arterial stiffness and cognitive dysfunction, the reader is referred to Chapter 41.

Epidemiologic association of obesity and the metabolic syndrome with the development of increased arterial stiffness

The stronger association of type 2 DM, versus type 1 DM, with arterial stiffness may in part be due to higher rates of obesity and other metabolic diseases that promote vascular aging in patients with type 2 DM. Several studies have demonstrated an independent association between LAS and both obesity and the metabolic syndrome.[116-120] For example, in a cross-sectional study of 806 asymptomatic adults aged 24−44 years, Li et al. demonstrated that brachial-ankle PWV increased significantly as number of metabolic syndrome components increased.[116] Similarly, in a prospective cohort study of 476 patients classified by number metabolic syndrome components, Safar et al. observed that CF-PWV was higher in the group with multiple components of the metabolic syndrome at baseline compared with those without any components of the metabolic syndrome. Additionally, over six years of follow-up, CF-PWV increased most among those with more components of the metabolic syndrome.[117] These findings have been corroborated by several other longitudinal studies that have demonstrated an association of additional components of the metabolic syndrome with increase in CF-PWV over time.[119,120]


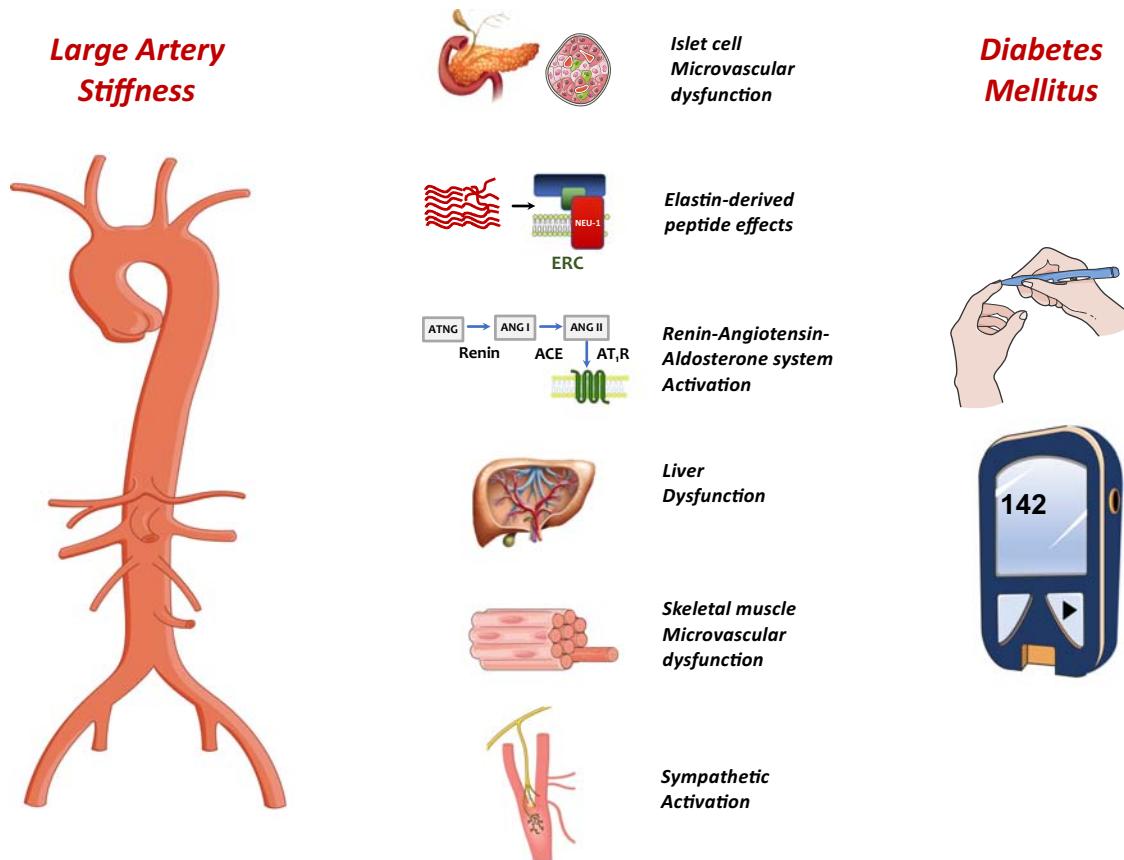
Increased arterial stiffness as a potential contributor to the development of diabetes mellitus

A number of recent studies suggest a relationship of LAS with new onset DM. For example, in 2450 Swedish participants of the Malmo Diet and Cancer Cardiovascular cohort study followed for a mean of 4.4 years, Muhammad

et al. observed that the highest tertile of CF-PWV was associated with a 3.2-fold higher risk of new onset DM than the lowest tertile (adjusted HR 3.24, 95% CI 1.51−6.97).[11] This association was independent of various potential confounders. Similarly, in an analysis of 2429 participants of the China Stroke Primary Prevention Trial, Zhang et al. demonstrated that every standard deviation increase in brachial-ankle PWV was associated with a 33% increased odds (adjusted odds ratio 1.33%, 95% 1.13−1.56) of new-onset DM.[12] Additionally, Zheng et al. observed that elevated brachial-ankle PWV ($\geq$18 m/s) was associated with a twofold increased risk of new onset DM (adjusted HR 2.11, 95% CI 1.71−2.61) over a mean of 3.7 years of follow-up compared with brachial-ankle PWV <14 m/s.[121] Moreover, the authors used cross-lagged regression, which estimates directional relationships from one variable to another and vice versa (hence the term "crossed") using longitudinal data recorded at multiple time points (hence the term "lagged"). In these analyses, baseline baPWV was associated with follow-up FBG, but there was no significant relationship between baseline FBG and follow-up baPWV. Similarly, pulse pressure independently predicted new-onset DM among 2685 hypertensive patients enrolled in the Candesartan Antihypertensive Survival Evaluation in Japan (CASE-J) trial.[122]

Whether LAS contributes to the pathogenesis of future new-onset DM remains to be determined. LAS may contribute to the pathogenesis of insulin resistance and DM through its hemodynamic effects. As discussed throughout this textbook, LAS has ill-effects in various organs, particularly those that require torrential blood flow and must operate at very low vascular resistance. While the relationship between LAS and microvascular disease in high-flow, low-resistance organs such as the kidneys and the brain have been the focus of many studies, little is known about the relationship between increased aortic stiffness and pancreatic microvascular disease. Interestingly, the endocrine pancreas, which comprises only $\sim$1−2% of the pancreatic mass, receives $\sim$10−20% of its blood supply, implying that pancreatic islet blood flow is among the highest in the body and actually higher than renal and cerebral blood flow when normalized for tissue mass.[3,123] Therefore, LAS has the potential to impact microvascular health in pancreatic islets, which may lead to dysfunctional or dysregulated endocrine function (Fig. 30.3).

Pancreatic islets (islets of Langerhans) are supplied by up to $\sim$5 arterioles per islet, which branch into a dense glomerular capillary network. Endocrine cells reside within this network and receive chemical signals across the capillary endothelium. Pancreatic islets are made up of five major endocrine cell types: β-cells (which secrete insulin),

FIGURE 30.3   **Microstructure and blood flow distribution in pancreatic lobules**. Pancreatic islets (endocrine) and their anatomic relationship with exocrine pancreatic tissue (acini) are shown. See text for details.


α-cells (which secrete glucagon), δ-cells (which secrete somatostatin), PP-cells (which produce pancreatic polypeptide), ε-cells (which produce ghrelin). Although type 2 DM is primarily associated with insulin resistance, insufficient insulin secretion and an imbalance in insulin versus glucagon secretion play a key role in its pathogenesis. Islet blood flow is a highly regulated process under complex metabolic, autonomic, and paracrine dynamic control. Hyperglycemia and the associated beta cell activation result in islet arteriolar dilation, capillary dilation, and increased islet capillary pressure.[124] Moreover, vascular integrity may be essential to maintain an order of sequential perfusion of β, δ, and α cells, which appears to allow for an adequate inhibition of glucagon secretion by insulin.[125] Given the key role of the pancreatic microvasculature, pancreatic islet microvascular dysfunction is thought to contribute to the pathogenesis of type 2 DM, providing a plausible mechanistic causal link between LAS and the pathogenesis of DM.

In addition to its potential effect on the pancreatic islet microvasculature, other potential mechanisms could be involved in the relationship between LAS and new-onset DM (Fig. 30.4). Elastin degradation in the aortic wall may impact insulin sensitivity via the production of elastin-related peptides, which block insulin signaling, likely by triggering an interaction between the insulin receptor and the neuraminidase-1 subunit of the elastin receptor complex. Increased sympathetic tone, a modulator of arterial stiffness, can lead to renin-angiotensin-aldosterone system activation, which influences insulin sensitivity via multiple mechanisms in skeletal muscle, adipocytes, and pancreas. Finally, the

liver (which receives ∼25% of the cardiac output) also exhibits a high-flow, low-resistance arterial circulation, since the hepatic artery provides approximately one-third of the liver blood flow.[3] The hepatic arterial circulation constantly regulates arterial flow to maintain total liver blood flow constant, regardless of changes in portal vein flow (hepatic arterial buffer response), which contributes to metabolic homeostasis.[126] Additionally, abnormal pulsatile hemodynamics due to LAS may impair normal postprandial vasodilation of skeletal muscle,[127−129] further promoting insulin resistance.[9,10] However, it remains to be seen whether LAS contributes to skeletal muscle or liver microvascular dysfunction. The bidirectional association between LAS and DM requires further study.

Conclusions and future directions

A growing body of literature supports a strong pathophysiologic and epidemiologic link between LAS and microvascular complications due to DM, as well as cardiovascular disease and mortality risk. Furthermore, emerging evidence suggests that LAS may also contribute to the pathogenesis of new onset DM. CF-PWV is an important prognostic marker for adverse outcomes among patients with DM, and may be an important indicator of future diabetes risk. Further investigations are needed to clarify the underlying mechanisms and temporal relationship of arterial stiffness with new onset DM. Therapies targeting mechanisms of arterial stiffness may be critical in preventing the development and progression of target organ damage in this patient population.

Cardiovascular risk prevention in clinical medicine: current guidelines in the United States and in Europe

Chee H. Liew[1] and John W. McEvoy[1,2]

[1]National Institute for Prevention and Cardiovascular Health, National University of Ireland Galway, Galway, Ireland; [2]Ciccarone Center for the Prevention of Cardiovascular Disease, Johns Hopkins University School of Medicine, Baltimore, MD, United States

Epidemiology of hypertension

Elevated blood pressure (BP), or hypertension, is a well-established and modifiable driver of cardiovascular disease (CVD),[1] with more than 1.13 billion adults worldwide diagnosed with hypertension in 2015.[2] The first report of increased CVD risk associated with hypertension came from the Framingham Heart Study.[3] Abundant evidence has since demonstrated the benefit of hypertension treatment in reducing important adverse health outcomes.[4–9] In this chapter, we will compare and contrast the 2017 American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for the prevention, detection, evaluation, and management of high BP in adults[10] with the 2018 European Society of Cardiology (ESC)/European Society of Hypertension (ESH) guidelines for the management of arterial hypertension.[11] We will also highlight key areas in CVD risk assessment that are relevant to the management of hypertension. Particular attention will be placed on aspects of these hypertension guidelines that relate to the assessment and management of large artery stiffness (LAS) and pulsatile hemodynamics.[12] Where pertinent, we also provide suggestions for future iterations of hypertension guidelines with a view to better integrating the assessment and management of LAS into the management of hypertension.

Definition and classification of hypertension

It goes without saying that the epidemiology of hypertension is heavily influenced by its definition, particularly because BP itself is a continuous physiologic variable while hypertension is defined based on a binary BP threshold.

The 2017 ACC/AHA BP guidelines[10] altered the definition of hypertension from a cutoff of $\geq$140/90 mm Hg (i.e., the previous 2003 threshold from the Joint National Committee [JNC] 7 guideline[13]) to a lower threshold of $\geq$130/80 mm Hg. This seismic change in the clinical approach to millions of US adults was motivated in large part by results from the Systolic BP Intervention Trial (SPRINT).[14] By contrast, the 2018 ESC/ESH BP guidelines[11] maintain the level of BP that defines hypertension at $\geq$140/90 mm Hg (Table 31.1) and also recommend that most adults not receive antihypertensive drug treatment until their BP exceeds this level. However, for persons at very high cardiovascular risk due to established CVD, the ESC/ESH guidelines recommend that drug treatment be considered (Class 2b) at 130–139/85–89 mm Hg (i.e., high normal BP) because these individuals appear to benefit from further BP-lowering treatment.[15] In addition, and more in line with US guidelines, the ESC/ESH document recommends that, once drug treatment has commenced and is well tolerated, a systolic BP target of 130 mm Hg or lower be applied to most patients.

The landmark SPRINT,[14] which comprised 9361 nondiabetic hypertensive individuals aged 50 years or older at high cardiovascular risk, reported a 25% reduction in the primary composite cardiovascular outcome and a 27% reduction in all-cause mortality among those randomized to an intensive target (systolic BP <120 mm Hg), compared with the standard target (systolic BP <140 mm Hg). The mean systolic BP achieved in SPRINT was 121.4 mm Hg in the intensive arm versus 136.2 mm Hg in the standard arm. Interestingly, the ACC/AHA decided on a more conservative systolic threshold to redefine hypertension (i.e., a systolic of $\geq$130 mm Hg), rather than the threshold directly

TABLE 31.1 Blood pressure classification in the ACC/AHA[a] and ESC/ESH[b] guidelines.

ACC/AHA 2017				ESC/ESH 2018			
Category	SBP[c] (mm Hg)		DBP[d] (mm Hg)	Category	SBP (mm Hg)		DBP (mm Hg)
Normal	<120	and	<80	Optimal	<120	and	<80
Elevated	120−129	and	<80	Normal	120−129	and/or	80−84
Stage 1 hypertension	130−139	or	80−89	High normal	130−139	and/or	85−89
Stage 2 hypertension	≥140	or	≥90	Grade 1 hypertension	140−159	and/or	90−99
				Grade 2 hypertension	160−179	and/or	100−109
				Grade 3 hypertension	≥180	and/or	≥110
				Isolated systolic hypertension	≥140	and	<90

[d]*Diastolic blood pressure.*

supported by SPRINT (≥120 mm Hg). This more conservative threshold of 130 mm Hg accounts primarily for the technique of BP measurement in SPRINT (which was often unattended compared to the attended measurements usually performed in routine care[10,16−18]), as well as the fact that BP values from research studies tend to be lower than the corresponding values from clinical measurements (with the latter often being done without the recommended delay of 5 min rest and without adherence to standardized measurement protocols[19]).

According to the new ACC/AHA definition, approximately 46% of adults in the United States now meet diagnostic criteria for hypertension—a 14% increase in prevalence based on the prior JNC 7 definition.[20] It is worth noting that the decision to lower the ACC/AHA diastolic threshold for hypertension from 90 to 80 mm Hg was based on expert opinion and not on randomized clinical trial (RCT) data,[10] which is an important consideration because almost one in three of those newly diagnosed with hypertension using 2017 ACC/AHA guidelines are eligible due to a diastolic BP ≥80 mm Hg despite a systolic BP <130 mm Hg.[21]

Cardiovascular risk assessment in the management of hypertension

Blood pressure measurement

The recommended approach to BP measurement is consistent between the ACC/AHA and ESC/ESH guidelines. To confirm the diagnosis of hypertension and for treatment recommendations, both guidelines endorse greater use of out-of-office BP measurements, obtained by either home BP monitoring (HBPM) or ambulatory BP monitoring (ABPM).

Similar to the differences in office BP, both guidelines propose different out-of-office BP thresholds to define hypertension (Table 31.2). Both guidelines state that ABPM, performed over 24 h, provides useful information on 24-h mean BP and nighttime BP (both of which appear to be the best BP measures for accessing cardiovascular risk[22]). Out-of-office monitoring is also useful for the detection of white-coat hypertension and masked hypertension. The latter refers to untreated patients with normal BP values in the office but with elevated BP readings on either HBPM or ABPM. Endorsement of more widespread use of out-of-office BP measurements has important clinical implications, given that masked (and to a lesser extent white-coat) hypertension is associated with increased cardiovascular morbidity and mortality.[23] There are also cost implications that remain understudied.

Risk assessment tools

For primary prevention, the 2017 ACC/AHA guideline recommends the estimation of 10-year atherosclerotic CVD (ASCVD) risk when considering drug treatment among adults with stage 1 hypertension (i.e., office systolic BP 130−139 and/or office diastolic BP 80−89 mm Hg). Specifically, drug treatment for stage 1 hypertension is recommended only among persons with a 10-year CVD risk of greater than 10%. To this end, the ACC/AHA endorse the pooled cohort equations (PCEs) to estimate 10-year CVD risk,[24,25] which have been validated for US adults aged 40−79 years. Irrespective of CVD risk estimates, all adults with confirmed stage 2 hypertension by US definitions are recommended for drug therapy according to US guidelines.

By contrast, European guidelines do not endorse the use of risk assessment tools in deciding on specific BP

TABLE 31.2 Comparison of ACC/AHA[a] and ESC/ESH[b] definitions of hypertension.

Level of BP[c] defining hypertension	ACC/AHA 2017			ESC/ESH 2018		
	Systolic (mm Hg)	and/or	Diastolic (mm Hg)	Systolic (mm Hg)	and/or	Diastolic (mm Hg)
Office/clinic BP[d]	≥130		≥80	≥140		≥90
Home BP mean	≥130		≥80	≥135		≥85
Daytime mean, ABPM[e]	≥130		≥80	≥135		≥85
24-h mean, ABPM[e]	≥125		≥75	≥130		≥80
Nighttime mean, ABPM[e]	≥110		≥65	≥120		≥70

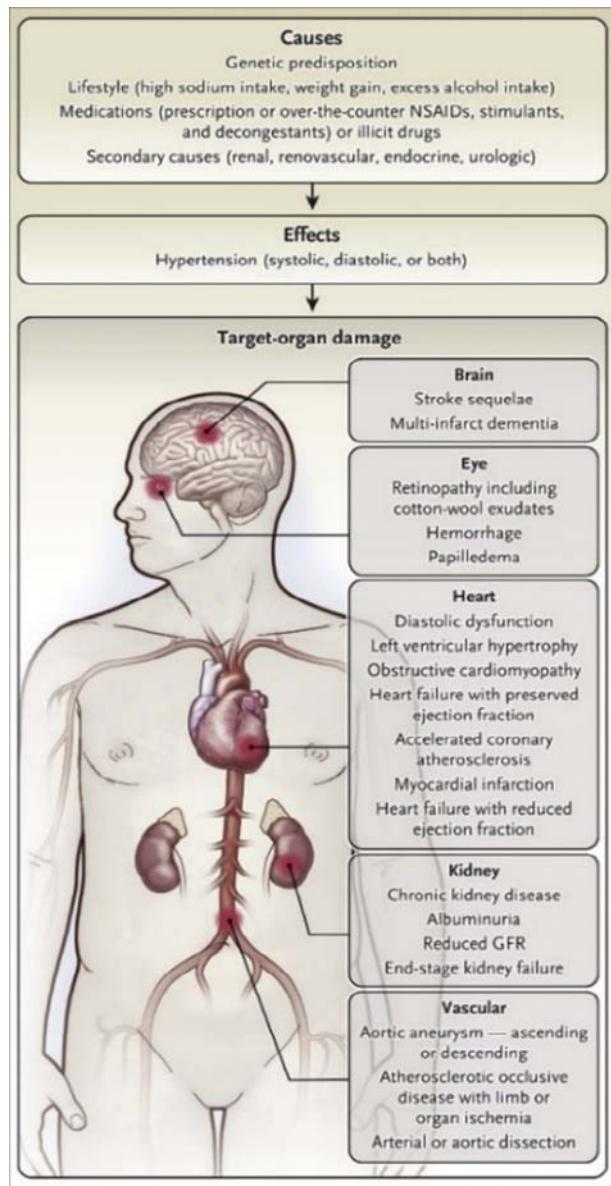
thresholds or targets for drug therapy, instead recommending that drugs only be initiated once BP ≥140/90 mm Hg (irrespective of 10-year CVD risk). However, European guidance does incorporate assessment of CVD risk into the timing of antihypertensive drug initiation. Specifically, for persons with BP 140−159/90−99 mm Hg, immediate commencement of drug therapy is recommended only among those with evidence of target organ damage (see section directly below) or those with high or very high risk. Patients at lower risk are advised lifestyle modifications and to wait three−six months prior to initiating drug treatment. To this end, the ESC/ESH recommend the use of Systematic COronary Risk Evaluation (SCORE),[26,27] which is based on a large, representative European population, for patients between 40 and 65 years of age. High or very high risk according to SCORE is defined as a 10-year risk of ≥5% using this tool.

The SCORE system allows for calibration for different cardiovascular risk levels across European countries. Notably, risk classification by SCORE is based on the risk of fatal events only, whereas the PCEs predict risk of both fatal and nonfatal (i.e., total) ASCVD events. Given that the main goal of primary prevention should be on preventing the first ASCVD event,[28] exclusion of nonfatal ASCVD events from risk assessment tools seems counterintuitive and future iterations of SCORE are planned to incorporate these outcomes. Development of a SCORE algorithm specifically for patients aged 65 or older (i.e., SCORE Older Persons [SCORE OP]) is also underway.[29,30]


However, it must be acknowledged that risk estimation using either PCE or SCORE is not perfect[31] and both provide modest discrimination for ASCVD events at best, as they can overestimate or underestimate 10-year ASCVD risk at the individual level.[25,30,32−36] These equations also do not assess risk for heart failure (HF) for which intensive BP control is especially beneficial.[14,37] Recognizing the imprecision of ASCVD risk prediction scores,[31] both guidelines recommend consideration of additional testing to support cardiovascular risk stratification. Assessment of LAS and pulsatile hemodynamics may both be particularly suitable to this effort.

Hypertension-mediated organ damage and risk modifiers

The 2018 ESC/ESH, and to a lesser extent the 2017 ACC/AHA BP guidelines, recommend that risk estimation be complemented by assessment of hypertension-mediated organ damage (HMOD), which includes hypertension-induced structural and/or functional changes in major organs (e.g., the heart, brain, and kidney, Fig. 31.1). This helps to identify asymptomatic hypertensive patients at increased cardiovascular risk who may otherwise be misclassified as having a lower level of risk by PCE or by SCORE. Furthermore, European guidelines include the assessment of carotid-femoral pulse wave velocity (PWV), as a surrogate for LAS, in their definition of HMOD. Given the focus of this book on LAS, we have allocated a dedicated section, below, to the use of LAS and pulsatile hemodynamics as risk modifiers in the management of hypertension.

In terms of non-HMOD risk modifiers, the ESC/ESH guidelines cite resting heart rate (RHR) greater than 80 beats per minute (bpm) as one example. The Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial reported that increased heart rate predicted future cardiovascular events among high-risk patients with hypertension.[38] An analysis of the Henry Ford Hospital Exercise Testing (FIT) Project demonstrated increased risk of hypertension among traditionally normotensive individuals with a RHR greater than 85 bpm.[39] A Multi-Ethnic Study of Atherosclerosis (MESA) analysis showed that a higher

FIGURE 31.1 Target organ damage in hypertension. *From Taler SJ. Initial treatment of hypertension.* **N Engl J Med.** *2018; 378(7):636−644; with permission.*

RHR was associated with increased arterial stiffness independent of atrioventricular nodal blocker use and physical activity level in an asymptomatic multiethnic population.[40] Whether therapeutic RHR reduction is useful for reducing incident hypertension or cardiovascular events is unknown and warrants further study.

Risk modifiers not specifically endorsed in US/EU hypertension guidelines but with emerging data suggesting promise in guiding hypertension management include coronary artery calcium (CAC), measured by noncontrast cardiac computerized tomography (CT), and cardiac biomarkers measured in blood. For example, CAC is associated with incident hypertension[41] and is a strong independent predictor of future cardiovascular events.[42−45] Selective use of CAC measurement coupled with ASCVD risk scores[46,47] may help guide cardiovascular risk stratification and support a personalized approach to initiation and intensification of antihypertensive therapy.[48−50] According to CVD prevention guidelines, CAC should be considered to guide preventive therapies among adults at borderline (5%) or intermediate (7.5%) 10 year risk by the PCEs (2019 ACC/AHA)[51] or, in Europe, those with calculated SCORE risks close to the 5% or 10% risk thresholds (2016 ESC/ ESH).[26] However, these broad prevention guidelines focus much of the discussion around CAC on allocating statin therapy and make little reference to modulating antihypertensive drug intensity according to CAC. Forthcoming evidence may address the potential use of CAC scoring to guide treatment decisions in high-risk primary prevention patients, inclusive of antihypertensive therapy.[52−54]

Related to CAC, thoracic aortic calcium (TAC) is also quantifiable on noncontrast chest CT imaging and may offer indirect insights into the LAS status of a given individual that could inform treatment decisions regarding hypertension. Among Framingham Heart Study Third Generation and Offspring Cohort participants who were free of CVD, TAC was associated with both higher values of carotid-femoral PWV and central pulse pressure (PP).[55] There is also evidence that TAC is associated with incident hypertension[41] and with other important cardiovascular outcomes.[56,57] Nonetheless, the use of TAC in guiding treatment in stage 1 hypertension and in providing incremental prognostic value for risk assessment (particularly when CAC is available) remains under debate.[50,58]

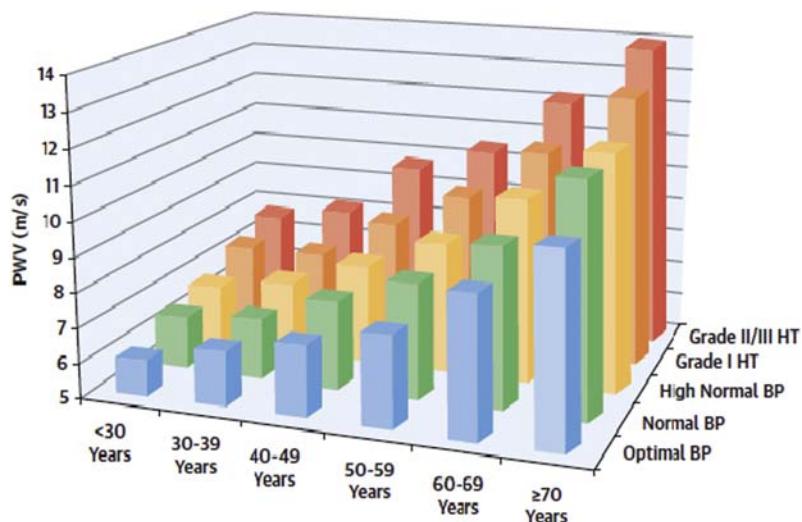
Additional biomarker candidates that have demonstrated promise for risk stratification in the management of hypertension include high-sensitivity cardiac troponin T (hs-cTnT) and N-terminal pro-brain natriuretic peptide (NT-proBNP).[59,60] Like CAC, these biomarkers are associated with incident hypertension and they also indicate subclinical structural damage to the heart.[61,62] Elevations in hs-cTnT or NT-proBNP may help identify individuals not currently recommended for antihypertensive medication who are at higher risk for CVD events and thus may benefit from initiation of BP-lowering medication. Further research is needed to assess the potential for combined use of different biomarkers to improve CVD risk assessment.[63,64]

Arterial stiffness and cardiovascular risk

Measurement of carotid-femoral PWV[65−67] for evaluating LAS as part of HMOD assessment received a Class 2b recommendation in the 2018 ESC/ESH hypertension guidelines. A meta-analysis including 15,877 participants showed that those in the higher tertiles of carotid-femoral PWV had increased risk of future cardiovascular events

and all-cause mortality.[68] A subsequent participant-level meta-analysis of prospective studies including 17,635 participants found that each standard deviation increase in carotid-femoral PWV was associated with a 35%, 54%, and 45% increase in the risk of coronary artery disease (CAD), stroke, and overall CVD, respectively.[69] Carotid-femoral PWV was an independent predictor of risk across multiple subpopulations, with a more pronounced effect among those aged 60 or younger.[69] Accordingly, LAS may add incremental prognostic information to CVD risk estimates derived from traditional risk factors.[70]

The European Reference Values for Arterial Stiffness' Collaboration reported a marked increase in carotid-femoral PWV across BP categories at any particular age (Fig. 31.2).[71] According to the ESC/ESH, a PWV more than 10 m/s is a conservative estimate of significant alterations of aortic function in middle-aged hypertensive patients. The 2017 ACC/AHA BP guidelines consider carotid-femoral PWV a noninvasive estimate of vascular target organ injury and atherosclerosis without further elaboration.

A prospective study of 34,649 adults showed that large- and small-artery disease/stiffness (as measured by cardio-ankle vascular index [CAVI] and retinal fundoscopy, respectively) were independently associated with incident hypertension,[72] suggesting their distinct implications on the pathway to hypertension. CAVI is a derived measure of LAS that includes PWV in the calculation but that is reportedly influenced less by the BP at the time of estimation than the PWV is.


Another useful and easily measured surrogate of LAS is PP, which is the simple difference between systolic BP and diastolic BP. Accordingly, PP may serve as an independent prognostic marker of cardiovascular risk, particularly in middle-aged and older hypertensive patients.[11,73,74] In the international Reduction of Atherothrombosis for Continued Health (REACH) registry, a higher PP quartile was associated with increased risk of adverse CVD outcomes.[75] The prognostic utility of PP has also been demonstrated in other studies.[76–80] Furthermore, studies have shown associations of isolated systolic hypertension (ISH) and wide PP with abnormalities in biomarkers such as hs-cTnT and NT-proBNP, findings that may potentially guide personalized antihypertensive treatment of older patients with these BP aberrations.[81] This comes with the caveat that PP is not just influenced by LAS, but also cardiac output and other important physiologic parameters. It is important to also acknowledge that PP remains a relatively poorly studied parameter in trials of BP management compared to other BP parameters or risk-modifiers.

Therapeutic goals in the management of hypertension

Blood pressure treatment thresholds and targets in US/EU guidelines

As noted earlier, the BP threshold for a diagnosis of hypertension recommended by guidelines has changed over the years. An early Framingham report in 1957 defined hypertension as BP $\geq$160/95 mm Hg.[3] Subsequent observational studies and BP treatment trials (initially focusing on diastolic BP targets[82–84] then transitioning to systolic BP targets[85–87]) provided further insights into BP treatment effects that resulted in hypertension being redefined at lower BP values. The safety of treating systolic BP to <140 mm Hg was first demonstrated in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).[88] More recently, SPRINT was the

FIGURE 31.2 Mean reference values for pulse wave velocity according to age and blood pressure categories. Note that blood pressure categories correspond to European guidelines, rather than to 2017 AHA/ACC categories. *From Reference Values for Arterial Stiffness' Collaboration. Determinants of pulse wave velocity in healthy people and in the presence of cardiovascular risk factors: 'establishing normal and reference values'.* **Eur Heart J.** *2010; 31(19):2338–2350; with permission.*

first trial to suggest a benefit to treating high-risk individuals to even lower BP targets, in the case of this trial, a systolic BP of <120 mm Hg.

The Heart Outcomes Prevention Evaluation (HOPE)-3 trial provides additional insight beyond persons at high risk by evaluating the use of antihypertensive therapy among intermediate-risk hypertensive individuals with mean BP of 138/82 mm Hg at baseline.[89] While the trial did not show any significant benefit in the composite endpoints, a prespecified subgroup analysis of HOPE-3 demonstrated lower rates of both first and second composite outcomes among those in the highest tertile of baseline SBP (above 143.5 mm Hg). Taken together, both SPRINT and HOPE-3 suggest that benefits from BP reduction to lower values than previously recommended may be related to baseline estimated CVD risk. Indeed, the recent published STEP (Strategy of Blood Pressure Intervention in the Elderly Hypertensive Patients) trial also confirmed that the benefit seen in the arm randomized to a more intensive SBP target (<130 mm Hg) appeared to be limited to those with (15% 10-year risk of CVD.[90] This ever-evolving evidence base has informed the recommendations in the most recent BP treatment guidelines.

In this context, and for the first time, the ACC/AHA guidelines recommend a target BP of less than 130/80 mm Hg for all hypertensive patients across all age groups.[10] This class I recommendation applies to all secondary prevention patients, as well as to primary prevention patients with either (1) an estimated 10-year ASCVD risk ≥10% and BP ≥ 130/80 mm Hg or (2) an estimated 10-year ASCVD risk <10% and BP ≥140/90 mm Hg. In other words, US guidelines state that BP treatment should be initiated once BP ≥130/80 mm Hg and treated to <130/80 mm Hg among persons with a history of prior CVD or among primary prevention adults with 10-year CVD risk estimates ≥10%. For primary prevention, adults with 10-year CVD risk estimates <10%, treatment initiation is not recommended until a BP ≥140/90 mm Hg; however, the target of treatment remains <130/80 mm Hg. As discussed earlier, SPRINT[14] was among the major drivers of the new lower BP therapeutic target. A meta-analysis of 144,220 patients in 42 trials showed a linear association between mean achieved SBP and risk of CVD mortality with the lowest risk at 120−124 mm Hg.[91]

The lower SBP target in the 2017 ACC/AHA BP guidelines is justified by a number of lines of evidence, not just SPRINT alone.[90] However, the new ACC/AHA diastolic target of <80 mm Hg is more debatable. Indeed, in the Hypertension Optimal Treatment (HOT) trial, there was no difference in outcomes between the groups who were allocated to a DBP target of ≤90 mm Hg, 85 mm Hg, or 80 mm Hg.[92] Whether this lower 2017 US diastolic target is justifiable remains to be proven in future outcomes trials of antihypertensive drug treatments. Nevertheless, the new BP goal of 130/80 mm Hg recommended by the ACC/AHA enables earlier execution of preventive lifestyle efforts than ever before (which can only be a good thing), as well as resulting in the eradication of the vague "prehypertension" category that was used in previous US BP guidelines.[13]

Although the 2018 ESC/ESH BP guidelines have seemingly taken a more restrained stance on BP treatment, their core recommendations are in fact not too dissimilar to those endorsed by the 2017 ACC/AHA BP guidelines. Nonetheless, there are clear differences in BP thresholds above which treatment initiation is recommended in EU guidelines. Specifically, the BP threshold above which treatment initiation is recommended by the ESC/ESH is ≥140/90 mm Hg for all patients. The only exception to this treatment initiation threshold is a weaker recommendation that treatment initiation may be considered at BP 130−139/85−89 mm Hg those with established CVD or primary prevention adults with a >5% 10-year risk of fatal CVD by the SCORE equation.

In contrast to the differences between guidelines in recommended BP thresholds above which to initiate drug therapy, similarities begin to emerge between the US and EU guidelines when considering treatment targets. The general recommendation for treatment targets by the ESC/ESH comprises two parts. To start, the guidelines mention that the first therapeutic objective should be to reduce BP to a target of <140/90 mm Hg in all patients,[11] rendering the ACC/AHA recommended target of <130/80 mm Hg appear "aggressive" at first glance. However, a second objective, which may not be readily apparent to some and is important to stress, then recommends a treatment target BP of 130/80 mm Hg or lower in most patients, provided that antihypertensive therapy is well tolerated. Indeed, for persons under 65 years, ESC/ESH recommend that a systolic BP target of 120−129 mm Hg be pursued as long as treatment is tolerated (which is arguably more intensive than the US recommendation). Notably, the 2018 ESC/ESH BP guidelines also recommend against a target BP of <120/70 mm Hg (a stipulation that not in the 2017 ACC/AHA BP guidelines). There are several other key differences between the transatlantic BP guidelines that deserve further attention.

Blood pressure goals in older adults

BP increases predictably with age and as many as 70% of adults over the age of 70 develop hypertension.[93] Consistent with the 2017 ACC/AHA BP guidelines, there is acknowledgment by the 2018 ESC/ESH BP guidelines of the difference between biological versus chronological age. However, in contrast to the "one-size-fits-all" approach by the ACC/AHA (who recommend the same BP target of <130/80 mm Hg irrespective of age), the ESC/ESH propose a target BP of 130−139/80 mm Hg for adults aged 65 or older (note that the previous 2013 ESC/ESH target for

this age group was 140−149/90 mm Hg[94]). As such, European guidance recommends a lower systolic BP limit of 130 mm Hg below which treatment should be de-escalated among those ≥65 years, contrasting with the lower systolic BP limit of 120 mm Hg recommended for adults below 65 years.

Active treatment of systolic BP among older adults is well supported by evidence. A prespecified subgroup analysis of SPRINT involving 2636 ambulatory adults aged 75 years or older showed that intensive systolic BP treatment was associated with lower rates of total cardiovascular events and all-cause mortality.[95] Although event rates were higher with increasing frailty in both treatment groups, within each frailty stratum absolute event rates were lower for the intensive treatment group. The Hypertension in the Very Elderly Trial (HYVET), which included 3845 individuals aged 80 years or older, demonstrated risk reductions in all-cause mortality and HF with antihypertensive therapy,[96] and that the benefit on outcomes was not influenced by frailty status.[97] The SPRINT Memory and Cognition in Decreased Hypertension (SPRINT MIND) trial reported a lower risk of mild cognitive impairment[98] with more intensive BP treatment despite not meeting the primary endpoint of risk of dementia. Intensive antihypertensive therapy also delayed the progression of white matter lesions on brain imaging.[99] A subsequent meta-analysis of 12 RCTs found a lower risk of incident dementia or cognitive impairment with antihypertensive medication use.[100]

The new and lower BP targets in both guidelines raise several age-related concerns. First, based on observational data, the heightened possibility of a J-curve for diastolic BP in older persons[93] may signify potential harm with intensive BP treatment, particularly when applying the ACC/AHA guidelines (which do not provide lower bounds for BP level below which treatment should be de-escalated). However, this J-curve concern is allayed in analyses that adjust for competing risk comorbidities[101] and by the randomized data from SPRINT.[102] Second, orthostatic hypotension (OH) is a major concern with more intensive BP treatment and, importantly, prevails among individuals aged >65 or with increased LAS.[103] Data from analyses evaluating the association of intensive BP treatment with OH-related adverse outcomes such as falls are mixed.[104−106] A SPRINT study found no association between intensive BP treatment and risk of cardiovascular events, syncope, electrolyte abnormalities, injurious falls, or acute renal failure, irrespective of baseline OH status.[107] An important caveat; however, is that SPRINT excluded persons with a standing systolic BP <110 mm Hg at baseline. Finally, third, with intensive BP treatment comes greater polypharmacy and associated repercussions (e.g., cost,[108] medication errors, nonadherence, interactions, and side effects[109−111])—a key consideration for older patients who, by and large, are more prone to polypharmacy due to underlying medical comorbidities. In SPRINT, the intensive arm required a mean of three medications compared with 1.9 in the standard arm.[14] In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, the mean number of medications was 3.4 and 2.1 in the intensive and standard arms, respectively.[112]

The more cautious approach to the treatment of older adults taken by the ESC/ESH hypertension guideline may reflect some of these concerns. Nonetheless, results from SPRINT, STEP and HYVET reinforce the concept that risk reductions in CVD events and mortality from hypertension treatment are evident regardless of frailty status, and suggest that older independent patients perhaps should not be treated any differently than their younger counterparts. However, benefit-risk assessment and personalization remain integral to the intensity of antihypertensive therapy in older patients.

Chronic kidney disease

For hypertensive patients with chronic kidney disease (CKD), the 2018 ESC/ESH hypertension guidelines contend that there is insufficient evidence to support a target systolic BP <130 mm Hg (Table 31.3), despite the fact that this target is endorsed by the 2017 ACC/AHA hypertension guidelines in persons with CKD. In SPRINT, among those with CKD at baseline, there was no significant difference in adverse renal outcomes between treatment groups with a caveat that the number of adverse renal events was small.[14] Indeed, analyses of SPRINT focusing on patients with CKD demonstrated lower rates of all-cause mortality and potential reductions in major cardiovascular events with intensive BP treatment,[113] and that this benefit was evident across the spectrum of kidney function and albuminuria.[114,115] Notably, the majority of CKD participants in SPRINT had relatively mild CKD (baseline estimated glomerular filtrate rate ≥45 mL/min/1.73 m^2).

Diabetes

The target BP of <130/80 mm Hg for diabetic adults recommended by the ACC/AHA (all age groups) and ESC/ESH (age less than 65 years) has come into question because: (1) no trial has specifically proven a benefit for a target BP of 130/80 mm Hg or lower among diabetics[112], and (2) SPRINT did not include diabetic patients. Of note, a factorial trial showed that intensive BP treatment in ACCORD Blood Pressure (ACCORD BP) was beneficial among those randomized to standard (but not to intensive) glycemic control.[116] A post hoc observational analysis of the Examination of Cardiovascular Outcomes with Alogliptin versus Standard of Care (EXAMINE) trial showed that among type 2 diabetes patients with recent acute

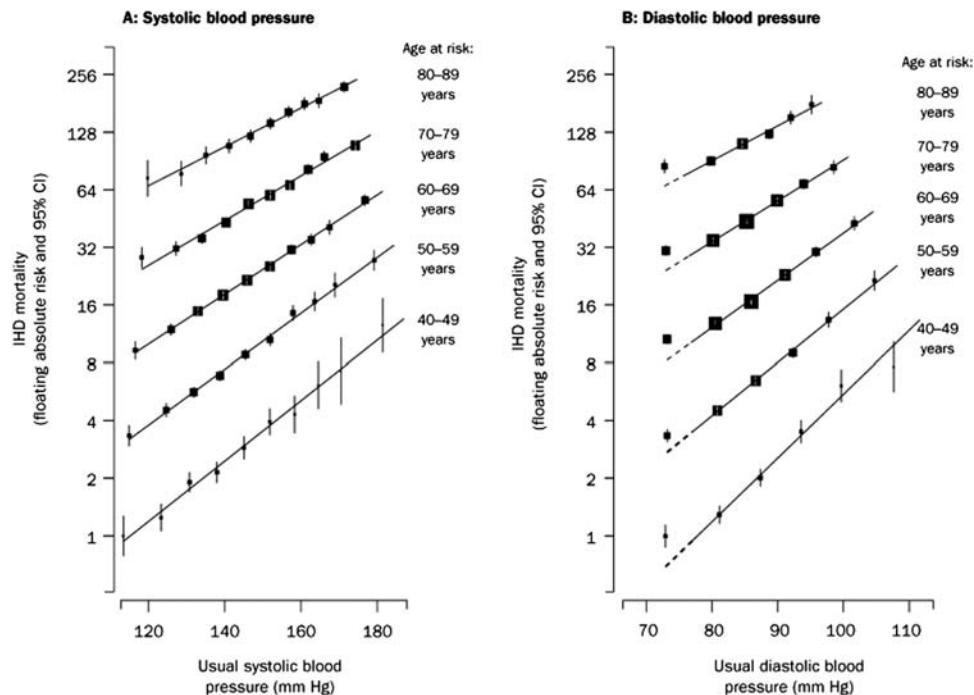
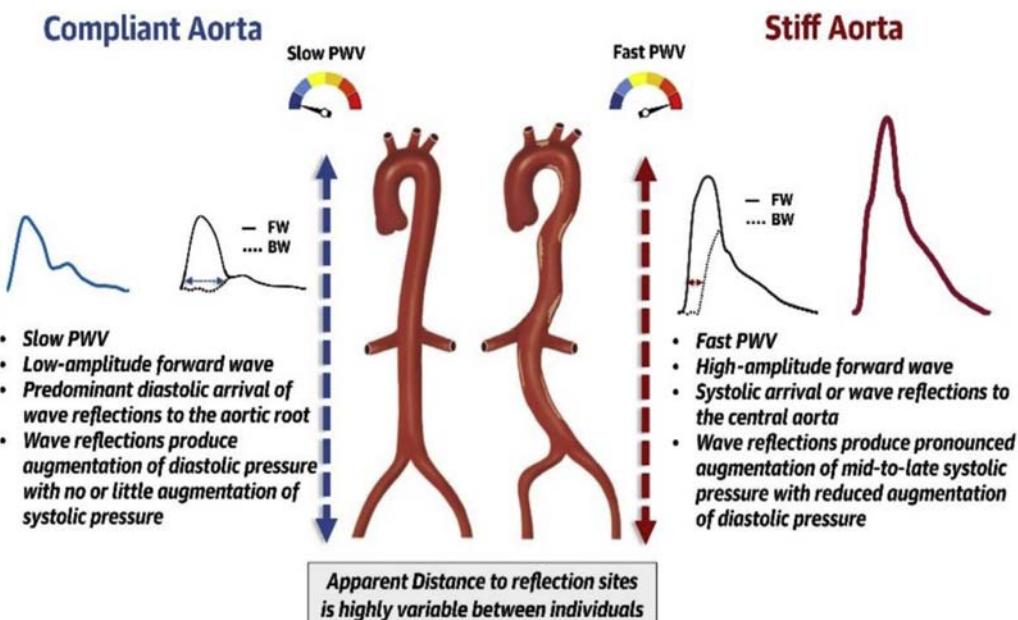
coronary syndromes, BP <130/80 mm Hg was associated with worse cardiovascular outcomes.[117] This analysis is subject to the same potential biases mentioned earlier for other observational analysis suggesting a BP J-curve. Contradicting this finding, and lending indirect evidence that supports the assertion by the ACC/AHA and ESC/ESH, an analysis from the Action in Diabetes and Vascular disease: preterAx and diamicroN-Modified Release Controlled Evaluation (ADVANCE) trial[118] found that the benefit of more intensive BP treatment, seen in the ADVANCE trial overall, also extended to the subgroup of diabetics with baseline systolic BP between 120 and 140 mm Hg. Moreover, this benefit was largely independent of baseline cardiovascular risk. Consistent with this evidence and the 2017 ACC/AHA recommendations, the American Diabetes Association endorses the lower BP target of <130/80 mm Hg for high-risk diabetic patients (defined as existing ASCVD or 10-year ASCVD risk ≥15%) in their 2020 recommendation document (Grade C evidence), provided that this target can be safely attained.[119]


Blood pressure J-curve: role of large artery stiffness and implications for treatment targets

In a meta-analysis of one million individuals without CVD at baseline who were enrolled in prospective observational studies, the risk of CVD death increased at systolic BP above 115 mm Hg and diastolic BP above 75 mm Hg.[120] However, this meta-analysis also signaled a potential J-curve for diastolic BP with a trend for increased ischemic heart disease (IHD) events, but not stroke, among those with diastolic BP <70 mm Hg (Fig. 31.3)—a finding supported by subsequent observational studies[121−123]. This


J-curve finding is thought to be attributable in part to impaired coronary perfusion to the myocardium at low diastolic BP.[124] Nonetheless, post hoc analyses of SPRINT[102] and ACCORD[125] have shown no evidence that the benefit of intensive systolic BP lowering differed across quintiles of baseline diastolic BP, suggesting that the diastolic BP J-curve seen in observational studies is confounded and that, when studied in the context of a randomized trial, further BP reduction among individuals with low diastolic BP but elevated systolic BP is not harmful. A potential weakness of the post hoc SPRINT analysis was that increased PP, as a marker of LAS, was not adjusted for.[126]

Some if not most of the diastolic BP J-curve may be confounded by LAS or PP. Wave reflections arrive at the aorta predominantly during diastole in young, healthy adults, augmenting diastolic pressure.[70] As PWV increases due to wall stiffening, reflections arrive at the aorta in mid-to-late systole instead. This results in systolic pressure augmentation, with loss of diastolic pressure augmentation and widening of the aortic PP (Fig. 31.4). These important physiologic changes may explain why a low diastolic BP is a marker of risk in observational studies (specifically because it is correlated with LAS) and also why treatment of elevated systolic BP appears beneficial irrespective of baseline diastolic BP; highlighting the fact that the diastolic BP J-curve may be mostly due to confounding by LAS and that naturally occurring low diastolic BP may not directly cause harm in the vast majority of adults.[101]

It is worth briefly noting that some observational data have suggested a systolic BP J-curve also, though this is more controversial (and not anticipated to be related to LAS) so will not be covered in detail in this chapter. In brief, several studies have reported either lack of reduction

in major CVD events or increased risk of events/mortality with "excessive" systolic BP lowering.[112,123,127−129] For example, results from the Prospective Observational Longitudinal Registry of Patients with Stable CAD (CLARIFY)[123] study suggest that a systolic target around 120 mm Hg is probably safe, but that further reductions may lead to adverse outcomes, particularly among individuals with preexisting restrictions to coronary blood flow. However, these prior observational reports are contradicted by SPRINT[14] and by analyses of BP studies that

comprehensively adjusted for confounding variables.[101,130,131] Comprehensive adjustment of potential confounders is critical because individuals with worse health status may have lower systolic BP and therefore reverse causation is a major concern with observational reports suggesting a systolic BP J curve. Indeed, a recent MESA study including 1457 individuals free of baseline ASCVD and without any other ASCVD risk factors found no evidence of a J-curve for systolic BP levels as low as 90 mm Hg.[132] Nonetheless, because of concerns around a diastolic and systolic BP J-curve, 2018 ESC/ESH hypertension guidelines introduced for the first time lower limits of recommended BP levels (specifically to not reduce BP with medication to lower than 120/70 mm Hg).

Additional therapeutic considerations for hypertension management in current guidelines

Nonpharmacologic and pharmacologic interventions

Lifestyle modifications remain the cornerstone of hypertension prevention and treatment, regardless of cardiovascular risk,[133] with strong endorsement from both 2017 ACC/AHA and 2018 ESC/ESH guidelines (Table 31.4). Among patients in whom pharmacologic antihypertensive therapy is needed, concurrent lifestyle efforts should continue to be advocated. There is general consensus on the pharmacological approaches to hypertension management between guidelines, including significant emphasis on medication adherence. Because of their slightly weaker BP lowering effects, both guidelines now restrict the use of beta blockers for the treatment of hypertension to patients with other specific and compelling clinical indications, such as IHD or HF.

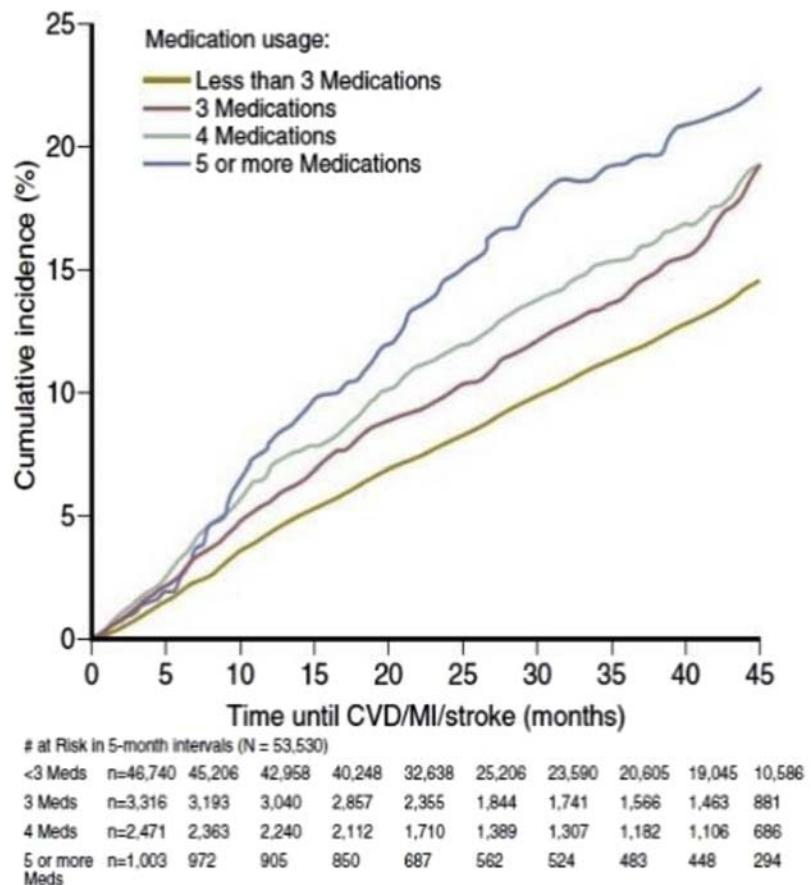
Notably, the ESC/ESH strongly recommend the use of an initial single pill combination (SPC) therapy comprising a renin-angiotensin system blocker (either an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker) with either a thiazide diuretic or a calcium channel blocker, for all stages of hypertension. In the United States, according to the ACC/AHA guideline, this recommendation pertains to patients with stage 2 hypertension and BP >20/10 mm Hg above their BP target (i.e., 150/90 mm Hg). There is little doubt that initial SPC therapy, as proposed by EXC/ESH, improves medication adherence, increases likelihood of achieving BP goals, is more cost effective, and has fewer adverse effects,.[134–136] However, the inherent risk of therapeutic inertia with SPC should not be overlooked, nor should the more limited titration and combination options.[137] Of interest, recent reports have suggested there is potential for an initial triple combination therapy to improve BP control,[138,139] a possibility that calls for further outcomes trials.

Other considerations in the approach to hypertension management

Available evidence suggests that nocturnal BP may be a stronger predictor of cardiovascular outcomes than daytime BP.[140,141] Taking antihypertensive medications at nighttime is neither endorsed nor opposed by the ACC/AHA and ESC/ESH. In 2019, the Hygia Chronotherapy Trial (open label) of 19,084 hypertensive patients reported significant reductions in the primary CVD outcome, CVD death, and all-cause mortality among those randomized to bedtime dosing compared with upon awakening dosing[142]—a finding that requires further trial replication. Unfortunately, concerns have been expressed about the conduct and reporting of Hygia[143] and, as such, nocturnal dosing of antihypertensive medications should not be endorsed routinely at this time.

Resistant hypertension, defined as either above-goal elevated BP despite concomitant use of three antihypertensive drug classes (one of which must be a thiazide diuretic) or BP that achieves target values on four or more antihypertensive medications, affects approximately 15% of treated adults with hypertension (when considering a traditional cutoff of 140/90 mm Hg).[144] In the REACH registry, among patients with resistant hypertension and BP above target, an increasing number of antihypertensive medications were associated with an increased risk for a composite of cardiovascular death, myocardial infarction, or stroke over 4 years in a dose-response fashion (Fig. 31.5), though the association between number of antihypertensives and outcomes was attenuated after adjustment for BP.[145]

Various device-based therapies have emerged for the treatment of hypertension, although both 2017 ACC/AHA and 2018 ESC guidelines do not endorse their routine use at present due to insufficient clinical evidence regarding their safety and efficacy. Despite early setbacks,[146] renal denervation, which involves catheter ablation of renal sympathetic nerves, has shown promising results in more recent trials and global registry using a circumferential renal denervation system (SPYRAL).[147–151] There is evidence that ISH (which is typically present in the setting of LAS) is associated with an attenuated or blunted therapeutic response to renal denervation with older technologies.[152,153] Future studies of the new denervation technologies in patients with ISH are warranted.

How do isolated systolic hypertension, pulse pressure, and LAS factor into current guideline recommendations for the treatment of hypertension and what gaps exist that could be filled in future guideline iterations?


ISH, defined as BP that meets the systolic (but not diastolic) threshold for hypertension, is the predominant BP

TABLE 31.4 Lifestyle modifications for prevention and treatment of hypertension.

Nonpharmacologic intervention	Dose	Approximate impact on SBP	
		Hypertension (mm Hg)	Normotension (mm Hg)
Physical activity			
Aerobic	• 90—150 min/week • 65%—75% heart rate reserve	−5 to −8	−2 to −4
Dynamic resistance	• 90—150 min/week • 50%—80% 1 repetition maximum • 6 exercises, 3 sets/exercise, 10 repetitions/set	−4	−2
Isometric resistance	• 4 × 2 min (hand grip), 1 min rest between exercises, 30%—40% maximum voluntary contraction, 3 sessions/weeks. • 8—10 weeks	−5	−4
Healthy diet DASH dietary pattern	Diet rich in fruits, vegetables, whole grains, and low-fat dairy products with reduced content of saturated and total fat	−11	−3
Weight loss weight/body fat	Ideal body weight is best goal but ≥1 kg reduction in body weight for most adults who are overweight	−5	−2 to −3
Reduced intake of dietary [Na^+] Dietary sodium	<1500 mg/day is optimal goal but ≥1000 mg/day reduction in most adults	−5 to −6	−2 to −3
Enhanced intake of dietary [K^+] Dietary potassium	3500—5000 mg/day, preferably by consumption of a diet rich in potassium	−4 to −5	−2
Moderation in alcohol intake and alcohol consumption	In individuals who drink alcohol, reduce alcohol to • Men: <2 drinks/day • Women: <1 drink/day	−4	−3

phenotype in older adults due to age-related LAS.[154] Both 2017 US and 2018 EU BP guidelines recommend BP lowering in ISH to reduce risk of major cardiovascular events.[10,11] The EU BP guidelines also uniquely outline suggestions for the management of ISH in younger adults (age less than 50 years), which comprise of lifestyle modification (particularly smoking cessation) and maintenance of longer-term follow up, noting that the role of drug therapy in these individuals remains unclear. With ISH comes increased PP.[154] Again, both guidelines acknowledge the additional prognostic significance of increased PP (≥60 mm Hg), particularly in middle-aged and older people. However, compared with SBP and DBP, the guideline writing committees felt the evidence base for using PP in making hypertension treatment decisions is not as robust.

In addition to the importance of LAS in understanding a given hypertensive patient's physiology, PWV, a marker of HMOD, may be sensitive to treatment-induced BP changes.[155,156] This might be particularly useful to indicate a given antihypertensive medication is being taken and is working, with a caveat that the correlation between carotid-femoral PWV and BP changes seems to diminish after six months of initiating therapy.[157,158] The 2018 EU (but not the 2017 US) BP guidelines appreciate the incremental value of PWV above and beyond traditional cardiovascular risk factors. In a secondary analysis of SPRINT,[159] intensive treatment to SBP <120 mm Hg was superior to standard treatment SBP <140 mm Hg only when it was accompanied by a temporal reduction in estimated PWV (derived from an equation that incorporates age and mean BP). Furthermore, within the standard treatment group,

TABLE 31.5 Suggested clinical applications of measurements of large artery stiffness in primordial and primary prevention of cardiovascular disease.

Clinical scenario	Rationale	Impact on clinical management
Hypertension		
ACC/AHA Stage 1 Hypertension (130–139/80–89 mm Hg) with PCE-calculated 10-year ASCVD risk ~10% without diabetes or CKD	LAS can be useful to refine risk stratification when PCE-calculated 10-year ASCVD risk is close to the threshold for treatment, after an informed clinician-patient discussion.	• Initiation of pharmacologic antihypertensive therapy
Stage 2 isolated systolic hypertension (>140 mm Hg) in very young adults with paucity of other cardiovascular risk factors	The combination of high pulse pressure amplification (with normal central systolic pressure) and low or normal LAS for age support a low CV risk.	• Withholding of pharmacologic antihypertensive therapy
Nonhypertensive adults <40 yrs of age with family histories of ISH	LAS is partially heritable. LAS precedes and predicts the development of ISH, a potentially avoidable threshold in the life course of cardiovascular disease. A high PWV for age is consistent with early vascular aging.	• Guide clinician-patient risk discussions • Intensification of lifestyle interventions • More frequent assessments of cardiovascular risk before age 40 (<4 to 6 yrs)
Other CV risk-assessment scenarios		
Refinement of cardiovascular risk assessment in nondiabetic adults 40–75 years of age at intermediate PCE-calculated 10-year ASCVD risk	In this group of patients, risk-based decisions for preventive interventions may be uncertain and LAS measurements can be used to refine risk assessment (particularly if various "risk-enhancing" clinical parameters do not clearly favor a specific course of action).	• Guide clinician-patient risk discussion • Guide decision making regarding initiation of pharmacologic therapy (i.e., statins)
Refinement of cardiovascular risk assessment in middle-aged nondiabetic adults at borderline PCE-calculated 10-yr risk of ASCVD (5%–<7.5%) who also have other factors that increase their ASCVD risk ("risk enhancers")	In this group of patients, LAS measurements may be useful to improve risk-based deepens as an alternative or as a "gate keeper" for coronary calcium score testing, particularly when concerns about radiation exposure (younger age, overweight/obese) or about cost are present.	• Guide clinician-patient risk discussion • Guide decision making regarding further testing (coronary calcium score) or initiation of therapy (i.e., statins)
Assessment of CV risk in special populations	PCE-calculated 10-year risk estimations can provide miscalibrated estimates in non-US populations, particularly those at earlier stages of the epidemiologic transition. This may also apply to immigrants from those populations in the United States.	• Guide clinician-patient risk discussions and various interventions • An abnormal PWV for age indicates subclinical arterial damage and suggests a higher-risk. Expert clinical judgment must guide result interpretation and decision making depending on the specific clinical scenario.

individuals in whom estimated PWV responded to antihypertensive treatment at 1 year demonstrated a 42% lower risk of death compared with nonresponders; noting that effects were independent of changes in systolic BP.

We appreciate the limitations with deploying LAS/PWV assessment more broadly in clinical practice. These include cost, technical difficulties, operator dependency, and the need to uncover the groin for femoral assessment in the case of carotid-femoral PWV. It is likely that future technologies will be designed to overcome these limitations. Additionally, methods that use cardiac imaging modalities commonly used in clinical practice may enable more widespread assessment of LAS by clinicians. One example is the echocardiographic assessment of thoracic aortic PWV.[70]

How do large artery stiffness and pulsatile hemodynamics factor into guideline recommendations for the treatment of other cardiovascular risk factors?

Because measures of LAS (like PP and PWV, for example) provide prognostic information over and above traditional risk factors alone, they may also have utility in guiding the therapeutic approach to other CVD risk factors, not just the management of hypertension (Table 31.5). For example, the 2018 AHA/ACC/Multisociety guidelines[160] and the 2019 ESC/European Atherosclerosis Society (EAS) guidelines[161] for lipid management both stress the importance of an accurate assessment of CVD risk in allocating the intensity of lipid reduction therapies. In this section, we briefly discuss the similarities and differences between the two major society lipid guidelines, acknowledging that LAS assessment is not as germane to this aspect of CVD prevention as it is for hypertension.

Risk enhancers

The use of risk-enhancing factors is supported in patients at borderline/intermediate risk by the PCE (AHA/ACC) or at low/moderate risk by SCORE (ESC/EAS), because they can reclassify individual risk and therefore might up-classify or down-classify risk sufficiently to make the therapeutic decision to treat or not treat with statins and other lipid lowering therapies more clear for the patient and health-care provider. There are several risk-modifying or risk-enhancing factors highlighted in both guideline documents; carotid-femoral PWV is specifically mentioned as a marker of excess risk by ESC guidelines.

Risk groups

One notable difference between the US and EU lipid guideline documents relates to the definition of the very high-risk group (those considered to benefit from the most aggressive lipid-lowering therapy). The 2019 ESC/EAS lipid guidelines define this group more broadly and include patients with not only clinical ASCVD but also selected patients with peripheral arterial disease and those with subclinical CVD (arguably this could be extrapolated to include measures of abnormal LAS). This very high-risk ESC group also encompasses primary prevention patients, including those with severe CKD, certain patients with diabetes, and patients with an estimated risk by SCORE $\geq 10\%$. The definition of very high-risk by ESC guidance has implications for lipid treatment goals as well as lipid therapies that should be considered. For example, the 2019 ESC/EAS guidelines recommend PCSK9 inhibitor as an add-on for primary prevention for those at very high risk if LDL-C goals are not met (class IIb). In contrast, only patients with clinical ASCVD (classic secondary prevention) are included in the very high-risk group by the 2018 AHA/ACC lipid treatment guidelines (with the caveat that US guidelines do recommend PCSK9 inhibitors where necessary for primary prevention patients with genetic familial hypercholesterolemia).

Summary

The 2017 ACC/AHA and 2018 ESC/ESH hypertension guidelines find more common ground than major key differences. The perceived discordance between guidelines may stem from incompatible definitions of hypertension and, to a lesser extent, BP treatment targets. A closer inspection reveals the same target BP <130/80 mm Hg for most adults in both guidelines. Admittedly, the ESC/ESH approach this more gently and, notably, with a few exceptions. With an appreciable downward trend in the target "normal" BP over time, a thorough understanding of guideline documents, ideally allied with an open mind, is crucial. Personalization is key to help clinicians concentrate intensity of therapy in patients who are most likely to benefit. Arterial stiffness may allow for better risk estimation in addition to quantitative ASCVD risk scores (which applies to both the treatment of elevated BP but also other risk factors like hyperlipidemia). Further studies will help

refine our individualized approach to hypertension management so as to yield "as low as reasonably achievable" BP, thereby maximizing CVD risk reduction.

Chapter 32

Cardiovascular risk prevention in clinical medicine: current guidelines in Asia

Hae-Young Lee[1] and Jeong Bae Park[2]

Cardiovascular risk prevention in clinical practice: current guidelines in Asia

Sociodemographic factors and an increase in average life expectancy have dramatically increased the burden of cardiovascular (CV) disease in Asia. There are important differences in the characteristics of CV risk factors in Asia compared to populations in the United States and Europe. In general, the Asian population has a lower body mass index (BMI) but higher salt intake compared with European and North American populations. Although the prevalence of hypertension is similar, large artery stiffness in Asian hypertensive patients is more elevated, possibly due to aging and high salt intake. Higher forward pulse wave and its reflection to the central aorta can cause higher systolic blood pressure (BP) and pulse pressure, which are critical in target organ damage. These differences may explain a higher prevalence of stroke in Asian and more non-atherosclerotic CV disease with aging. Although CV risk prediction tools developed in Europe and North America are used in Asians, many reports suggest overestimation of risk and low performance for risk prediction in Asians. However, Asians might be more susceptible to hypertension-mediated organ damage such as stroke,[1] requiring more sophisticated risk calculation and management for the intermediate- and high-risk population.

Characteristics of cardiovascular risks in Asia, in comparison to the United States, Europe, and other populations

The CV risk in the Asian population is stiffly increased with increased BP, which is different from that seen in patients from Western regions.[2] In an analysis of data from the Asia Pacific Cohort Studies Collaboration, Asian patients with hypertension had a 4.5-fold higher risk of cardiovascular disease (CVD) compared with those with normal BP.[3] Moreover, the relationship between overall CV risk and hypertension was shown to be significantly stronger for Asian patients. Overall, stroke is generally more common than coronary artery diseases in Asians, whereas the converse is seen in Western subjects.[4,5]

Accurate CV risk stratification presents a major challenge for Asian populations. Still there were no established CV risk prediction models for Asians. The Pooled Cohort Equation is used to estimate 10-year ASCVD risk and determine BP targets in US guidelines.[6] The Pooled Cohort Equation is known to overestimate risk in Asian populations and is not a universal risk calculator for all ethnicities.[7,8] Similarly, the Framingham General CVD Risk Prediction Score overestimated especially for Asian women.[9] In the 2018 European Society of Cardiology (ESC)/ European Society of Hypertension (ESH) guideline, the Systematic COronary Risk Evaluation (SCORE) system is used to estimate risk of the first fatal atherosclerotic event. Unlike the Pooled Cohort Equation, SCORE includes a correction factor for first-generation immigrants to Europe based on their country of origin[10]. In this regard, the potential of vascular measures to enhance estimation of global risk could be made. For instance, the presence or absence of prevalent subclinical vascular disease (such as arterial stiffening) could better calibrate risk estimations especially in intermediate risk group.[11]

Current Asian guidelines on cardiovascular prevention

Hypertension

Hypertension is a global public health issue, reported to be responsible for almost 13% of all deaths and 3.7% of total

disability-adjusted life-years.[12] The worldwide prevalence of hypertension in adults was estimated to be approximately 40% in 2008. The prevalence of hypertension is similarly high across different Asian countries, ranging from 30% in South Korea to 47% in Mongolia. Moreover, the prevalence also increases with advancing age.[13] With a rapidly aging population, the prevalence of hypertension and related CV morbidity in Asian patients continues to rise, placing a substantial and escalating social and economic burden on this region.[14]

The risk of coronary artery disease and stroke increases linearly as levels of systolic BP increase.[15] In particular, the linear relationship between BP and stroke risk is markedly more pronounced in Asian patients than in Caucasian populations.[16] This may be attributable to the higher proportion of hemorrhagic versus ischemic strokes reported in the Asian population, as hemorrhagic strokes correlate more closely with BP than do ischemic strokes.[3]

The prevalence of isolated systolic hypertension in Asians, which is reported to be 3.9%−12.5%, is age dependent.[17,18] A meta-analysis of 41 cohort studies conducted by the Asia Pacific Cohort Studies Collaboration clearly illustrated the progressive increase in systolic BP with advancing age in Asian patients.[19] The increasing proportion of older patients across Asia means that the burden of systolic hypertension is continuously growing. It is also anticipated that this increase will be more pronounced than in the Western countries, primarily as a result of lifestyle changes such as consuming Western-style diets and undertaking less physical activity.

Although it was previously reported that there was no difference in prognosis between BP targets of 140 and 150 mmHg,[20] SPRINT trial showed clear evidence of BP lowering effects in elderly patients with HYPERTEN-SION.[21] Therefore, the target systolic BP is below 140 mmHg with a diastolic BP that is not excessively low, i.e., less than approximately 60 mmHg.[20,22]

Since 2017 American College of Cardiology (ACC)/ American Heart Association (AHA) BP guideline, there were discrepancy in the definition of hypertension between ≥130/80 mmHg in ACC/AHA BP guidelines and ≥140/90 in other countries including European guidelines. Most Asian society hypertension guidelines, including Korea, Japan, and China, define hypertension as BP ≥ 140/90 mmHg.[13,23,24] The Japanese Society of Hypertension recommends a target BP of <130/80 mmHg, while the Korean and Chinese guidelines recommend a target BP of <140/90 mmHg or <130/80 mmHg if treatment is well-tolerated especially for high-risk patients such as chronic kidney disease and diabetes. The evaluation of subclinical organ damage including vascular stiffness may be valuable in excluding masked hypertension and correlates with the variability of 24 h BP.[25] If increased vascular stiffness is detected or even worsened during follow up, it may be a clue to the presence of masked hypertension, which can be detected by home BP or ambulatory BP monitoring.[26]

Dyslipidemia

The distribution of serum lipid concentrations varies according to sex and age, and there is a notable difference among women before and after menopause.[27] Generally, the total blood cholesterol concentration is higher among men, but women actually have a higher total cholesterol concentration after the mid-50s. The distribution of low density lipoprotein-cholesterol (LDL-C) concentration is similar to that of total cholesterol. Triglyceride concentrations rapidly increase from the age of 10 to 40 years, are maintained at a high level between ages 40 and 60, and gradually decrease after the age of 60 in men. Conversely, in women, triglyceride concentrations are very low until the ages of 30−40, begin to increase after the mid-40s, and peak after the age of 65.[28] HDL-C concentration is higher among women than men in across all age groups, and the gap is greater in the 20- to 30-year-old group.[28]

The prevalence of hypercholesterolemia in adults aged 30 years or older in South Korea (total cholesterol ≥240 mg/dL or use of cholesterol-lowering drugs) has risen consistently, from 7% to 8% in men and women, respectively, in 2005, to 19% and 20%, respectively, in 2016. The prevalence of dyslipidemia was more than double that of hypercholesterolemia at 40.5%. Sex and age differences indicate that the prevalence of dyslipidemia in men is the highest between the ages of 55 and 59 years (49%) and gradually declines thereafter, while prevalence in women is low between the ages of 20 and 44 years, after which it rapidly increases to 50% between the ages of 60 and 64 years, eventually exceeding that of male counterparts. The prevalence of dyslipidemia is higher among individuals with other comorbidities, such as obesity, abdominal obesity, and diabetes than among those with no comorbidities.[29] In general, the Asian population maintained relatively lower cholesterol levels compared with white Western populations as reported in the international Dyslipidemia Interventional Study II (DYSYS II).[30,31] One characteristic feature of Asia is the high prevalence of hypertriglyceridemia and low HDL cholesterolemia compared with Western populations.[32] In the Korean National Health and Nutritional Examination Survey from 1998 to 2010, hypertriglyceridemia and low HDL cholesterolemia are more common than hypercholesterolemia.[27]

The ACC/AHA published new guidelines in 2013 on the management of cholesterol levels.[33] This guideline no longer targeted specific lipid goals. Instead, it emphasized the administration of high-potency statin therapy instead of "treat to target" goals for LDL-C levels. The concept of "lower is better" for LDL-C levels was replaced by the "more is better" approach to statin therapy.[34] The 2016

ESC/European Atherosclerosis Society (EAS) guidelines made it clear that an LDL-C goal of <70 mg/dL should be achieved, or at least 50% reduction of the baseline LDL-C level in very high-risk patients.[35] However, most Asian guidelines maintained the target LDL-C concentration based on the level of CVD risk factors. Although 2013 ACC/AHA treatment guideline is beneficial by simplifying the criteria for statin administration to "four statin benefit groups,"[33] the 2013 ACC/AHA treatment guidelines could not be directly applied in Asia, as it did not reflect individual differences in drug responses by uniformly recommending a moderate-to-high dose of statin for all patients without a specific LDL-C target level, did not clearly examine the benefits and adverse reactions of high-dose statin administration, and may overestimate CVD risk in Asia. Especially the lipid goal of 50% LDL-C reduction by high-potency statins as recommended in 2013 ACC/AHA guidelines probably received high reluctance.[36] Also, compared with North Americans and Europeans, Asian patients reported having superior statin responsiveness and lower LDL-C levels.[37,38] The plasma levels of statins were higher, and the half-life of the statins was longer after a given dose of any statin[39]. Therefore, the usual recommended doses of statins were lower in Asian guidelines, for instance, atorvastatin 40 mg/day instead of 80 mg/day.[40]

Key elements of the pharmacologic treatment for dyslipidemia are generally the same as 2016 European guidelines. Patients with established CVDs are classified as a very high-risk group, and the treatment goal is to lower LDL-C levels to <70 mg/dL (<100 mg/dL in Japanese guidelines[41]) or by 30%−50% from the baseline level for secondary prevention. Patients with two or more major risk factors other than LDL-C are classified as a moderate risk group, and are recommended to administer statin if the LDL-C concentration is ≥ 120−130 mg/dL for primary prevention. Patients with one or fewer major risk factors other than LDL-C are classified as low-risk group, and statin treatment in this population is recommended for LDL-C concentrations ≥160 mg/dL. When the triglyceride level is between 200 and 499 mg/dL, the primary treatment goal is to lower the LDL-C to below the target on the basis of the calculated CV risk and the secondary goal is to lower non-HDL-C to below the target by therapeutic lifestyle modification and statin therapy. When fasting triglyceride concentrations are still >200 mg/dL despite achieving the target LDL-C goal through therapeutic lifestyle modification and statin therapy, triglyceride lowering drug therapy such as fibrates or omega-3 fatty acids can be used, especially in high-risk and very high-risk groups.[42,43] Similarly, the primary treatment goal for low HDL cholesterolemia is to lower the LDL-C to the target level. To increase HDL-C while lowering the LDL-C to the target, therapeutic lifestyle modification, such as smoking cessation, weight loss, and exercise, should be concurrently performed. It is still debated whether dyslipidemia treatment has long-term beneficial effects on vascular stiffness.[44] However, statin treatment has been reported to improve vascular stiffness the in short-term.[45]

Diabetes mellitus

Type 2 diabetes mellitus (T2DM) is becoming a global health threat owing to its increasing prevalence worldwide.[46] Although the prevalence of diabetes is increasing globally, the situation is particularly alarming in Asia. Two Asian countries, China and India, are home to the largest number of patients with diabetes in the world.[47] Three other Asian countries, Indonesia, Japan, and Bangladesh, are also ranked among the countries with the highest number of patients with diabetes worldwide.[48] In case of South Korea, the prevalence of diabetes among adults 30 years or older was 14.4%; however, when the analysis was limited to adults older than 65 years, the prevalence of diabetes was even higher (29.8%), meaning that one in three Koreans 65 years or older had diabetes.[49] Given the increasing prevalence of obesity and the rapid adoption of a Westernized lifestyle in most Asian countries (especially developing countries), the diabetes epidemic will likely continue to impose a burden on public health systems across Asia.[50]

T2DM develops in East Asian patients at a lower mean BMI compared with those of European descent. At any given BMI, East Asians have a greater amount of body fat and a tendency to visceral adiposity.[51] Greater visceral adiposity can lead to increased fatty acid influx to the liver, altered adipokine production, fatty liver, and hepatic insulin resistance.[52] In Asian patients, diabetes develops at a younger age and is characterized by early β cell dysfunction in the setting of insulin resistance, with many requiring early insulin treatment.[53] T2DM in Asian population tends to occur approximately three years earlier than Western population.[54] The increase in the prevalence and decrease in the age of onset of diabetes in young Asian generations may be explained by the increasing prevalence of obesity and abundant nutrition, including during the intrauterine period: that is, "the thrifty genotype" hypothesis.[55] In developed countries, T2DM affects mainly those older than 65 years, as dietary patterns and energy intake have not changed dramatically in the past decades. Although Asians are not accustomed to Western dietary patterns, most developing countries in Asia accept these as markers of economic development. The younger generations in Asian developing countries are born in relative wealth compared with their parents and, although they retain their parents' genetic background, they usually have access to an abundantly nutritional diet throughout their lives.[56]

Besides lifestyle factors, Asians are known for dysfunctional pancreatic insulin secretory function.[57] A study performed in South Koreans suggested that impaired insulin secretion was induced by insufficient pancreatic

β-cell mass, functional defects within β-cells themselves, or a combination of both. They reported a linear correlation between β-cell mass and BMI in patients with T2DM, suggesting the possibility of reduced insulin secretory function in Asians due to lower BMI and, thus, smaller β-cell mass.[58] Also, there was possibility that Asians have a higher risk of developing diabetes due to genetic defects affecting insulin secretory function and β-cell mass. Several T2DM loci, including KCNQ1, were first discovered in Asians and meta-analysis of East Asian studies identified eight novel loci for T2DM; most of these variants were predicted to influence the risk of T2DM by affecting insulin secretion.[59]

Asian individuals with diabetes are at increased risk of microvascular complications and albuminuria compared with Caucasian first reported in the WHO Multinational Study of Vascular Disease in Diabetes.[60] These patterns of higher microvascular complications in Asians compared with Caucasians were replicated across multiple studies. In a cross-sectional study involving 32,308 patients with T2DM from 33 countries, Asian diabetic patients had the highest prevalence of microalbuminuria as well as macroalbuminuria.[61] In the Action in Diabetes and Vascular Disease (ADVANCE) study, patients with T2DM from Asia had a higher incidence of renal complications and ischemic stroke but a lower risk of coronary artery disease than their counterparts in Eastern Europe.[62] Although, the exact mechanisms underlying these distinctive patterns remain unknown, more intensive risk factor control especially hypertension will be necessary in Asian diabetic population to prevent microvascular complications.

As it is well known that several chronic complications can occur owing to poor glycemic control, long-term glycemic control is important not only in the prevention of diabetic complication but also in the management of combined risk factors such as hypertension and dyslipidemia. In the Kumamoto study in Japan and the UK Prospective Diabetes Study (UKPDS) study showed that intensive glycemic control proved to be effective in preventing microvascular complications.[63,64] In the Kumamoto study, the intensive glucose control group targeting HbA1c <7% decreased retinopathy by 69%, nephropathy by 70%, and improved nerve conduction velocity. Most Asian guidelines recommended glycemic target as HbA1c concentration <6.5% to 7%.[65,66] However, the glycemic control is largely suboptimal worldwide. The mean baseline HbA1c was higher in India (8.6%), the Middle East and Latin America (both, 8.5%) compared with those in East Asia and Europe (7.7% and 7.9%).[67] Even in East Asian countries, for example, South Korea, the control rate, defined by an HbA1c level <6.5%, was only 25.1%, which

was relatively low considering the high awareness and treatment rates.[49] Even if the target HbA1c level was defined as <7.0%, the control rate remained 50%.[29,68]

Life style modification

Nonpharmacologic therapy or lifestyle modification, such as adoption of a healthy diet, increasing exercise, smoking cessation, and moderation of alcohol intake, has shown great ability to lower BP and is strongly recommended in all patients with hypertension and also in population with BP ranged 120−139/80−89 mmHg.[69]

Asians generally have a higher salt intake than Westerners.[70] Recent studies indicate that salt consumption remains high throughout the Asia−Pacific region in countries including Australia (9.6 g/day),[71] China (9.1 g/day),[72] Korea (10 g/day),[73] Japan (11 g/day),[23] and India (9.45−10.41 g/day).[74] These estimated intakes are almost double the WHO's recommended maximum daily salt intake of 5 g/day. The main source of salt in Asians is spices, vegetables, and grains.[75,76] Excessive salt intake is associated with significantly increased BP and the progression of target organ damage.[77,78] Salt intake is more closely correlated with central hemodynamics than peripheral hemodynamics of the brachial artery in patients with hypertension.[79] Salt intake predominantly influences central BP, which is implicated in the development of arterial stiffening. It is noteworthy, therefore, that measuring brachial BP is likely to underestimate the detrimental effects of salt intake on central BP.[80] High sodium intake was positively linked to subsequent vascular stiffness measured by brachial-ankle pulse wave velocity (baPWV) and carotid intima-media thickness levels in South Korean adults.[81] High salt intake may also increase the risk of stroke and CVD independently of the effects of elevated BP, a hypothesis that has been supported by research demonstrating that dietary sodium alters vascular endothelial function independently of systolic BP changes.[82] Reducing dietary sodium effectively reduces systolic BP in Asian patients.[83,84] The daily recommended amount of salt in Asian guidelines is less than 6 g (sodium (g) × 2.5).[69] Substitution of normal salt with reduced sodium, high potassium salt has been shown to significantly reduce BP in Chinese patients with hypertension.[83] Reducing dietary sodium may be particularly effective in reducing systolic BP in older patients.[85]

BP increases with increasing BMI and waist circumference in Asian subjects.[86,87] Obesity was defined as a BMI equal to or higher than 25 kg/m^2, according to the Asia−Pacific Region definition.[88] Over the past 10 years, the prevalence of obesity in Asia markedly increased. For example in South Korea, the prevalence of obesity in the total population was 29.7% in 2009, which increased to

35.7% in 2018.[89] As a result, the prevalence of obesity was 45.4% in men and 26.5% in women, showing a higher prevalence in men than in women. The prevalence of abdominal obesity similarly increased over the past 10 years in Korean adults, with prevalence rates of 23.8% in the total population, 28.1% in men, and 18.2% in women recorded in 2018. The impact of obesity on hypertension appears to be elevated in Asian subjects compared with Western subjects[90]; a BMI of 25 kg/m^2 in Asians has a similar impact on prehypertension and hypertension as a BMI of 30 kg/m^2 in Western individuals.[91,92] Obesity and associated metabolic syndrome are becoming more common in Asian regions.[93] Both of these conditions increase salt sensitivity.[94] Hence, Asians with high salt intake or salt sensitivity may experience increases in BP if they are overweight or only mildly obese. Conversely, the combination of weight reduction with exercise, moderation of alcohol consumption, and reduction of salt intake has synergistic effects on BP. A report on data from 1.2 million Koreans revealed that the risk of death from any cause was lowest among patients with a BMI of 23.0−24.9 kg/m^2 and recommended a BMI of less than 25 kg/m^2.[95] In cohorts of East Asians, including Chinese, Japanese, and Koreans, the lowest risk of death was seen among persons with a BMI of 22.6−27.5.[96] A waist circumference of less than 90 cm for men and 85 cm for women is recommended for Asian individuals.[97]

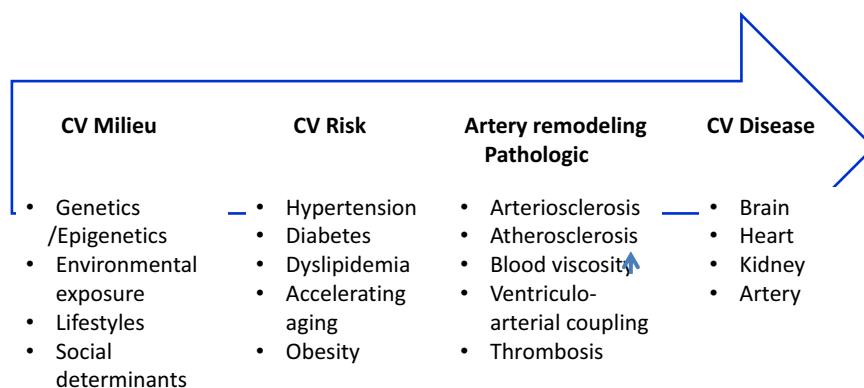
Table 32.1 shows the specific characteristics of CV risk and their relevant guidelines in East Asia. Compared to those of the United States and Europe, East Asian have higher stroke incidence and mortality but lower CVD incidence and mortality. However, In India and South and Middle East Asia, they have higher CVD and stroke incidence and mortality than those of East Asia and the United States and Europe. Insulin resistance and cental obesity is key difference between East Asians and South Asians.

Role of vascular markers in Asian cardiovascular prevention guidelines

There was no consensus for the role of vascular markers in the risk prediction models. Recently, Japan Brachial-Ankle Pulse Wave Velocity Individual Participant Data Meta-Analysis of Prospective Studies (J-BAVELs) suggested steno-stiffness approach for CVD risk assessment in primary prevention using the interarm BP difference, the ankle-brachial index, and brachial-ankle PWV, showing improvement of the risk assessment.[98] As a result, there were no specific indications for the vascular markers in Asian CV prevention guidelines. However, the recently published Japanese Society of Hypertension Guidelines introduced the implication of vascular markers.[23] The carotid artery intima-media thickness is considered as unsuitable as an indicator for evaluation of exacerbation/improvement of the risk following changes in condition or treatment, whereas ABI measurement is highly recommended in high-risk patients. Both cfPWV and baPWV have been shown to improve the evaluation results of existing risk models, with the improvement of the prognostic ability larger when baPWV was used in the low-risk group.[99] cfPWV may be useful when measured in cases at moderate or higher risk.[100] baPWV may be applicable to risk assessment also in low-risk cases, but there is a need of verifying the medicoeconomic efficiency of its

TABLE 32.1 Asian characteristics of cardiovascular risk and their relevant guidelines.

	Characteristics	Guidelines
Hypertension	■ More blood pressure dependent CVD, particularly stroke ■ Predominant isolated systolic hypertension	■ Target BP, initially less than 140/90 followed by 130/80 mmHg when tolerated
Dyslipidemia	■ Higher prevalence of dyslipidemia, relatively low cholesterol and high triglyceride and low HDL-cholesterol in serum	■ Prominent LDL-C lowering effect with statin and therefore the lower dose of statin needed ■ Emphasis on therapeutic lifestyle modification
Diabetes	■ Relatively lower body weight, but more visceral fat ■ Young age-onset of diabetes ■ Dysfunctional pancreatic insulin secretion ■ Increased comorbidity	■ Early intervention of lifestyle modification ■ Strict control of concomitant risk factors
Lifestyles	■ Still high salt intake ■ Rapidly growing obesity	■ Education ■ Early intervention of therapeutic lifestyle modification

BP, blood pressure; *CVD*; cardiovascular disease; *HDL-cholesterol*, high density lipoprotein-cholesterol; *LDL-C*, low density lipoprotein-cholesterol.


measurement, and its measurement may be useful in patients aged 50 and over or patients having risk factors other than BP. Although the guideline mentioned potential usefulness as a prognostic indicator, there were no specific recommendations for the cardio-ankle vascular index, pulse wave analysis, or endothelial function test. Also, the guideline recommended to conduct vascular marker evaluation upon stabilization of BP after the start of antihypertensive treatment rather than before starting treatment.

Perspective for the prevention of cardiovascular risk in Asia

One of characteristic feature of Asia is rapid "Population aging."[101,102] Regarding vascular health, it is particularly important, because vascular aging—related medial degeneration is the dominant factor associated with increased arterial stiffness (arteriosclerosis) more than the narrowing of the artery (atherosclerosis) in the Asian population.[103] Asian populations may have a particular predisposition to increased central aortic pulse pressure.[104] Age-related changes in arterial mechanical properties increased arterial stiffness and wave reflection are themselves potent and independent risk factors for CV diseases.[105] More importantly, CV risk factors often form a vicious cycle in CV complications. For example, salt intake has an independent effect on arterial wall properties contributing to increased arterial stiffness with age[106] which in turn increases pulse pressure. Urinary salt excretion, a surrogate for intake, is higher among the obese and the elderly.[107] More vigorous CV prevention strategies to cut the vicious cycle should be implemented for Asian populations. Moreover, since most CV risk factors ultimately lead to CV disease through pathologic artery remodeling, the prevention or reversal of pathologic artery remodeling itself should be a central component of prevention strategies (Fig. 32.1).

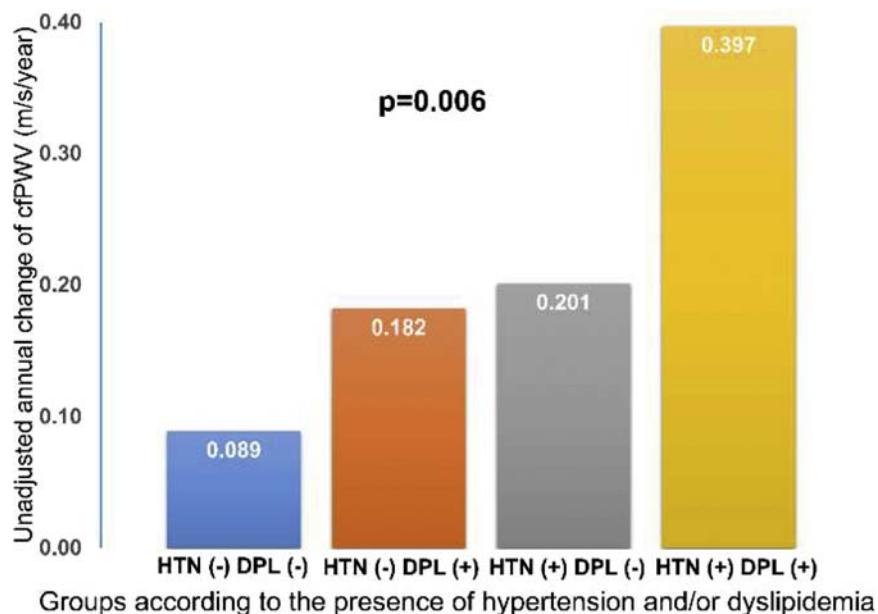
Arterial stiffness for cardiovascular risk stratification in clinical practice

Dimitrios Terentes-Printzios and Charalambos Vlachopoulos


First Department of Cardiology, Hippokration Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece

Introduction

Biological markers or biomarkers are valuable tools in prediction of risk. Some traditional individual risk factors, or other proposed biomarkers can fluctuate over time and their values, recorded at the time of risk assessment, may not reflect their true impact on the arterial wall. Arterial biomarkers have the advantage that they can better integrate both the cumulative effect of a traditional risk factor on the arterial wall over a long period of time and the synergistic effects from risk factor combinations (Fig. 33.1).[1] Before a biomarker can be introduced as a surrogate endpoint in clinical practice, important conditions/criteria must be fulfilled.[2,3] According to the American Heart Association (AHA),[4] these criteria (and the relevant questions that need to be answered) are:

1. Proof of concept: Do novel biomarker levels differ between subjects with and without outcome?
2. Prospective validation: Does the novel biomarker predict the development of future outcomes in a prospective cohort or nested case-cohort study?
3. Incremental value: Does it add predictive information over and above established, standard risk markers?
4. Clinical utility: Does it change predicted risk sufficiently to change recommended therapy?

FIGURE 33.1 Unadjusted mean annual change of carotid-femoral pulse wave velocity according to the presence of hypertension and/or dyslipidemia. *DPL*, dyslipidemia; *HTN*, hypertension. *P* value by ANOVA. *Modified from Terentes-Printzios D, Vlachopoulos C, Xaplanteris P, et al. Cardiovascular risk factors accelerate progression of vascular aging in the general population: results from the CRAVE study (cardiovascular risk factors affecting vascular age).* **Hypertension.** *2017;70:1057−1064.*

5. Clinical outcomes: Does the use of the novel biomarker improve clinical outcomes, especially when tested in a randomized clinical trial?
6. Cost-effectiveness: Does the use of the biomarker improve clinical outcomes sufficiently to justify the additional costs?
   Further, there is requirement of three additional criteria (not present in the AHA scientific statement) to be fulfilled for a biomarker to qualify as clinical surrogate endpoint:
7. Ease of use; this will allow widespread application.
8. Methodological consensus
9. Reference values, or, at least, cut-off values to allow for practical implementation.

Arterial stiffness

Predictive value: Clearly, since the predictive role of a certain biomarker for future events is the cornerstone of its clinical usefulness, prospective survival studies are warranted as an early step for its clinical applicability. A considerable number of studies have examined the ability of arterial stiffness to predict the risk of future fatal and nonfatal cardiovascular events (myocardial infarction [MI], stroke, revascularization, aortic syndromes, and peripheral vascular events) and total mortality (Table 33.1, Fig. 33.2) and the list is growing. At a critical point of the accumulation of studies, we performed a meta-analysis in which we pooled the aortic pulse wave velocity (PWV) data for 15,877 subjects from 17 available published studies who were followed up for a mean of 7.7 years.[5] Several populations, such as patients with hypertension, diabetes, end-stage renal disease (ESRD), and coronary artery disease, and subjects from the general population or ethnic minorities were included in that analysis. Aortic stiffness emerged as a strong predictor of future CV events and all-cause mortality. An increase in aortic PWV by 1 m/s corresponded to an age-, sex-, and risk factor–adjusted risk increase of 14%, 15%, and 15% in total CV events, CV mortality, and all-cause mortality, respectively. Importantly, the predictive ability of arterial stiffness is higher in subjects with a higher baseline CV risk, such as renal disease. The results of this meta-analysis were confirmed by a subsequent meta-analysis with individual data of 17,635 subjects, which also importantly added that reclassification was significant for those at intermediate risk (13% for 10-year CVD risk) and in younger subjects (Fig. 33.3).[6,7] Importantly, the latter delineates the group of patients (intermediate risk) that would benefit more from the clinical implementation of PWV.

A closer look at the studies reveals considerable heterogeneity in study design, methodology, and endpoints. This heterogeneity is two-faced. It vividly demonstrates the wide applicability of arterial stiffness measurements in various populations and underlying diseases. On the other hand, it identifies that techniques and conclusions specific to one patient group cannot be used interchangeably. Therefore, there is a need to answer specific questions based on the available prospective data. These questions are:

1. How was arterial stiffness measured?
2. In which populations was arterial stiffness predictive of future events?
3. Which cut-off should be used to identify patients at high risk?
4. Which future endpoints are more closely related to arterial stiffness measurements?
5. What is the effect of blood pressure (BP)/antihypertensive treatment at the time of measurement?

Measurement of arterial stiffness: The techniques of assessing aortic PWV include invasive measurements (considered to be the gold standard), tonometry (the most popular noninvasive technique), oscillometry (either single or two sites), imaging techniques (including MRI and echocardiography), photoplythesmography and, finally, use of estimated values of PWV (derived either by equations or machine learning methods using hemodynamic data or pulse wave form characteristics). For a more comprehensive review regarding methods to assess arterial stiffness, please refer to Chapters 1–4, and 7. Based on the review of the current literature, the large body of evidence stems from two-sites tonometry measurements and thus this should be considered as the first choice for use in clinical practice, despite its inherent technical difficulties (relatively time-consuming in a busy outpatient clinic, need for exposure of the groin, challenges in obese subjects, and availability). However, in an ever-changing world that everything needs to be faster and easier it is possible that alternative techniques might also rise high in user preference. As far as the predictive role is concerned, these techniques should be compared to the current gold standards. In such an effort, recently Hametner et al.[8] compared in patients undergoing coronary angiography the predictive role of invasive PWV, formula-based PWV (calculated by age and BP), and an estimated PWV (by a model incorporating age, central systolic BP, and pulse waveform characteristics) showing comparable predictive effects. Although these results are promising toward the applicability of these alternative techniques, studies comparing them with the two-site tonometry technique in low-to-intermediate cardiovascular risk populations are warranted. Moreover, it should be noted that formula-based PWV estimations based on only age and BPs do not represent genuine individual measurements, but rather mathematical transformations that incorporate the prognostic information contained in age and BP values.

Study population: Historically, the earliest studies included patients belonging to high-risk groups, such as ESRD (Table 33.1). Progressively, studies extended to other patient groups, such as hypertensive, diabetic, or

TABLE 33.1 Overview of studies on the association between aortic pulse wave velocity and clinical events with at least 300 subjects.

Author, year, country/study name	Population-sample size	Age (years)	Follow-up duration	Systolic blood pressure and diastolic blood pressure in mmHg (mean, standard deviation)	Events	Aortic pulse wave velocity in m/s (mean, standard deviation), measurement method	Aortic pulse wave velocity cut-off (high vs. low)
Avramoski et al. (2016), Northern Macedonia[61]	General population (n = 558)	56.2 ± 11.6	36 months	N.a.	17 CV deaths	9.21 ± 1.98, Doppler	>9.4 m/s

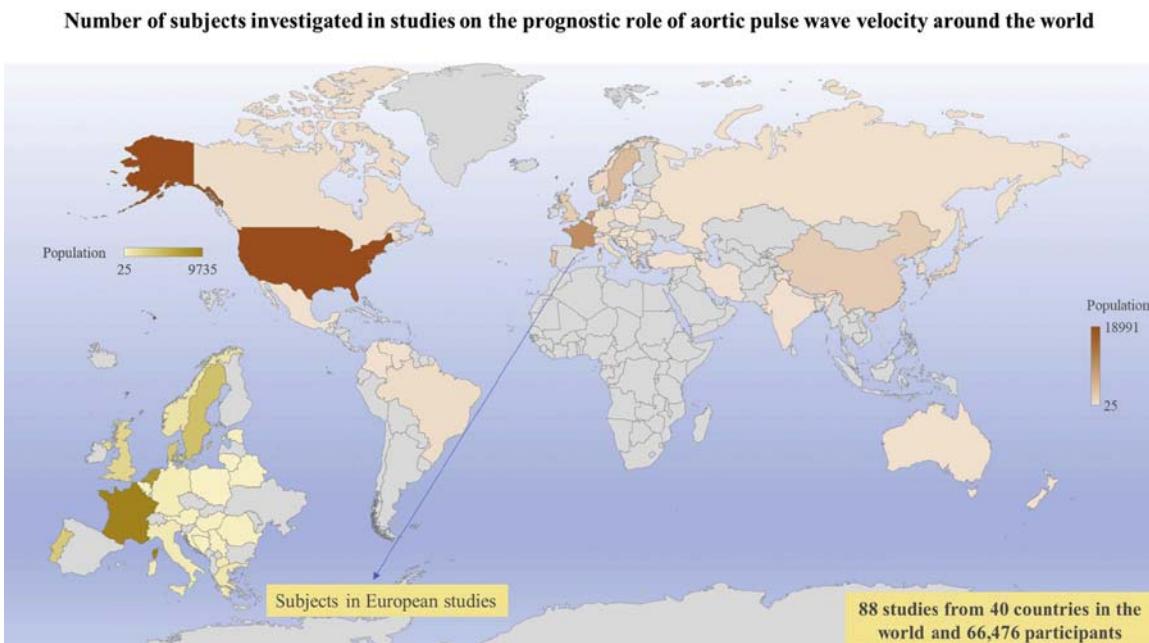
Number of subjects investigated in studies on the prognostic role of aortic pulse wave velocity around the world


FIGURE 33.2 Distribution and number of subjects investigating the prognostic role of pulse wave velocity worldwide up until the end of 2019.
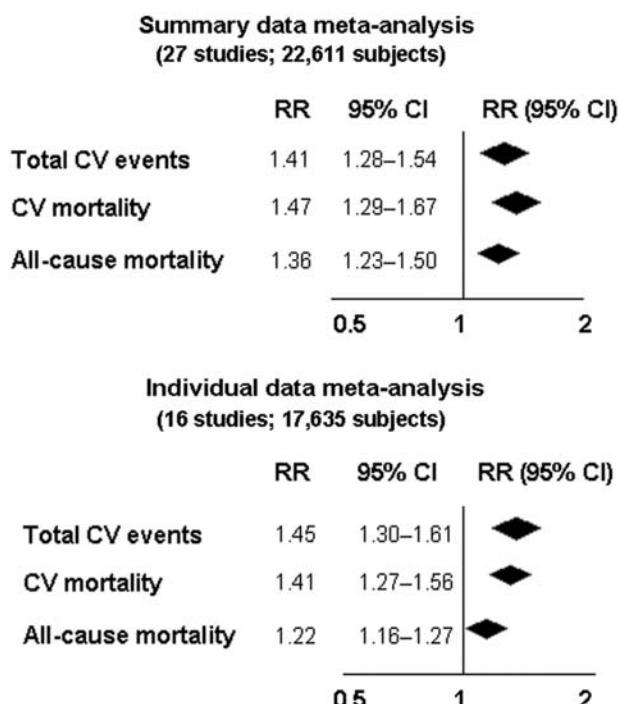

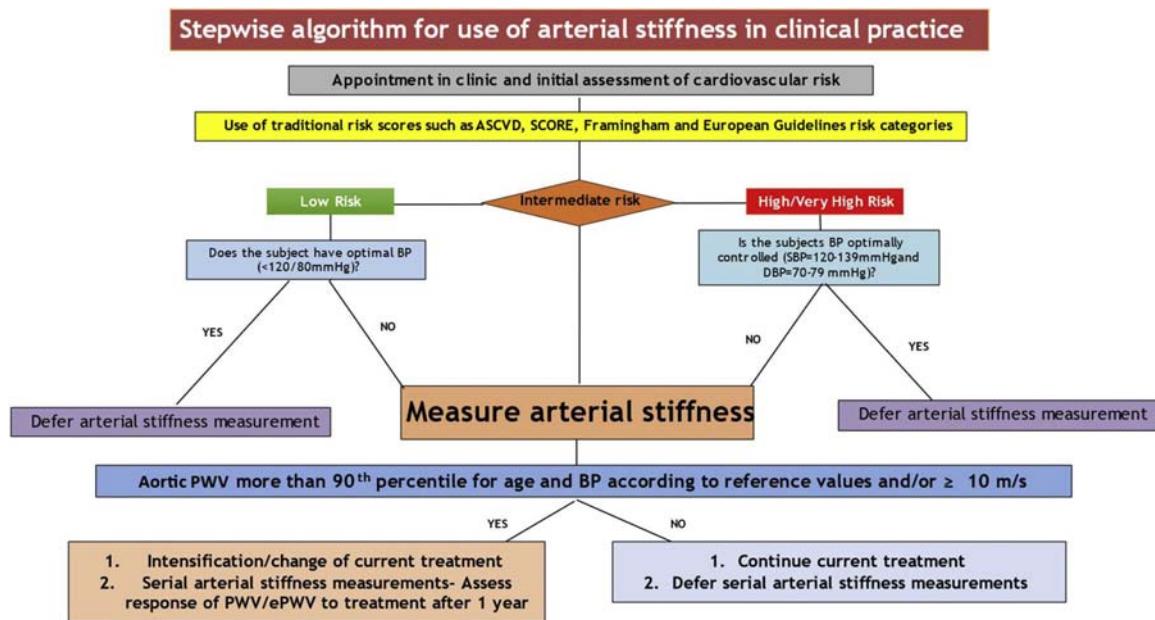

FIGURE 33.3 Relative risks (RRs) and 95% confidence intervals (CIs) for a 1-SD increase in aortic pulse wave velocity (aPWV) and total cardiovascular (CV) events, CV mortality, and all-cause mortality according to summary data meta-analysis. *Modified from Vlachopoulos, et al. J Am Coll Cardiol. 2014.*

coronary artery disease patients, and subsequently, to the general population. As PWV is a measure of arteriosclerosis, the use of subjects prone to these pathological entities (ESRD, hypertension, and diabetes) was the appropriate first step. Interestingly though, PWV provided evidence of its predictive role in other populations as well, including patients with heart failure, acute coronary syndromes, or inflammatory diseases, thus providing a useful tool for risk stratification in other disease states. In a diagnostic arena overflown with diagnostic modalities, the real conundrum from all these data is which one of these populations would benefit the most from having PWV as an addition risk stratification tool. It appears that individuals who would benefit the most are, apart from patients with hypertension or renal insufficiency those who, according to office-based evaluation with available risk calculators (Framingham, European SCORE, Atherosclerotic CVD) belong to the intermediate risk category. Additionally, measurement of PWV could provide incremental prognostic information in individuals belonging to a low-risk category but with the presence of risk factors, such as family history of early onset of CVD, substantially elevated single risk factor, elevated estimates of arterial biomarkers, such as increased SAGE risk score (systolic BP, age, fasting glucose and estimated glomerular filtration rate [eGFR]), and estimated pulse wave velocity (ePWV), and novel risk factors (Fig. 33.4 and 33.5).

Cut-off: Unfortunately, studies have used different measurement techniques and cut-offs to identify subjects with increased arterial stiffness. The proposed cut-off by the European Society of Cardiology (ESC) Guidelines at 10 m/s is a rough estimate in order to provide clinicians with an easy to remember number.[9,10] However, is this solution supported by evidence and has it provided help

FIGURE 33.4   Algorithmic approach of the use of measurement of pulse wave velocity in the clinical practice.

FIGURE 33.5   SAGE score chart according to the four constituents of the score. Combinations of risk factors resulting in a SAGE score equal or higher than eight are marked in orange color and indicate a high probability of elevated arterial stiffness (PWV>10 m/s). Combinations or risk factors resulting in a SAGE score of less than eight are marked in green and indicate a low probability of elevated arterial stiffness. *Modified from Xaplanteris, et al. J Hypert. 2019.*

into the introduction of PWV into clinical practice? In the studies, cut-offs range usually from 8 to 13 m/s, while even the individual data meta-analysis of many of these studies[6] did not provide any cut-off confirming the difficulties and

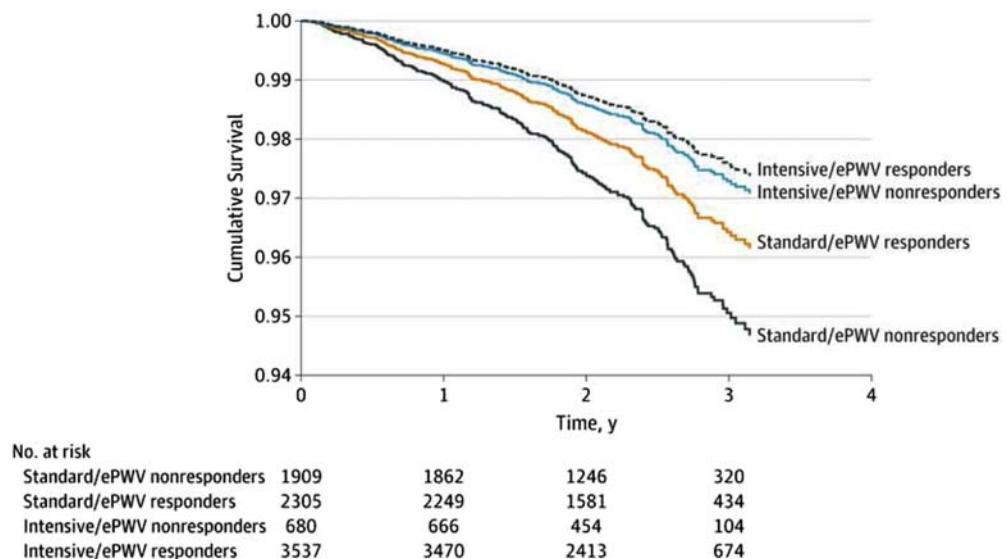
oversimplification of such an approach. A more elaborate method has been recently proposed with the introduction of EVA and the use of an estimation of vascular age based on PWV and its comparison to the true age of each

participant.[11] This approach seems more suitable as it incorporates the effects of age, BP, and treatment in the identification of patients at high CV risk, but is hampered by the more cumbersome estimation process. It seems reasonable that a cut-off based on the PWV reference values for certain age, BP, and treatment might be the best solution, but this remains to be proven in future studies.

Endpoints: The fact that arterial stiffness is predictive of CV events is largely expected since it is pathophysiologically important for both arterial and overall CV performance. PWV is a BP-dependent biomarker and thus has a strong correlation with endpoints, such as stroke and other cardiovascular events (including heart failure). Interestingly though, arterial stiffness is predictive also for all-cause mortality, with 45%−50% of deaths attributed to noncardiac causes. This important finding should be emphasized and further scrutinized. Although pathophysiological explanations are not readily identifiable, this could reflect the existence of common pathogenetic mechanisms, such as aging, inflammation, and oxidative stress, over a wide range of conditions.

Effect of BP/antihypertensive treatment: When gauging cardiovascular risk with PWV, it is essential to take into account the BP and whether patient is on antihypertensive treatment. One cut-off value does not fit all, and this is especially important in patients with optimal BP levels, or hypertensives with well-controlled BP with antihypertensive treatment. This has not been properly addressed in the prospective studies but data from ePWV showed that the predictive value of ePWV equal or more than 10 m/s was significantly higher in untreated rather than treated patients in the Paris cohort.[12] Also, from a post hoc analysis of the Systolic Blood Pressure Intervention Trial (SPRINT), intensive treatment was superior to standard treatment only when it was accompanied with a response in ePWV at the first year, while, within the standard group, those with an ePWV response had improved all-cause mortality.[13]

Inclusion in clinical recommendations and guidelines: Based on the available data to date, we believe that inclusion of arterial stiffness by guidelines on the disease prevention is justified. European recommendations have been rather favorable.[2,9,10] The current recommendation of the European Society of Hypertension/ESC hypertension guidelines is IIb (i.e., "may be used"). Accumulating evidence, increased clinical integration, and awaited data on PWV as a plausible treatment target (SPARTE trial [Stratégie de Prévention Cardiovasculaire Basée sur la Rigidité Arterielle])[14] may require reappraisal of level of recommendation in the near future.

Estimated PWV: When actual measurement of PWV is not feasible, additional approaches that could aid integration into clinical practice have been tested. One is based on the determination of reference values for carotid-femoral PWV: an estimated aortic PWV is derived by relevant equations that take into account age and BP. Despite its dependence on these two parameters, ePWV was shown to be predictive of future events and improved risk prediction over traditional risk scores.[12,13] The other strategy employs a simple clinical score (SAGE score) that predicts high aortic PWV values based on widely available clinical variables (systolic BP, age, glucose, and eGFR) and can prioritize actual measurement of aortic PWV in those with high score.[15] Both approaches can ultimately result in greater evidence accumulation and appreciation of the clinical role of aortic stiffness.


Association with intermediate endpoints: Apart for the (preferred) hard endpoints, arterial stiffness has been associated with intermediate ones. In patients with essential hypertension, indexes of large-artery stiffness indicate the presence and extent of atherosclerotic disease and correlate with CV risk estimates as assessed by the Framingham risk score.[16] Aortic PWV is associated with left ventricular (LV) hypertrophy,[17] while it is an independent marker of cognitive impairment,[18] cerebral blood flow, and cerebrovascular reactivity[19] and correlates with silent small vessel cerebral disease.[20] Furthermore, carotid-femoral PWV is an independent predictor of coronary flow reserve[21] and renal function, as assessed by eGFR[22] and microalbuminuria.[23]

Arterial stiffness as a therapeutic target: From the therapeutic standpoint, aortic stiffness appears as a worthwhile treatment target. However, to date, there is only one study in patients with ESRD showing that improvement in outcome was mediated through an improvement in aortic stiffness.[24] Despite the similar reduction in pressure, only survivors experienced a reduction in aortic stiffness, whereas nonsurvivors exhibited an increase in PWV. Interestingly, in a hypothesis-generating study, we showed in a post hoc analysis from data of the SPRINT trial that patients in the standard treatment arm that had an effective ePWV reduction at 1 year had an improved survival independently of the reduction in systolic BP (Fig. 33.6).[13] Undoubtedly, more studies are needed and soon-to-revealed studies, such as the SPARTE study, will further clarify the role of PWV as a therapeutic target.[14]

Additional indices of arterial stiffness: It should be stressed that results supporting the role of arterial stiffness as an appealing biomarker are at this stage valid for aortic PWV (an index of regional arterial stiffness) only and are not necessarily expandable to indices of local arterial stiffness (aortic, carotid, and femoral) or systemic arterial stiffness. Regarding other indices of regional arterial stiffness, carotid-radial PWV is unlikely to have predictive value,[25] while data are accumulating on local stiffness parameters, such as carotid and femoral[26]; for these, reference values are now available.[27,28]

Accumulating evidence on brachial-ankle PWV (baPWV) appear convincing. baPWV capitalizes on the assumption that it evaluates a large part of the arterial pathway. It has shown an independent and incremental predictive role for future events[29−31] and a considerable number of patients (up to 25%) can be reclassified as an individual-data meta-analysis showed that also can predict

FIGURE 33.6 Combined effect of treatment allocation and response of estimated pulse wave velocity (ePWV) to treatment on all-cause death. *Modified from Vlachopoulos C, Terentes-Printzios D, Laurent S, et al. Association of estimated pulse wave velocity with survival: a secondary analysis of SPRINT. JAMA Netw Open. 2019;2:e1912831.*

the incidence of hypertension and ESRD. Subjects with values over 18 m/s are considered of high risk, whereas it has been suggested that subjects <60 years with values over 14 m/s should be counseled toward lifestyle modification.[32]

Central pressure and wave reflection indices

Central pressure waveforms, either directly measured, or estimated noninvasively from peripheral pressure waveforms have resurged into the forefront of research of hypertension in the last three decades as many devices have incorporated them in their measurement. Apart from the classic values of central systolic, diastolic, and pulse pressures, measurement of the central pressure waveform can provide clinically useful information beyond BP measured in the brachial artery, such as the quantification of wave reflections with aortic augmentation index (AIx) and pulse pressure amplification. Please refer to Chapters 2, 3 and 11 for a more extensive discussion of wave reflections and its impact on the pressure waveform. In this Chapter we will mainly focus on the central pressures and wave reflections as assessed by the aortic AIx and not to other waveform related indices such as reflection magnitude and backward wave amplitude.

Predictive value: Central (aortic and carotid) pressures are pathophysiologically more relevant than peripheral pressures for the pathogenesis of cardiovascular disease[33,34] and according to accumulating clinical evidence, this could be translated into a significant predictive role for future cardiovascular events. While several studies have shown an ability of central pressures and indices to predict future events, findings have not always been consistent (Table 33.2). We[35] meta-analyzed 11 longitudinal studies that had employed measures of central hemodynamics and had followed 5648 subjects for a mean follow-up of 45 months. The age- and risk factor−adjusted pooled relative risk (RR) of total CV events was 1.14 (95% CI 1.06−1.22) for a 10 mmHg increase of central pulse pressure. Furthermore, a 10% increase of central AIx was associated with an RR of 1.38 (95% CI 1.19−1.61) for all-cause mortality. When three more studies[36-38] that were published after the respective meta-analysis were included (a total of 9093 subjects and mean follow-up of 54.9 months), the RRs of total CV events were 1.12 (95% CI 1.03−1.21) for a 10 mmHg increase of central pulse pressure, and 1.30 (95% CI 1.10−1.55) for a 10% absolute increase of central AIx. Furthermore, a 10% increase of central AIx was associated with an RR of 1.33 (95% CI 1.17−1.51) for all-cause mortality.

As with arterial stiffness, taking a closer look at the studies, it is easy to observe a large degree of heterogeneity in several aspects of study design, methodology, and endpoints. So, there is a need to provide answers to specific questions based on the available prospective data:

1. How was central waveform derived?
2. How closely related were the central pressures to peripheral pressures and was central pressure's predictive ability independent of peripheral pressures?
3. In which populations were central pressures predictive of future events?
4. Which cut-off should be used to identify patients at high risk?

TABLE 33.2 Overview of large studies (more than 100 subjects) up to 2021 on the association between measured central pressures and clinical endpoints.

Author, year	Population-sample size	Age (years)	Follow-up duration (longitudinal studies)	Index	Events	Central indices versus peripheral blood pressures[a]
Safar et al. (2002)[110,111]	ESRD (n = 180)	54 ± 16	52 ± 36 months	Carotid SBP, PP, PPA	Deaths and CV deaths	Central better
Chirinos et al. (2005)	CAD or nonobstructive coronary atherosclerosis (n = 297)	63.8 ± 10.3	40 ± 14 months	Aortic PP, AP, AIx	Deaths and CV events	Central better
Weber et al. (2005)[53]	CAD/angioplasty (n = 262)	65 ± 10	24 months	AIx@75	Deaths and CV events	Central better
Williams et al. (2006)[53]	Hypertensives (n = 2199)	62.8 ± 8.2	Up to 4 years	Central SBP, PP, AIx, PPA	CV events and procedures plus renal impairment	Similar
Dart et al. (2006)[112]	Elderly female hypertensives (n = 484)	72 ± 5	49 months (median)	Carotid SBP, PP, AIx	CV events	Peripheral better
Roman et al. (2007)[113]	American Indians free of CVD (n = 2403)	63.5 ± 7.5	58 ± 16 months	Aortic SBP, PP	Deaths, CV deaths, and CV events	Central better
Jankowski et al. (2008)[114]	Subjects undergoing nonemergency coronary angiography (n = 1109)	52.7 ± 19.2	52.7 ± 19.2 months	Aortic PP	Deaths, CV deaths, and CV events	Central better
Pini et al. (2008)[115]	Community-dwelling individuals 65 years (n = 398)	73 ± 6	94 ± 24 months	Aortic SBP, PP, AIx	Deaths, CV deaths, and CV events	Central better
Mitchell et al. (2010)[36]	General population (n = 2232)	63 ± 12	7.8 years	Carotid AIx, PPA, carotid PP	CV events	Central indices not anymore significant when adjusted for RFs
Wang et al. (2010)[37]	General population (n = 1272)	52 ± 13	15 years	Carotid SBP, PP, AP, AIx, RWTT, RI, Pi, Pf, and Pb	Deaths, CV deaths	Central better
Weber et al. (2010)[38]	Males undergoing coronary angiography (n = 520)	64.0 (54−71.5)	49 months	Aortic AIx, Aix@75, pulse wave transit time	Deaths and CV events	Central better
Manisty et al. (2010)[116]	Hypertensives (n = 259)	63.9 ± 7.4	5.9 years	Log WRI (wave reflection index), carotid SBP, PP, AIx, Pb/Pf	CV events	Only WRI and carotid PP (not in multivariable model) were significant
Huang et al. (2011)[117]	Normotensives or untreated hypertensives (n = 1014)	52 ± 13	15 years	Central SBP, PP	Deaths, CV deaths	Central better
Verbeke et al. (2011)[100]	Renal transplant recipients (n = 512)	52.4	5 years	Central SBP, PP, AP, Aix	Fatal and nonfatal CV events	Central better
Benetos et al. (2012)[63]	Elderly (n = 1126)	88 ± 5	2 years	PPA	Deaths and major CV events	PPA better than peripheral

AIx, augmentation index; *AIx@75*, augmentation index corrected for a heart rate of 75 bpm.; *AP*, augmented pressure; *BP*, blood pressure; *CAD*, coronary artery disease; *CKD*, chronic kidney disease; *CVD*, cardiovascular disease; *DM*, diabetes mellitus; *ESRD*, end-stage renal disease; *FU*, follow-up; *HF*, heart failure; *MI*, myocardial infarction; *Pb*, backward pressure amplitude; *PCI*, percutaneous coronary intervention; *Pf*, forward pressure amplitude; *Pi*, incident pressure wave height; *PP*, pulse pressure; *PPA*, pulse pressure amplification (brachial-carotid); *RF*, risk factors; *RI*, reflection index; *RM*, reflection magnitude; *RWTT*, reflected wave transit time; *SBP*, systolic blood pressure; *SEVR*, subendocardial viability ratio.
[a]"better" denotes numerically larger RR, not necessarily tested in a statistically adjusted statistical test.

Measurement/estimation of central pressure waveform/central pressures: The techniques of assessing central hemodynamic indices include invasive measurements (considered to be the gold-standard), tonometry (the most popular noninvasive technique), oscillometry (either single- or two-sites), imaging techniques (including echocardiography), photoplethysmography, and finally use of estimated values of central pressures (derived mainly by equations, and more recently, by machine learning techniques).[34] Based on the review of the current literature, the large body of evidence stems from tonometry measurements and thus this technique could the first choice for use in clinical practice, despite its inherent technical limitations (use of peripheral pressures measured in other arterial segments to derive the central pressure waveform through a transfer function). All approaches have their advantages and disadvantages. Some are limited by methodological shortcomings. Unquestionably, all should be rigorously and carefully validated with a standardized method before commercialization.[39] Central pressures may be more easily adopted by the clinician compared to calculated indices, such as AIx and pulse pressure amplification, but, on the other hand, they may be more prone to error since they rely on the (in)accuracy of the cuff measurement.[40] The development of 24-h measurement of central BP is appealing. It remains to be investigated whether the 24-h values have better predictive ability for future events and target organ damage than single measurements of central BPs or peripheral BPs[41] as already has been shown for 24-h ambulatory peripheral BPs compared to single office BPs. For a more extensive discussion of ambulatory measurement of central aortic pressures and pulsatile hemodynamics, the reader is referred to Chapter 8.

Correlation of central pressures and peripheral pressures: A crucial issue to be addressed is whether central indices have a predictive ability over and above peripheral pressures. This can be difficult since central pressures are usually derived by peripheral pressures, and their correlation is extremely high (correlation coefficient of approximately 0.9). Despite this strong correlation between them, it seems that when central pressures are measured properly,[39] they can be at least as good or even better than peripheral pressures. According to our meta-analysis, AIx has a predictive value independent of peripheral pressures, whereas central pulse pressure has a marginally better predictive value compared to peripheral BP ($P = .057$). This marginal but existent superiority of central BPs was supported by a recent large individual-data meta-analysis in 22,433 subjects from 15 studies,[42] where although the predictive ability for MI was similar for central and peripheral systolic BP, there was a statistically significant superiority of central BP compared to peripheral BP for the prediction of stroke, especially in subjects below 61 years. However, it must be acknowledged that so far there are no

published data of an improved reclassification with the use of central BP with the inclusion of peripheral BP in the model.

Study populations: The majority of the studies have been conducted in hypertensive subjects and patients with renal dysfunction. Further, as wave reflection indices have been strongly correlated with atherosclerosis and inflammation, studies on patients on high underlying risk have also been conducted. Finally, the pathophysiological close relationship of the central pressure waveform with heart failure makes it a very attractive biomarker both for the prediction of incident HF,[43,44] as well as for predicting events in patients with HF. Undoubtedly, there is room for further refinement since the degree of pressure amplification toward the periphery is variable, depending on several factors including age, gender, and heart rate. Further, an extension of predictive ability over and above brachial BP in a wider range of populations and disease states is mandatory. Lastly, it should be noted that evidence for a specific central pressure component or index does not necessarily apply to the others.

Cut-off: The publication of reference values has been a facilitation for the implementation of central BPs in clinical practice.[45] Unfortunately, studies have used different measurement techniques and cut-offs (when used) to identify subjects with increased central pressures. Guidelines have not adopted any single cut-off for central pressures, but it has been proposed by several studies that a value of 130/90 mmHg might be the ideal cut-off for prediction of events.[46]

Association with intermediate endpoints: In a recent meta-analysis, central BP was shown to be slightly, but consistently superior to the peripheral BP in predicting end-organ damage, such as carotid intima-media thickness, PWV and LV mass index, except for albuminuria.[47] Increased aortic AIx is associated with coronary artery disease.[48] In fact, in young patients with suspected coronary artery disease, increased wave reflections can discriminate patients with coronary artery disease from those without. The late systolic augmentation of the central pressure waveform is associated with an increase in LV mass index independent of age and mean BP,[49] and carotid systolic pressure is an independent determinant of LV wall thickness.[50] Moreover, central pressure is also more closely related to other important cardiovascular intermediate endpoints, such as vascular hypertrophy, the extent of carotid atherosclerosis.[51] Higher carotid pressure augmentation in older individuals has been linked to increased flow pulsations entering the cerebral circulation, which may increase the risk of cerebral microvascular damage.[52]

Central pressures as a therapeutic target: Despite similar effects on brachial pressure, antihypertensive drugs have differential effects on central pressure, and this may explain the superiority of arterial vasodilating drugs in

outcome trials. In the Conduit Artery Function Evaluation study, a substudy of the Anglo-Scandinavian Cardiac Outcomes Trial, a higher treatment-related decrease of central pulse pressure, that was not evident in brachial pressure measurements, was independently associated with clinical benefit and reduced cardiovascular events.[53] Other studies have also shown that endpoints related to organ damage can be predicted by indices of central hemodynamics after therapy. Aortic and radial AIx, as well as amplification of the pulse between central and radial arteries, were superior to conventional cuff measures in predicting a reduction in LV mass during antihypertensive therapy.[54] Furthermore, the reduction in carotid wall diameter and hypertrophy with antihypertensive treatment was related to carotid pulse pressure, but not to mean BP.[55] The pREterax in regression of Arterial Stiffness in a contrOlled double-bliNd (REASON) trial, which compared a perindopril/indapamide combination against atenolol, showed that normalization of brachial systolic BP is achieved with a significantly greater reduction of carotid systolic BP after a 12-month treatment with the combination.[56] In this study, compared with atenolol, the perindopril/indapamide combination was associated with a greater fall in LV mass, and this was related to carotid but not brachial BP.[57]

Whether central pressures can provide superior results compared to peripheral BP should they were the guide of therapy instead of the latter[2] awaits confirmation. In this direction, in two recent small studies in which central BP in hypertensives[58] and AIx in heart failure[59] were used as therapeutic targets there were modest but clinically apparent benefits for the patients. Specifically, in the first case measurement of central pressures led to decrease in the number of antihypertensive medications used, as well as to a marginal improvement in reduction of LV mass; in the second case, there was a slight improvement in exercise capacity.

Conclusions/future perspectives

Both cfPWV and central pressures have convincingly shown their ability to predict future cardiovascular events and could provide crucial prognostic information especially in younger individuals at intermediate risk and with borderline office or 24h BP values.[60] Measurement of cfPWV seems to be able to integrate the long-term deleterious effects of various cardiovascular risk factors[1] and principally of increased BP, overcoming the inherent shortcomings of BP detection that stem from its large variability even in 24 h readings. Also, cfPWV provides an easily accessible window toward the possible hypertension-related target organ damage. Contrary to central pressures that need to prove their worth beyond the closely to them correlated peripheral BPs, cfPWV has no other major competitors that can describe better the vascular damage caused by risk factors and aging.

However, the journey toward clinical implementation and larger adaptation from guidelines is still long and full of challenges. First, ongoing and future large randomized controlled studies need to confirm the clinical utility of cfPWV in decision-making by providing robust evidence of its ability to guide therapy and improve prognosis. Second, this should be done in a relatively simple and cost-effective manner so that the regulatory authorities will give the green light for its further clinical implementation by providing reimbursement for its measurement. Finally, what seems reasonable but still remains to be seen is that the experts in the field should provide a clear and collective proposal to the nonexperts on the field that would clearly state what physicians should measure and how in order to avoid confusion and alienation from the biomarker. It seems that such a coalition is feasible and based on the promising results on cfPWV the above-mentioned scenario seems to be closer than ever.

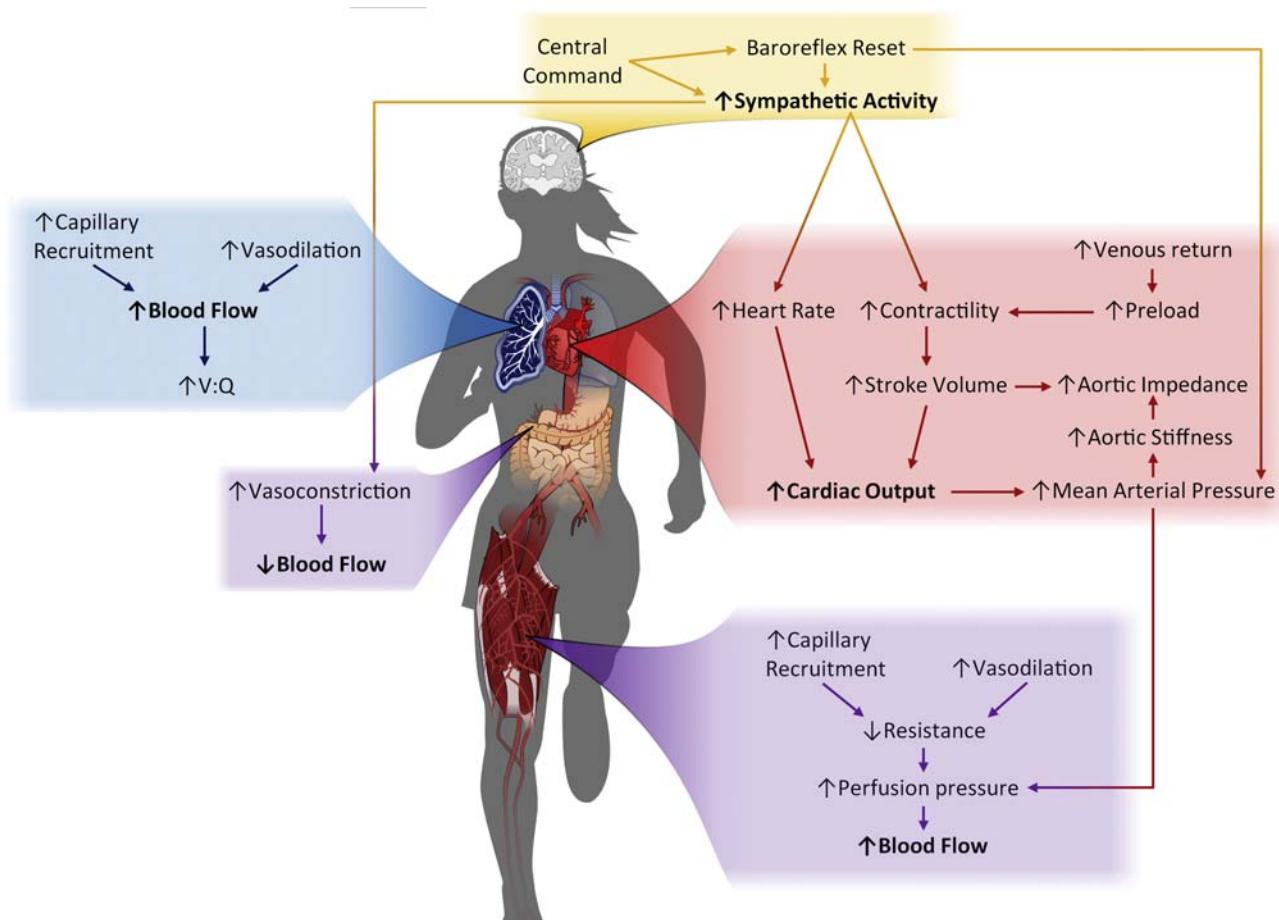
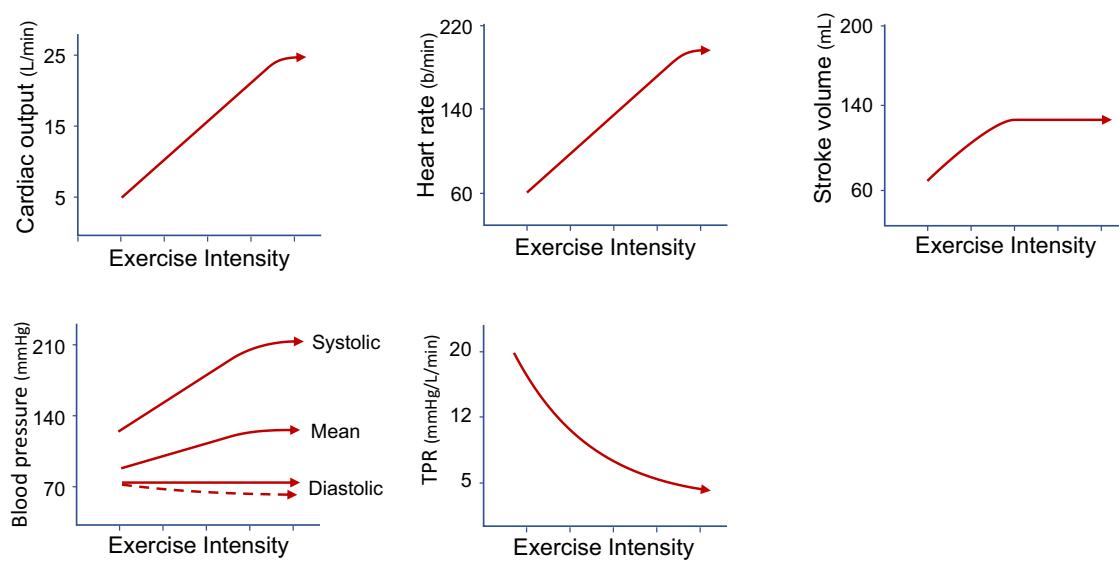
Aerobic exercise challenges the cardiovascular system to increase oxygen and nutrient delivery to the active skeletal muscle to meet their increase in energy requirements. To do so, a highly integrated response (depicted in Fig. 34.1) is elicited by the cardiovascular system to increase blood flow to specific tissues while also maintaining blood pressure. This chapter examines the intense demands of aerobic exercise and how the heart and pulmonary, central, and peripheral arteries work in concert to meet the dramatic increase in blood flow demand at the working skeletal muscle.

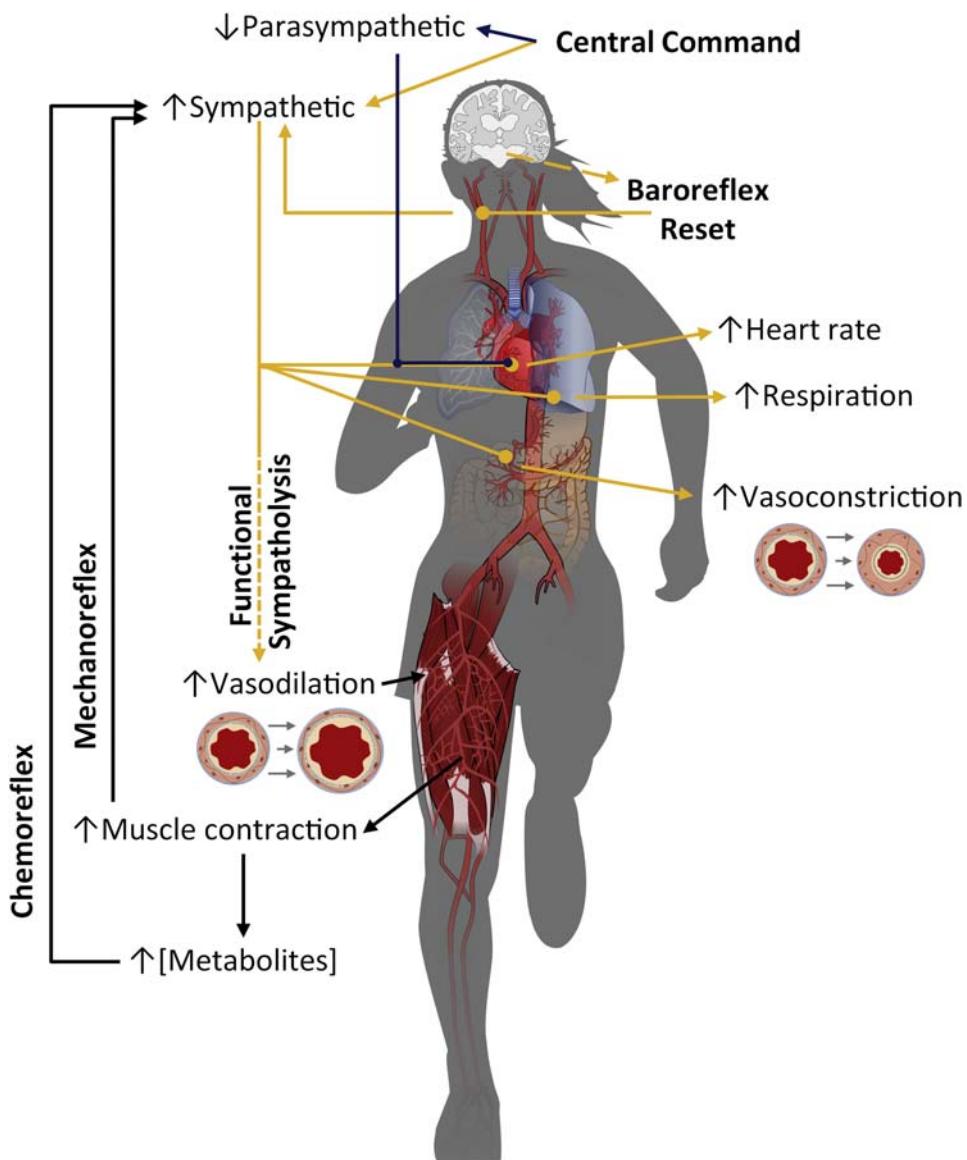
Cardiac output

Exercise is dependent on the ability of the heart to increase cardiac output and match the metabolic demands of the working tissue. Cardiac output increases five- to eightfold from rest to heavy exercise depending on exercise training status (Fig. 34.2). The magnitude of increase in cardiac output during exercise matches exercise intensity, as increased oxygen demand is met with increased blood flow. The ability to increase cardiac output is dependent on (1) compensatory increases in heart rate, (2) increases in stroke volume, and (3) a prioritizing of left ventricular (LV) work to overcome the load presented by the vasculature (described by ventricular-vascular coupling).


Heart rate response during exercise

Heart rate increases linearly during exercise in an intensity-dependent manner and eventually plateaus at maximal exercise intensity (Fig. 34.2). Heart rate is critical to exercise-induced increases in cardiac output, particularly during moderate-to-high intensity exercise. Increases in heart rate during exercise occur via redundant direct and indirect (i.e., reflex-driven) pathways resulting in greater sympathetic nerve activity (neural) and catecholamine release (hormonal).


Initial increases in heart rate with exercise occur due to withdrawal of parasympathetic outflow to the heart and subsequent increases in sympathetic activation (Fig. 34.3). When the motor cortex in the brain elicits the contraction of peripheral skeletal muscles, a simultaneous coordinated response is initiated from the cardiovascular control center in the medulla. This coordinated response is known as central command and is responsible for initial increases in heart rate via parasympathetic withdrawal and sympathetic activation.[1–3] Central command is a feedforward mechanism that increases activation based on perceived effort and can be independent of actual muscle activation and force production.[4,5]

The exercise pressor reflex is an important peripheral feedback mechanism contributing to the increase in heart rate during exercise. The exercise pressor reflex involves both the mechanoreflex and chemoreflex from the periphery (Fig. 34.3). Muscle contraction elicits mechanical (muscle length and tension) and chemical stimuli (metabolic by-products) that activate the mechanoreflex and chemoreflex, respectively.[6,7] While the mechanoreflex is immediately activated by muscle contraction, the chemoreflex is delayed due to the time required for metabolites to accumulate. The mechano- and chemoreflex activate group III (thinly myelinated) and group IV (unmyelinated) afferent nerve fibers within the skeletal muscle and increase neural discharge frequency to the central nervous system. In response, the central nervous system increases sympathetic nerve activity, which increases heart rate.[6,8,9] The exercise pressor reflex remains active throughout exercise, providing continuous feedback to the cardiovascular control center and modulation of autonomic activity.[10,11]


Heart rate additionally increases during exercise via the direct effects of catecholamines and the Bainbridge reflex (also known as atrial reflex). Catecholamines (epinephrine and norepinephrine) released from the adrenal medulla (and

FIGURE 34.3 Overview of autonomic nervous system adjustments during aerobic exercise and its role in blood flow redistribution.

from synaptic spillover for norepinephrine) assist the neural input to the heart to increase heart rate during exercise, particularly at moderate and high intensities. The impact of catecholamines on heart rate is dependent on β-adrenergic receptor sensitivity.[12] Downregulation or desensitization of β-adrenergic receptors (as occurs in aging and disease) blunts the typical heart rate response during exercise.[12,13] The Bainbridge reflex may also support increases in heart rate during exercise. This reflex is triggered by stretch receptors in the atria that detect increases in venous pressure (as would occur with an increase in venous return during exercise, discussed further below), and results in sympathetic-driven increases in heart rate. Together, central command, the exercise pressor reflex, catecholamine release, and the Bainbridge reflex act in concert to elevate heart rate during

exercise, thereby supporting increases in cardiac output necessary to match blood flow requirements in the active tissue.

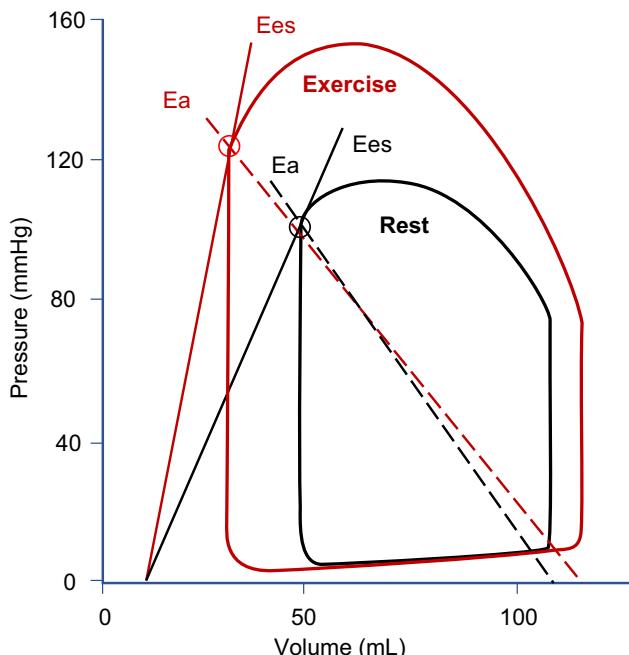
Stroke volume response during exercise

The amount of blood ejected per heart beat (stroke volume) may increase 2-fold from rest to moderate exercise (Fig. 34.2).[14] Stroke volume increases until light to moderate (40%−50% VO_2 max) intensity after which it plateaus.[15] The stroke volume response during aerobic exercise is the result of synergistic changes in preload, contractility (inotropy), afterload, and ventricular filling time.

During upright exercise, the volume of blood available for ventricular filling (i.e., preload) increases owing to

synergistic changes in venous return, atrial contraction, and ventricular relaxation. Venous return increases during exercise as blood is mobilized through the venous network by the skeletal muscle pump, abdominothoracic pump, and sympathetic-mediated arterial and venous vasoconstriction.[16–20] The vasoconstriction imposed in the splanchnic (liver, gastrointestinal tract, pancreas, and spleen) and renal circulation reallocates a large volume of blood as exercise intensity increases, with these regions receiving ∼25% of cardiac output at rest and only ∼3% of cardiac output during maximal exercise.[21] Increases in end-diastolic volume during the initial stage of upright exercise are further supported by increased contractility of the atria, forcing a larger volume of blood from the atria into the ventricle in late diastole.[22] Additionally, diastolic relaxation of the ventricle (lusitropic function) is improved during exercise with the rapid untwisting of the ventricle.[23–25] The rapid untwisting of the ventricle decreases ventricular pressure quickly and increases the filling pressure gradient, creating a "suction-like" force that enhances ventricular filling and aids in maintenance of stroke volume as heart rate increases (discussed further below).

Increases in end-diastolic volume during early stages of upright exercise stretch the myocardium and result in a more forceful ventricular contraction, following the Frank Starling relationship.[26] This end-diastolic volume-driven increase in contractility is further augmented by increased sympathetic activity to the myocardium. Contractility additionally increases owing to the Bowditch effect, whereby increases in heart rate alter calcium handling within myocardial muscle fibers, enhancing actin–myosin interaction and thus, contractility.[27] Greater ventricular contractility reduces the volume of blood remaining at end systole (i.e., end-systolic volume). Ultimately, these complementary mechanisms enhance the contractile function of the heart during exercise and play a role in both increasing stroke volume and maintaining stroke volume at high heart rates.[28]

The ability of the ventricles to eject blood (i.e. increase stroke volume) is dependent on the amount of pressure they must generate to overcome the pressure in the main arteries (pulmonary trunk for the right ventricle and aorta for the left ventricle). As described in more detail below, in spite of the increased cardiac output during exercise, aerobic exercise only produces a modest increase in mean arterial pressure, owing to arteriolar vasodilation in exercising muscle, which normally reduces total peripheral resistance (despite vasoconstriction elsewhere), thus preventing substantial exercise-induced increases in afterload. The impact of afterload on the heart during exercise is described in more detail in the next section. Even modest increases in afterload can be compensated for by via cardiac inotropy and the Anrep effect,[29–31] whereby an acute increase in afterload enhances ventricular contractility. Taken together,


the net increase in preload and contractility, and reduced afterload during exercise ensure increases in stroke volume as part of a concerted approach to augment cardiac output at lower exercise intensities.

Initial increases in stroke volume slow and plateau at moderate to vigorous exercise intensities. This plateau in stroke volume is related to the reduced diastolic duration from the increase in heart rate with increasing exercise intensity. The faster heart rate, and thus shorter diastolic duration, reduces ventricular filling time and causes end-diastolic volume to plateau or slightly decrease as exercise intensity increases.[15] As such, initial, synergistic changes in preload, contractility, and afterload that serve to increase stroke volume become somewhat limited at moderate to higher intensity exercise by heart rate–mediated reductions in filling time, thereby preventing further increases in stroke volume.

Ventricular-vascular coupling

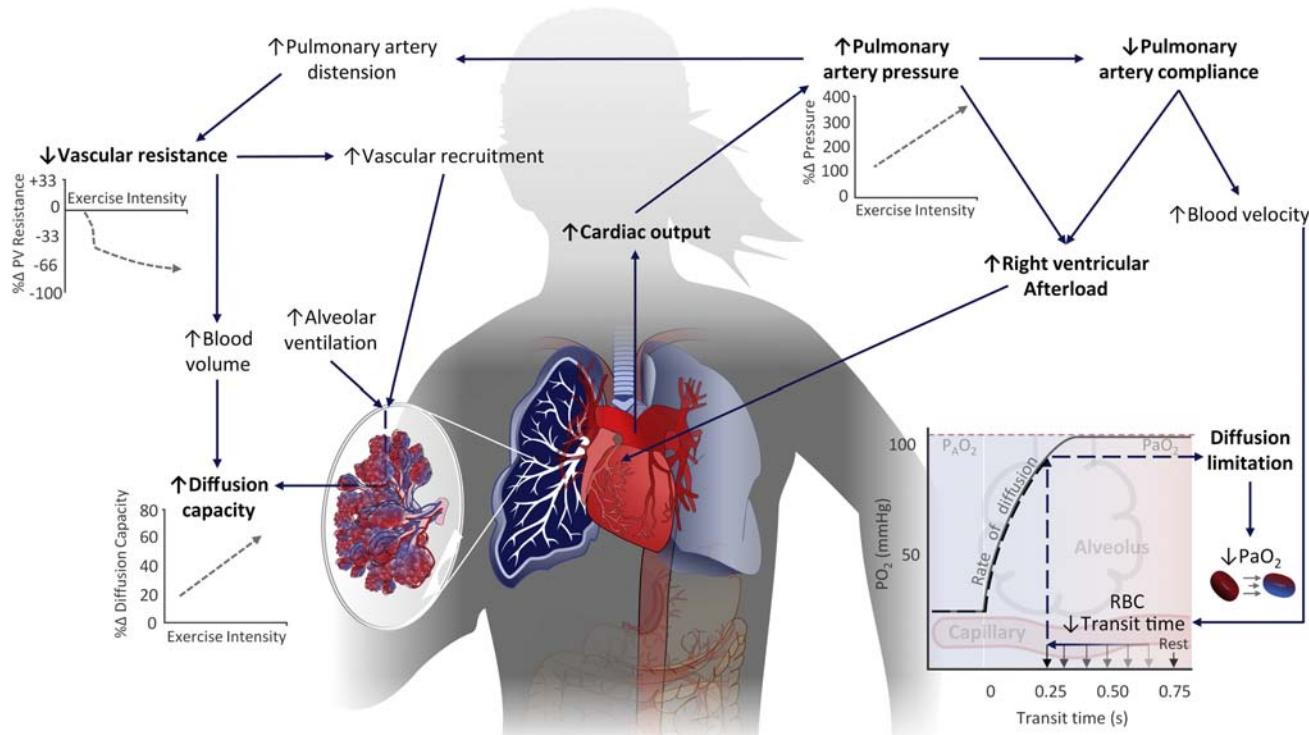
The ability of the cardiovascular system to match the demands of exercise depend on the left ventricle overcoming the load imposed by the arterial system to increase cardiac output. This dynamic interaction between the left ventricle and the arterial system is known as ventricular-vascular coupling[32] (explored more in-depth in Chapters 13–17). Ventricular-vascular coupling is traditionally measured by representing the heart and the arterial system as coupled elastances. In this setting, elastance is defined by the change in pressure for a given change in volume,[33] as illustrated for the ventricle with pressure volume loops acquired at different preloads (Fig. 34.4). The slope of the change in end-systolic pressure to end-systolic volume is a measure of contractility and represents ventricular elastance (Ees). The negative slope between end-systolic pressure and end-diastolic volume is arterial elastance (Ea), meant to represent total arterial load imposed on the ventricle. The ratio of arterial elastance to ventricular elastance (Ea/Ees) has been used to quantify ventricular-vascular coupling and provides a measurement of the interaction between the cardiac and arterial system.[2] This method of coupling assessment has inherent limitations (as discussed in detail in Chapter 15), but to date has been the most widely used method used to assess ventricular-vascular coupling during exercise.

Optimal ventricular-vascular coupling at rest results in a balanced cardiovascular system such that the system provides optimal transfer of blood without excessive changes in pressure. Thus, under resting conditions, the cardiovascular system is an efficient or coupled system that prioritizes energetic efficiency over cardiac work.[34] During exercise, however, the interaction between the ventricle and vasculature becomes uncoupled as energetic efficiency is sacrificed to favor greater cardiac work.[35,36] Indeed, cardiac

FIGURE 34.4 Theoretical changes in left ventricular pressure-volume relations at rest and during aerobic exercise. *Ea*, arterial elastance; *Ees*, ventricular elastance.

work (partially signified by stroke work, the area within the pressure-volume loop) increases during exercise owing to increased contractility (ejection fraction) and thus, stroke volume. The widening of the pressure-volume loop (i.e., increase in stroke volume) during exercise also demonstrates the changes in both ventricular and arterial elastance. Contractility and stroke volume increase during exercise, thereby reducing end systolic volume and increasing end systolic pressure. As such, both ventricular (end systolic pressure/end systolic volume) and arterial elastance (end systolic pressure/stroke volume) increase during exercise; but ventricular elastance increases to a greater degree to overcome arterial load, thus supporting increases in cardiac output. These changes subsequently impact the Ea/Ees coupling ratio.[35–38] The increase in ventricular elastance has led to both reductions[35,36] and maintenance of the Ea/Ees ratio during exercise,[37,38] depending on the simultaneous magnitude of change in Ea. Reductions in the Ea/Ees ratio (increases in efficiency of the heart during exercise) are blunted with age, suggesting an inability to attain maximal stroke work[36] among older individuals. The traditional elastance model of ventricular-vascular coupling is not without its limitations.[39] True arterial load is best characterized using pressure-flow relationships or aortic input impedance. While this method is not often used during exercise, optimal coupling would theoretically occur when greatest ejection (highest flow) occurs at frequencies where impedance is lowest. Increased heart rate during

exercise shifts the first harmonic of flow to a frequency where impedance modulus is lowest.[40,41] Exercise-induced increases in heart rate optimally couple the heart and arterial systems by aligning the greatest ejection with the lowest aortic impedance, thereby improving ventricular performance. Ultimately, redundant mechanisms increase heart rate and stroke volume during exercise which shifts the balance between ventricular performance and vascular load to prioritize increases in cardiac output into the pulmonary and central vasculature for oxygenation and distribution to the active tissue.

Exercise hemodynamics


Increases in cardiac output must be balanced between the left and right sides of the heart during exercise. This co-ordinated effort ensures adequate oxygenation of pulmonary arterial blood and subsequent transportation to specific active regions of the body. Thus, while the pulmonary circulation and vasculature differ considerably from the systemic circulation both anatomically and physiologically, they must respond in concert to adequately support efficient oxygenation of arterial blood and oxygen delivery to exercising muscle.

Pulmonary hemodynamics during exercise

The pulmonary circulation is designed as a low-pressure system, reflected in the anatomical design of both the right heart and the vasculature. Considering the pressure in the pulmonary circulation is about 1/20th of that on the systemic side, it is not surprising that both the right ventricle and the pulmonary vasculature are thin walled and highly compliant at rest. The pulmonary circulatory system is not as adaptive as the systemic circulation to accommodate the high levels of blood flow observed during intense and/or prolonged exercise; however, it serves a vital function to increase oxygenation of deoxygenated blood for transport to peripheral tissues. The discussion below will highlight the effect of aerobic exercise on the hemodynamics of pulmonary circulatory function as depicted in Fig. 34.5.

Pulmonary arterial pressure and resistance during exercise

Mean pulmonary artery pressure (PAP) increases from rest to high-intensity exercise (Fig. 34.5).[42–47] PAP can approach over 40 mmHg in young healthy adults but may increase to ∼46 mmHg among older (>50 years) adults.[46] PAP may be even greater during exercise among highly trained individuals, owing to the relationship between

FIGURE 34.5 Overview of pulmonary vascular hemodynamic adjustments during aerobic exercise in response to an increase in cardiac output. cardiac output and PAP (discussed below).[43] Increases in PAP during exercise reflect adjustments in its constituents: cardiac output, pulmonary vascular resistance, and left atrial pressure, where:

$$PAP = (cardiac\ output \times pulmonary\ vascular\ resistance) + left\ atrial\ pressure.$$

Ultimately, substantial changes in cardiac output, coupled with increases in left atrial pressure, offset modest reductions in pulmonary vascular resistance, thus increasing PAP during exercise.

Increases in cardiac output appear linearly related to changes in PAP during exercise.[42−47] Moreover, PAP does not change between workloads when cardiac output is not altered.[48,49] Theoretically, the relationship between PAP and cardiac output may be curvilinear due to the low distensibility of the pulmonary arteries, since the relationship between pressure and distension is nonlinear.[50] The distensibility of the pulmonary vasculature, however, is limited and may explain why most studies have found a linear relationship between PAP and cardiac output.[42−47] Increases in PAP during exercise are also related to left atrial pressure. Left atrial pressure (assessed as pulmonary

artery wedge pressure) increases in a linear manner with cardiac output during incremental exercise.[43,46] Thus, increases in cardiac output and left atrial pressure contribute to increased PAP during exercise.

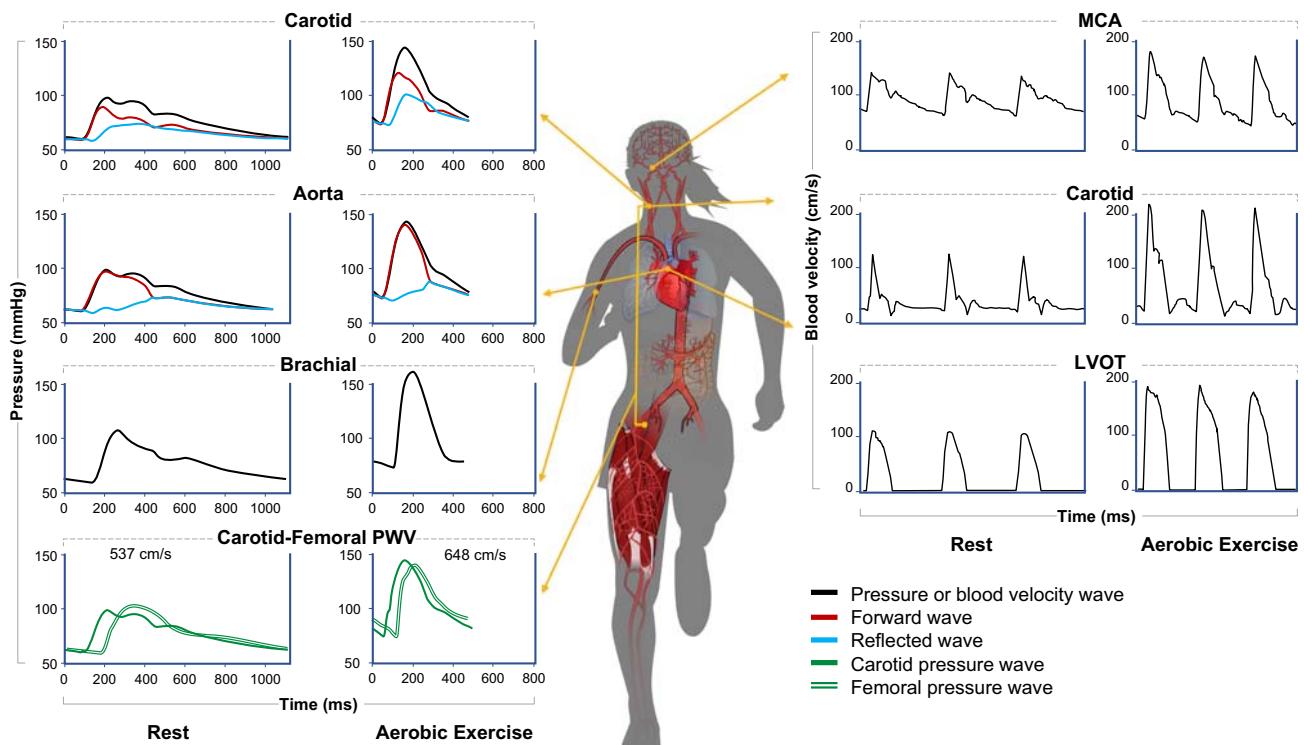
Vascular resistance decreases rapidly with initiation of exercise in the pulmonary circulation, similar to responses observed in the systemic circulation. The rapid fall in pulmonary vascular resistance, however, seemingly plateaus at cardiac outputs ∼7−10 L/min, with only a small additional reduction or no change until maximal exercise.[43,44] This plateau in pulmonary vascular resistance (approximately −Δ66%) at a low cardiac output is considerably different from the consistent, large reductions in resistance within the systemic circulation (approximately −Δ300%) with increasing exercise intensity. The limited reduction in pulmonary vascular resistance compared to the systemic circulation is likely related to the relatively "fixed" size of the pulmonary vascular system and its limited ability to vasodilate. The initial fall in pulmonary vascular resistance is thus attributed to pulmonary vascular recruitment coupled with distention of the pulmonary resistance vessels in response to increased blood flow.[43,51] Following the initial reductions in pulmonary vascular

resistance, pulmonary vessel recruitment is usually maximized and the slow gradual decline in vascular resistance is a function of the limited (1%−2%) distensibility of the pulmonary arterial bed (discussed further below)[43,51,52] Taken together, increases in PAP during exercise partially reflects increases in cardiac output and left atrial pressure, but is also driven by the limited vasodilatory reserve and vessel distensibility that attenuates reductions in pulmonary vascular resistance during exercise.

Pulmonary blood volume expansion, diffusion capacity, and pulmonary artery distensibility during exercise

Increases in cardiac output and PAP during exercise doubles the pulmonary arterial blood volume in an approximately linear manner from rest to maximal exercise. Theoretically, the blood volume expansion during exercise enhances ventilation—perfusion coupling when matched with sympathetic-mediated increases in minute ventilation and downstream alveolar ventilation.[43,53] This is accompanied by a linear increase in lung diffusing capacity and alveolar-capillary membrane conductance from rest to maximal exercise. Interestingly, aging reduces both lung diffusing capacity and alveolar-capillary membrane conductance but does not alter the rate of increase during exercise compared to young individuals.[53] Ultimately, while increasing pulmonary arterial blood volume is necessary and beneficial during exercise, this expansion of blood volume reveals structural limitations within the pulmonary vasculature that can influence exercise hemodynamics.

Increases in blood volume in the pulmonary circulation during exercise are primarily accommodated via distention of the arterial wall. The distension of the pulmonary vasculature reduces pulmonary arterial distensibility and compliance,[48,54] and increases pulmonary arterial stiffness during exercise (Fig. 34.5).[55] This blood volume—mediated shift in compliance and stiffness increases with exercising intensity and likely indicates a "mechanical constraint" of the pulmonary arterial bed to increased blood flow, and this constraint contributes to the increase in pressure with increased cardiac output during exercise. This "stiffening" of the pulmonary arterial bed during acute exercise may contribute to increased right ventricular afterload and reduced stroke volume in older populations.[48] However, the stiffening of the arterial bed may also contribute to an increase in flow velocity, especially in highly trained individuals who exhibit very high cardiac output which can decrease red blood cell transit time in highly trained individuals.

Limitations in both pulmonary arterial wall distensibility and vasodilation during substantial increases in cardiac output and increased pressure (e.g., highly trained


individuals during exercise) increases blood velocity through the pulmonary vasculature.[43,56] The accelerated speed of red blood cells through the pulmonary circulation reduces red blood cell transit time at the level of the capillary-alveolus interface.[43,56] Although red blood cell transit time may only decrease by ∼25% from rest to a maximal cardiac output of 20 L/min for a normal healthy sedentary or moderately active person, the reduction in transit time at a cardiac output of 30 L/min for a highly trained endurance athlete would be ∼50%.[43] This substantial decrease in capillary transit time at high cardiac outputs/blood velocities can lead to diffusion limitation, whereby oxygen does not have sufficient time to fully diffuse and equilibrate during the transient interaction between alveolus and red blood cell.[43,56] The "incomplete loading" of oxygen from the alveolus to the red blood cells results in a widening of the alveolar-arterial oxygen difference and arterial hypoxemia. As such, oxygen desaturation to levels of 85%−90% is not uncommon among highly trained endurance athletes.[57,58] Ultimately, while the PAP-driven expansion of blood volume in the pulmonary circulation during exercise is necessary to increase oxygenation of arterial blood, it pushes the limits of the pulmonary artery structure and function and may present challenges under certain exercise conditions.

Central hemodynamics during exercise

The central vasculature serves as a highway during exercise, facilitating transportation of oxygenated blood from the heart downstream to the peripheral vasculature where blood flow is directed to metabolically active tissue. Exercise-induced changes in cardiac output and peripheral redistribution of blood flow result in an expansion of pulse pressure and modest increase in mean pressure. This section will discuss the hemodynamic mechanisms driving central blood pressure and blood pressure amplification during exercise and their effects on hemodynamic pulsatility, arterial stiffness, and characteristic impedance, as depicted in Fig. 34.6.

Mean arterial pressure

Mean arterial pressure in the systemic circulation must increase during exercise in order to establish an adequate pressure gradient to drive adequate blood flow to active tissue (Fig. 34.2). This occurs through offsetting changes in systolic and diastolic pressure. Increases in systolic blood pressure during exercise are driven by increased stroke volume. The concomitant increase in mean arterial pressure during aerobic exercise is relatively modest. Cardiac-driven increases in systolic pressure are accompanied by peripheral vasodilation and reductions in total peripheral resistance (thereby maintaining or decreasing diastolic blood

FIGURE 34.6 Example central blood pressure, pulse wave dynamics, and blood velocity responses during moderate intensity aerobic exercise (60% heart rate reserve; heart rate ∼135 b/min, semirecumbent cycle ergometer) in a 30-year-old female. *LVOT*, left ventricular outflow tract; *MCA*, middle cerebral artery; *PWV*, pulse wave velocity.

pressure). The blood pressure response to exercise is highly variable and dependent on underlying cardiovascular disease, fitness, sex, age, and exercise intensity.[59,60] On average, peak systolic blood pressure during exercise ranges from ∼165 mmHg in young adults to ∼190 mmHg in older adults,[59] with exaggerated blood pressure responses linked to underlying cardiovascular disease.[60] Increases in systolic pressure >200 mmHg during maximal exercise among aerobically trained individuals may not be pathological in nature but solely reflect very high cardiac output and stroke volume.[61] The regulation of the blood pressure response to exercise is highly dependent on the exercise pressor reflex (discussed previously in the context of heart rate), arterial baroreflex, and compensatory autonomic control during exercise (Fig. 34.3).

Carotid and aortic baroreceptors are responsive to stretch and operate under a negative feedback loop to intricately control beat-by-beat arterial pressure. At rest, distension of the arterial wall from high pressure stretches the baroreceptors and initiates afferent nerve discharge. These afferent signals trigger subsequent efferent signals from the brainstem, increasing parasympathetic outflow and reducing sympathetic outflow, leading to reductions in heart rate and total peripheral resistance, ultimately decreasing blood pressure back to its original set point value. During exercise, the arterial baroreflex maintains its

role in regulating blood pressure but is reset by central command to operate around a higher exercise-induced blood pressure.[62-66] The upward and rightward resetting of the baroreflex occurs in an intensity-dependent manner from rest to heavy exercise and adjusts to greater sensitivity toward preventing excessive increases in blood pressure during exercise.[66-68] Interestingly, the regulation of arterial pressure is highly dependent on alterations in vascular tone and subsequent changes in total peripheral resistance. At rest, ∼25% of baroreflex-mediated changes in arterial pressure are achieved through changes in cardiac output. With increasing exercise intensity, however, baroreflex control of arterial pressure becomes almost entirely reliant on changes in total peripheral resistance.[69,70] Ultimately, baroreflex-mediated regulation of cardiac output and peripheral resistance contribute to changes in pulse wave dynamics in the central vasculature during exercise.

Central pressure and pulse wave dynamics

Left ventricular contraction generates a forward traveling compression wave, which increases central systolic pressure and drives flow. Exercise-induced increases in contractility increase the magnitude of the forward traveling compression wave generated by the left ventricle (Fig. 34.6).[71] This increase in forward wave energy appears to largely explain

exercise-induced increases in central systolic pressure, rather than increases in wave reflection.[71] The amount of wave reflection, relative to the forward wave (i.e., wave reflection magnitude) appears maintained during aerobic exercise,[71] despite substantial peripheral vasodilation. Our recent unpublished observations indicate reductions in wave reflection magnitude at the aorta during aerobic exercise (see representative data in Fig. 34.6, aortic reflection magnitude rest 32%, during exercise 18%). Emerging data appear to concur with this observation, suggesting reflection magnitude decreases among young, healthy adults despite increased forward wave magnitude and shortened reflected wave transit time.[72] Although reductions in wave reflection magnitude may relate to peripheral dilation of vasculature at the working muscle, the integrated wave reflection response during exercise is undoubtedly complicated by concomitant vasoconstriction at nonexercising tissue, large artery stiffening, constructive interference between upper and lower body wave reflections, and poor retrograde transmission of reflected pulse waves (i.e., reflected wave entrapment/dissipation).[73,74] As such, changes in aortic wave reflections during exercise remain an active area of investigation, and the mechanisms governing changes in wave reflection during exercise may differ by population, exercise modality, and intensity.

The contribution of pulse wave reflection to central systolic pressure (i.e., augmentation pressure/index) generally decreases during aerobic exercise.[75−78] It should be highlighted that augmentation index is a relatively poor index of wave reflection, thus reductions in augmentation index during exercise may reflect changes in heart rate and pattern of ventricular ejection rather than wave reflection per se.[77] Reductions in augmentation index during exercise appear attenuated with age, with older adults exhibiting increases in augmentation pressure and left ventricle wasted-pressure effort, and attenuated reductions in augmentation index during aerobic exercise.[75] As such, pulse wave reflection may contribute to increases in central systolic pressure during exercise when combined with age-related aortic stiffening and impaired functional sympatholysis that may alter the speed and magnitude of pulse wave reflection, respectively.[75] Ultimately, changes in cardiac chronotropy and central vascular pulse wave dynamics act to maximize flow output and transmission of forward-traveling pulse waves during exercise while minimizing wave reflection contributions to central systolic blood pressure. These mechanisms governing central blood pressure during aerobic exercise have further effects on the degree of blood pressure amplification traveling from the central to peripheral vasculature.

Pulse pressure amplification

The blood pressure waveform is distorted as it travels from the central to peripheral vasculature within the nonuniform viscoelastic arterial system.[79] This "distortion" manifests as an amplification of the blood pressure waveform, or an amplification of pulse pressure, while traveling distally, downstream.[74,79] Pulse pressure amplification occurs primarily owing to an increase in systolic blood pressure, with minimal changes in diastolic and mean pressure.[79] Data indicate that peripheral pulse pressure increases to a greater degree than central pulse pressure (i.e., greater pulse pressure amplification) during aerobic exercise,[75−78,80,81] although this is not universal.[82,83] Pulse pressure amplification increases during low-intensity exercise (i.e., 45% age-estimated maximal heart rate) and does not increase further during moderate- (50%−60% age-estimated maximal heart rate) or higher-intensity exercise (70% −80% age-estimated maximal heart rate).[75,77,84] These increases in pulse pressure amplification during exercise likely stem from changes in heart rate, reducing the potential contribution of wave reflection to central systolic pressure.[77]

Increases in pulse pressure amplification during aerobic exercise may be attenuated in older adults compared to young and middle-aged adults[75]; however, this is not universal[80] and may depend on presence of cardiovascular disease risk factors.[78] The degree of pulse pressure amplification during exercise also appears dependent on where peripheral blood pressure is assessed (i.e., at nonworking vs. active musculature). Pulse pressure amplification during exercise increases to inactive musculature (i.e., brachial artery during lower-body exercise),[85] while amplification at the level of working muscle may be attenuated[82] owing to local vasodilatory control in the working limb. Indeed, increases in pulse pressure amplification are attenuated when local vasodilator stimuli (e.g., heat, reactive hyperemia) are applied on top of an exercise stimulus.[81,86] While central pulse wave dynamics appear to minimize pulse pressure expansion in the central compared to peripheral vasculature, increases in pulse pressure ultimately relate to the manner in which blood flow is transmitted downstream.

Blood flow pulsatility

Blood flow in the arterial tree is inherently pulsatile (i.e., discontinuous) with greater blood velocity/flow occurring during systole than diastole. Blood flow pulsatility is linked with pulsatile pressure (i.e., pulse pressure) and forward pulse wave energy. As such, exercise-induced increases in pulse pressure and forward pulse wave energy are accompanied by concomitant increases in the degree of blood velocity pulsatility during aerobic exercise.[87−90] This has primarily been examined within the cerebral vasculature owing to growing links between hemodynamic pulsatility and brain health[91] and the implications of exercise on the brain.[92,93] Both extracranial (common carotid artery)[89] and intracranial (middle/anterior cerebral artery)[87,88,90] blood velocity pulsatility increase during aerobic exercise (Fig. 34.6). The mechanism governing the increase in cerebrovascular pulsatile blood flow may be multifactorial in

nature. Increased cerebral blood flow pulsatility during exercise could relate to downstream vasoconstriction via sympathetic activation and catecholamine release;[88] however, it remains plausible that local cerebral metabolic activity constrains sympathetic-mediated vasoconstriction (i.e., sympatholysis) within the cerebral vasculature.[94] Increases in pulse pressure and its effect on cerebral blood velocity may be a more likely explanation of exercise-induced increases in cerebral blood flow pulsatility.[90,95] Indeed, diastolic cerebral blood flow may decrease during exercise because of an inability of dynamic cerebral autoregulation to buffer the rapid decrease in pressure that occurs in diastole.[90] These reductions in diastolic velocity, concomitant with increases in systolic velocity[87] and forward pulse wave energy, likely explain increases in cerebral blood velocity pulsatility during exercise. Chronic exposure to pulsatile blood flow is linked with damage to sensitive vascular beds, such as the brain and kidney,[96] although causal data remain elusive. Importantly, there is no evidence that transient increases in pulsatility associated with exercise increases risk of accumulating such damage; rather, participation in exercise training is likely protective for organs like the brain.[92,93,97]

Large artery stiffness and characteristic impedance

Acute aerobic exercise increases the stiffness of the large elastic arteries (i.e., aorta, carotid; Fig. 34.6). Much of the literature to date has focused on the aorta, documenting significant increases in both proxy estimates (e.g., time to reflection)[71,76,77] and direct measures (e.g., pulse wave velocity) of aortic stiffness.[82,98−100] Aortic stiffness appears to increase during low and moderate-intensity aerobic exercise by roughly 1.0−1.5 m/s on average across studies. Similar observations have been made at the carotid artery, with reduced distensibility (i.e., increased stiffness) during aerobic exercise.[101] The exact hemodynamic mechanisms driving acute increases in large artery stiffness during exercise are likely multifaceted, and may include:

(A) Increases in mean and pulse pressure in the central vasculature, which would shift the pressure load burden within the artery wall from elastin to collagen,[102,103] functionally stiffening the vessel during exercise.[100] In support of this, reductions in aortic time to pulse wave reflection (Tr; a proxy of aortic stiffness) is associated with increases in mean pressure during aerobic exercise.[77]

(B) Increases in heart rate during exercise would shorten diastole and alter the time available for mechanical recoil of the artery wall.[104] The rate of diameter change lags behind reductions in pressure during diastole owing to vascular hysteresis and the nonlinear pressure-diameter relationship in the viscoelastic large arteries.[40,105] The magnitude of this delay appears dependent on the amplitude of stretch (imposed by pulse pressure).[105] As such, the shortened diastole imposed by exercise-induced elevations in heart rate likely prevents complete recoil of the aorta walls, thereby stiffening the vessel.

(C) Increases in sympathetic activity during exercise may directly modulate aortic stiffness,[106,107] although this is still debated.[108]

Ultimately, increases in large artery stiffness during exercise may alter large artery characteristic impedance. Changes in large artery characteristic impedance during aerobic exercise are still somewhat unclear. Early work suggested aortic characteristic impedance was maintained during aerobic exercise, despite increases in aortic stiffness.[100] Maintenance of characteristic impedance in this setting would require a roughly 10% increase in aortic diameter to offset the effect of increased aortic stiffness during exercise.[100] Work in canine models indicates that while aortic characteristic impedance is maintained during exercise in young animals, it increases during exercise in aged animals and impacts left ventricle performance.[109] Increases in distension pressure during exercise would tend to increase aortic diameter[109] while also stiffening the aorta owing to the preferential loading of collagen within the wall. Age-related dilation of the aorta[110] may limit further increases in diameter with exercise-mediated increases in distension pressure, thereby contributing to increased characteristic impedance during exercise with aging. Additional work is necessary to fully elucidate how aortic stiffness, diameter, and characteristic impedance respond during exercise, particularly since current data do not suggest aortic diameter increases during exercise. Indeed, imaging data obtained via MRI during exercise that report reductions, rather than increases, in ascending and proximal descending aorta cross-sectional area during exercise.[98] Cumulatively, changes in aortic stiffness, aortic characteristic impedance and pulsatile hemodynamics appear to largely be a consequence of cardiac adjustments to exercise. Taken together, the central hemodynamic response during exercise reflects complementary changes within the heart and peripheral vasculature that act to minimize arterial contributions to the already augmented workload of the left ventricle during exercise, supporting increases in blood flow for redistribution to working tissue.

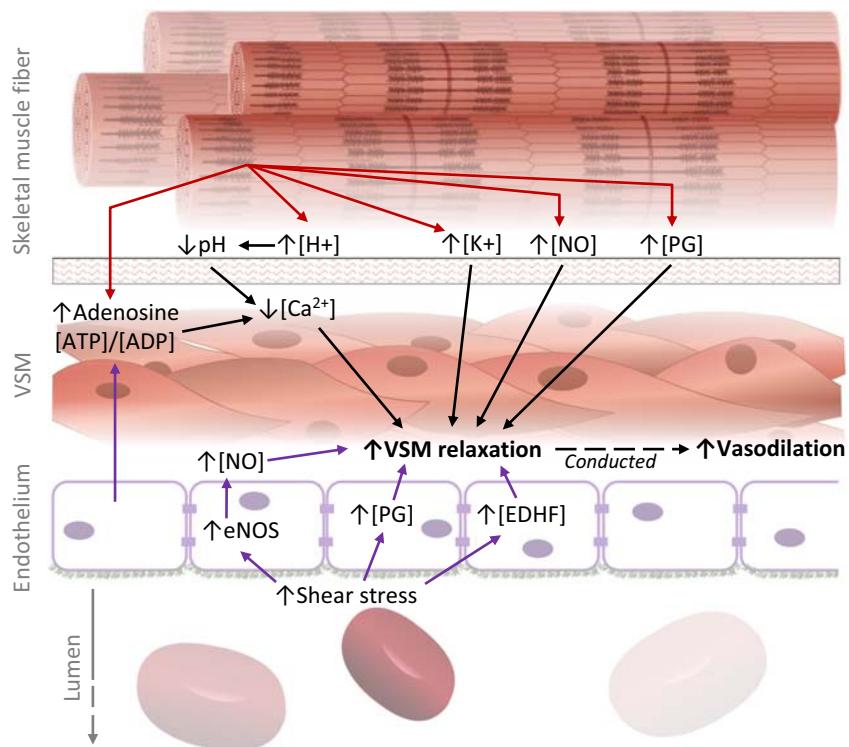
Blood flow redistribution

Increasing blood flow to meet the metabolic demand of working cardiac and skeletal muscle is one of the major challenges faced by the cardiovascular system during exercise. Increased blood flow delivers necessary oxygen and nutrients to active tissues, removes metabolic by-products, and is proportional to the oxygen requirement by the active tissue.[111,112] Cardiac output increases dramatically with exercise and blood flow is preferentially redistributed away

from inactive tissue to highly active tissue. One major contributor to the redistribution is the highly malleable splanchnic and renal vasculature. Splanchnic and renal blood flow is dramatically reduced to ~25% of resting values during high intensity exercise and is compensated by a large increase in oxygen extraction.[21,113,114] Subsequent redistribution of the splanchnic/renal blood volume results in large increases in absolute blood flow in the coronary vasculature and active muscle beds, with ~85% of cardiac output directed to the active muscle during peak exercise.[21,113] This redistribution of blood flow away from less active tissue during exercise facilitates a dramatic and critical increase in blood flow to active skeletal muscle and tissue. The redistribution of blood flow that ultimately supports metabolic processes and muscular work necessary for exercise is largely dependent on the reciprocal actions of systemic sympathetic activation and local regulation of blood flow.

Total peripheral resistance and functional sympatholysis

Blood flow is inversely related to total peripheral resistance. During exercise, the cardiovascular control center increases sympathetic nerve activity which serves to increase total peripheral resistance (Fig. 34.3). The increased sympathetic activity, however, does not have a systemic effect. Sympathetic activity causes vasoconstriction in inactive tissue; however, in active skeletal muscle, the metabolite build-up and release of local vasodilators attenuates the sympathetic vasoconstriction by interfering with α-adrenergic receptor vasoconstriction.[115] This mechanism has been deemed functional sympatholysis.[116] This balancing act between sympathetic-vasoconstriction and functional sympatholysis increases total peripheral resistance in the inactive tissue and decreases total peripheral resistance in the active tissue, thus contributing to blood flow redistribution. This concept of blood flow regulation is critical because (1) without partial vasoconstriction, total peripheral resistance would dramatically fall and result in a mean arterial pressure too low to maintain perfusion pressure, (2) without local vasodilation, skeletal muscle would not receive adequate blood flow for metabolic exchange, and (3) without redistribution, much of the increased cardiac output would be delivered to tissues which do not need it, therefore reducing the arteriovenous O_2 gradient essentially indicating an inefficient use of the cardiac output. As exercise intensity increases, the attenuation of sympathetic vasoconstrictor tone is increased suggesting functional sympatholysis occurs in an intensity-dependent manner;[117] however, there is not a complete attenuation of all sympathetic activity at the level of the active muscle.[118,119] This phenomenon allows blood flow to reach the metabolically active muscle without

compromising blood pressure control. In order to maintain adequate arterial pressure when large muscle mass is working though, some vasoconstriction is imposed which reduces perfusion of the active muscle.[120] Thus sympathetic-mediated vasoconstriction is critical in maintaining arterial pressure in the face of functional sympatholysis and local vasodilation that give rise to increased blood flow during exercise.


Exercise hyperemia

Blood flow increases to active skeletal muscle almost immediately following a single contraction. This quick and timely response is due to both rapid vasodilation and the mechanical effects of muscle contraction.[121−123] The initiation and maintenance of exercise hyperemia (i.e., increased blood flow) is largely due to vasodilation in the microcirculation, with minor contribution from the skeletal muscle pump, rather than increased pressure, as mean arterial pressure only increases modestly during aerobic exercise. Large conduit arteries, such as the femoral and brachial arteries, are also capable of vasodilating during exercise; however, this is not a functionally significant change for the regulation of blood flow. Exercise hyperemia is thus a coordinated response of the vasculature in and around the skeletal muscle and is successfully initiated and maintained by vasoactive substances, conducted vasodilation, and flow-mediated dilation.

Vasoactive substances

Local vasodilation is caused by chemical substances released from the muscle (e.g., nitric oxide, prostaglandins, adenosine, lactate, K^+), endothelium (e.g., nitric oxide, adenosine, K^+, ATP, prostaglandins), and red blood cells (e.g., ATP, nitric oxide) (See reviews[113,124]; overview presented in Fig. 34.7). The magnitude of vasodilatory substance release appears intensity-dependent, with higher intensities eliciting a greater vasodilatory stimulus and larger reduction in total peripheral resistance. Several redundant mechanisms exist through which vasodilation can occur within the microcirculation and increase local blood flow.

Muscle contraction changes the surrounding environment (i.e., lowers pH) and initiates production of several substances within the muscle itself that induce vasodilation, such as nitric oxide, prostaglandins, lactate, hydrogen ions, potassium, and adenosine. The production of ATP and muscular contraction leads to an accumulation of metabolites and byproducts that alter the environment within the muscle, which traditional dogma suggests cause vasodilation.[125] Indeed, exercise-induced increases in lactate, potassium,[126,127] and adenosine,[128] and decreases in pH[129] have been proposed to influence local regulation of blood flow and vasodilation. Nitric oxide and prostacyclin are

FIGURE 34.7   Overview of local regulation of vasodilation at metabolically active tissue during exercise. *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; Ca^{2+}, calcium; *EDHF*, endothelial-derived hyperpolarizing factor; *eNOS*, endothelial nitric oxide synthase; *H+*, hydrogen; *K+*, potassium; *NO*, nitric oxide; *PG*, prostaglandins; *VSM*, vascular smooth muscle.

also two proposed central vasodilators given that each is stimulated by several vasodilator compounds and mechanical stimuli, as discussed below.[130] Unfortunately, determining which vasodilator is the largest contributor to exercise hyperemia is experimentally difficult owing to the inherent redundancy. As such, no single vasodilator has currently been shown to contribute >30% of the vasodilatory response to exercise, suggesting local vasodilation during exercise involves multiple vasoactive substances. Indeed, while lactate and pH modify vasodilation, they do not solely determine exercise hyperemia.[126,129] However, adenosine (by itself or as ADP or ATP) is considered one of the stronger vasodilator substances released by the exercising skeletal muscle owing to strong correlations between adenosine concentration and leg blood flow during exercise.[128] Endogenous nitrate is also converted to nitrite and ultimately nitric oxide, particularly during hypoxia, implicating another pathway by which vasodilation is induced in active muscle.[124,131] The individual importance of these chemical and metabolic substances within the active muscle is complicated by their complex interplay as part of the integrated exercise hyperemic response. Ultimately, the complex interaction between vasodilators and redundant mechanisms within the vasculature system is critical to maintain blood flow and thus nutrient delivery and waste removal during exercise.

Conducted vasodilation

Adequate vasodilation of the feed arteries is necessary to achieve adequate perfusion pressure to the downstream terminal arterioles where the highest resistance to flow occurs.[132] Interestingly, the local vasodilator response initiated in the smallest arterioles proximal to the capillaries is conducted upstream to larger feed arteries. Thus, initial distal arteriolar vasodilation spreads proximally through the vasculature via cell-to-cell communication between neighboring smooth muscle and endothelial cells. This upstream transmission of vasodilation is termed conducted vasodilation.[133,134] Conducted vasodilation is a complex and highly integrated process that ensures upstream resistance decreases and blood flow increases to facilitate downstream/local metabolic exchange during exercise.

Flow-mediated vasodilation

The initial increase in blood flow with exercise is driven by local vasodilatory factors; however, sustained vasodilation during exercise is additionally linked to the effect of increased blood flow on the endothelium. Increased local blood flow during exercise from local vasodilators and conducted vasodilation produces a frictional force (i.e., shear stress) on endothelial cells. Elevated shear stress

results in increased production of endothelial nitric oxide synthase (which synthesizes nitric oxide) and other vaso-active molecules (e.g., nitric oxide, prostacyclin, and endothelial-derived hyperpolarizing factor).[113,130] The response of the endothelial cells to the shear stress is termed flow-mediated vasodilation and is important for maintenance of increased blood flow during exercise.

Mechanical actions of the muscle

Exercise hyperemia is also minimally contributed to by muscle contraction. Muscle contraction influences both the arterial and venous circulation. When the muscle contracts, arterial blood flow is temporarily reduced or cut-off. When the muscle relaxes, however, blood flow increases. This increased flow influences shear stress on the vessel, leading to a flow-mediated dilation and increased nitric oxide and prostacyclin release. In the venous circulation, muscle contraction leads to a pumping effect where venous return is enhanced and subsequently perfusion due to the magnified pressure gradient. This concept is referred to as the skeletal muscle pump. The mechanical compression of muscle contraction squeezes blood toward the heart by taking advantage of the inherent composition and structure of the veins. Each contraction-induced compression of the highly compliant venous walls forces blood flow toward the heart, with one-way valves preventing backflow (contributing to increased preload, discussed in cardiac output). This movement of blood volume from the nearby venous bed increases the pressure gradient in the capillary bed. As the muscle relaxes, the expanded pressure gradient leads to an increase in muscle blood flow. Given the rhythmic nature of muscle contractions during dynamic exercise, mechanical contraction of skeletal muscle does not limit overall blood flow to the active skeletal muscles.

Cardiovascular limitations to exercise

Aerobic exercise capacity is dependent on an integrated response that facilitates the intake, delivery, and consumption of oxygen. The Fick principle describes oxygen consumption as the product of oxygen delivery (cardiac output: heart rate, stroke volume) and oxygen extraction at the working muscle (arterial-venous oxygen content difference).[135] The magnitude of each of these variables can increase determining the upper limit of whole-body oxygen consumption (i.e., VO_2 max). The ability of the cardiovascular system to deliver oxygenated blood to working tissues during whole body exercise, however, can become limited at different steps throughout the oxygen pathway. Whether exercise is limited by central (cardiac output) or peripheral (muscle) mechanisms is highly debated within the literature. The limiting mechanism is likely dependent on several factors such as exercise training status, age, and/

or chronic conditions. Potential mechanisms limiting oxygen consumption, and thus exercise capacity, have been reviewed extensively elsewhere[136,137] but will be summarized here within the context of (1) pulmonary diffusing and oxygen carrying capacity, (2) cardiac output, and (3) skeletal muscle oxygen extraction.

Oxygen delivery depends on the arterial oxygen content, which is determined in part by pulmonary diffusion capacity. Attenuated increases in pulmonary diffusion capacity during exercise would reduce oxygen content in arterial blood and are associated with reduced exercise capacity.[53] Indeed, pulmonary diffusion capacity may limit exercise in certain populations vulnerable to exercise-induced diffusion limitation (e.g., highly trained athletes, chronic obstructive pulmonary disease patients).[56,136] In this setting, exercise capacity can be improved by supplementing with oxygen to offset exercise-induced hypoxemia.[138−140] In young, healthy individuals, however, pulmonary diffusion capacity does not limit exercise and increasing arterial oxygen content via hyperoxia does not necessarily increase oxygen consumption.[141,142] Red blood cell mass is an additional contributor to exercise capacity owing to its direct influence on arterial oxygen content. Greater red blood cell mass increases hemoglobin content (the transporter of oxygen in the blood), which augments oxygen-carrying capacity and thus, oxygen delivery.[137] While the arterial oxygen content (via pulmonary diffusion capacity or red blood cell mass) can influence exercise capacity in certain populations, it is likely less limiting in generally healthy populations.

Increased delivery of oxygen to the working tissue can only be accomplished by augmenting blood flow via cardiac output. Traditional dogma suggests that cardiac output (and specifically stroke volume) is the primary physiological determinant of exercise capacity in most adults.[137] Cardiac output has been estimated to account for 70% −85% of the limitation in exercise capacity.[136] Consequently, an inability to increase cardiac work (and decrease ventricular-vascular coupling) during exercise is associated with reduced oxygen consumption,[143] and may be related to impaired ventricular vascular coupling at rest (higher ratio owing to greater ventricular elastance)[144−146] which reduces functional reserve during exercise.[35−38] Alternatively, the pulmonary circulation and right ventricle may become limiting in certain environments/populations[43,53] such as aging and elite athletes. Older adults and highly trained athletes may exhibit substantial increases in pulmonary artery stiffness during exercise, owing to age-related elevation of resting artery stiffness and extreme increases in cardiac output (for athletes)/PAP during exercise, respectively. These large increases in pulmonary artery stiffness augment right ventricular afterload, thereby limiting stroke volume[48] and cardiac output during high intensity exercise.[43] As such, elevated pulmonary artery

stiffness is associated with reduced exercise capacity in certain populations.[54] Additionally, increased respiratory muscle work during high intensity exercise may create a "steal" phenomenon whereby competition between respiratory and skeletal muscle blood flow reduces oxygen delivery to locomotor muscles and limits exercise capacity.[147] Cumulatively, left or right ventricular limitations that impair increases in cardiac output may limit the ability to perform aerobic exercise.

Oxygen delivery to the periphery does not guarantee extraction by the active tissue. Exercise capacity may therefore be dependent on the ability of the mitochondria to extract and use oxygen during exercise. Although early data suggested oxygen extraction is maximized (extracting ∼88% of arterial oxygen content) at the active muscle during heavy whole-body exercise,[136] more recent data suggest oxygen consumption among untrained individuals appears limited by mitochondrial oxygen demand, rather than oxygen supply (e.g., cardiac output).[135] It is evident that the role of the periphery in limiting exercise capacity requires further research to determine the magnitude of its contribution. In summary, multiple mechanisms throughout the oxygen cascade can limit aerobic exercise capacity and may differ based on environment, age, sex, and clinical conditions.

Summary

Aerobic exercise requires a complex, coordinated response from the cardiovascular system to ensure adequate blood flow to metabolically active tissue and maintenance of blood pressure. The complementary cardiac and vascular responses during exercise act to minimize vascular contributions to the already prioritized increase in cardiac work during exercise. Increases in cardiac output are directed to metabolically active and away from inactive vascular beds through reciprocal actions of the sympathetic nervous system and local regulators of blood flow. Blood flow to skeletal muscle is maximized through multiple, redundant vasodilatory mechanisms that can be conducted upstream to ensure adequate oxygen delivery and removal of metabolic waste. Ultimately, the highly integrated cardiovascular response can become limiting at multiple levels of oxygen intake (pulmonary circulation), delivery (cardiac output, blood flow distribution), and use (mitochondrial O_2 extraction); however, the limiting factors may vary by population, modality, and environment.

Examining cardiovascular adjustments during exercise remains a formidable challenge owing to experimental/methodological constraints that are inherent with exercise (e.g., intense movement, physiological noise). Emerging methodologies and innovative research designs are making measurement of cardiovascular responses during exercise more achievable, lending optimism to the prospect of gaining new insight into the mechanisms and regulation of cardiovascular hemodynamics during exercise. Future work is still necessary to better understand clinical implications for cardiovascular adjustments to aerobic exercise and the degree to which responses differ in clinical populations with limited cardiovascular function or exercise capacity. Future work delineating the coupling of pulmonary circulation and right heart function with left heart function and impact on myocardial work and cardiac output is needed. Additional work is necessary to better interrogate changes in large artery characteristic impedance, artery stiffness, and upper/lower body pulse wave reflection during exercise. Further examination of ventricular-vascular coupling during exercise in health and disease requires use of pressure-flow relationships and aortic input impedance, rather than reliance on elastance which is not sensitive to pulsatile load.[39] Finally, the impact of sex, race, and ethnicity on the integrative cardiovascular response to aerobic exercise needs to be better understood. Although the mechanisms governing vasodilatory responses during exercise are redundant and complex, additional work seeking to understand limiting factors within specific chronic diseases may help inform therapeutic treatments.

Chapter 35

Invasive hemodynamic assessments during exercise: normal patterns and clinical value

Kazunori Omote, Yogesh N.V. Reddy and Barry A. Borlaug

Mayo Clinic, Rochester, MN, United States

Introduction

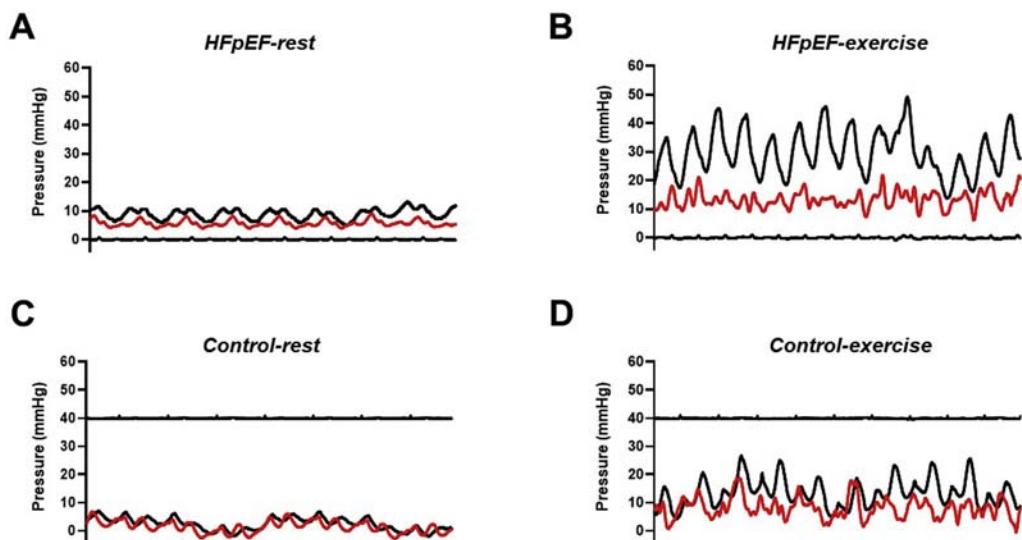
Exertional dyspnea is one of the commonest symptoms for which medical evaluation is sought, but dyspnea may develop from a number of causes. Cardiac catheterization provides direct assessment for evidence of heart failure (HF), but resting hemodynamics are often normal in ambulatory patients with early stage HF.[1] Common and simple stressors such as saline loading can provide some value but are inferior to exercise testing.[2] Noninvasive cardiopulmonary exercise testing (CPET) provides valuable information on gas exchange and aerobic capacity but may not discern cardiac from noncardiac sources of dyspnea.[1,3] Invasive exercise hemodynamics provides the most robust and direct method to evaluate the causes for exercise intolerance and serves as the gold standard to confirm or refute the presence of HF or pulmonary hypertension (PH).[1,3–5] In this chapter we will review the emerging utility of invasive exercise physiology assessment in modern clinical practice.

Role for invasive hemodynamics in diagnostic ambiguity

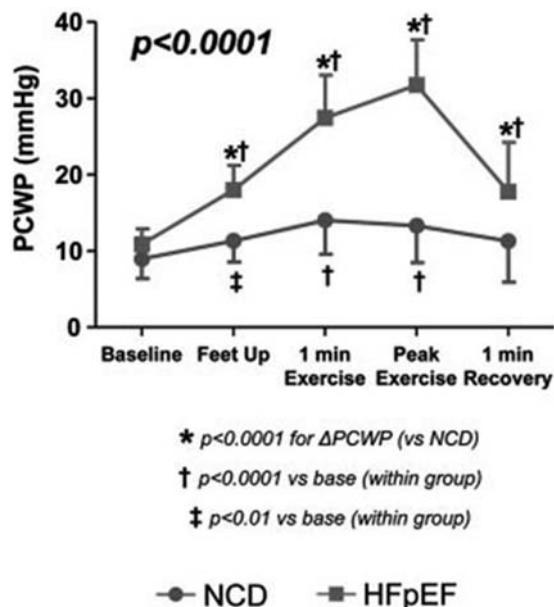
The diagnosis of HF is often challenging because symptoms or signs of HF commonly overlap with other conditions.[5] HF can be defined objectively as the inability of the heart to perfuse the body without pathological increases in filling pressure during rest or exertion. The diagnosis of HF therefore relies upon the demonstration of elevated filling pressures, on the basis of either physical examination, radiography, natriuretic peptide levels, or echocardiography data. Certain symptoms such as orthopnea and paroxysmal nocturnal dyspnea are highly specific for HF, while more

common symptoms of dyspnea and fatigue are more sensitive but less specific. Echocardiography often provides valuable information including assessments of ventricular structure and function and valve disease but is less accurate to assess right- and left-filling pressures, particularly in an earlier or milder stage of HF where hemodynamics become abnormal only during exertion.[3,6] When these tests are inconclusive, invasive hemodynamic assessments, which have the ability to directly assess ventricular filling pressures, pulmonary arterial pressures, cardiac output (CO), pulmonary vascular resistance (PVR), and measures of O_2 transport and utilization, provides much greater accurate information for diagnosing HF. The insertion of an arterial catheter can also provide continuous arterial pressure measurements in a peripheral artery during exercise, which are valuable to assess arterial resistive and pulsatile hemodynamics, as well as ventricular–arterial interactions, during exercise.

Physiology of invasive hemodynamic assessment

HF is defined hemodynamically as an inability of the heart to pump blood to the body at a rate commensurate with its needs or to do so at the cost of elevated filling pressures.[7] This definition applies to both HF with reduced ejection fraction (HFrEF) and HF with preserved ejection fraction (HFpEF), and indeed, invasive hemodynamics studies have shown that both HF phenotypes share similar elevations in right heart filling pressure (right atrial pressure [RAP]) and left heart filling pressure (pulmonary capillary wedge pressure [PCWP] and left ventricular [LV] end-diastolic pressure [LVEDP]).[8,9] These hemodynamic perturbations


are correlated with dyspnea severity, pulmonary limitations, impairment in aerobic capacity, and associated with increased risk of mortality in HF.[10−14] Noninvasive modalities such as echocardiography are specific when frankly abnormal but frequently have low sensitivity to identify elevated filling pressures at rest or during exertion.[3,6] Despite clinical euvolemia, normal natriuretic peptide levels, echocardiography, and normal resting filling pressures at rest, patients may show a number of hemodynamic changes during exercise (Figs. 35.1 and 35.2). Given its definitive and comprehensive nature, invasive CPET has emerged as the gold standard test to assess cardiac filling pressures.[1,3]

Assessment of left-sided filling pressures


The determination of left-sided filling pressures (PCWP or LVEDP) is clinically important because it allows estimation of pulmonary venous pressure as it relates to dyspnea and PH, but also used clinically as an estimate of LV preload. Preload can be defined by the magnitude of distention or stretching of ventricular myocytes before the onset of contraction, which dictates the extent of myofiber shortening in the subsequent contraction according to Frank−Starling principle.[4] The PCWP or LVEDP is a useful surrogate for preload and correlates with the LV end-diastolic volume [LVEDV] which determines end-diastolic myofiber stretch. Filling pressures for any preload (LVEDV) are determined by both the compliance properties of the myocardium and extrinsic pericardial restraint mediated by the right heart and pericardium. The PCWP reflects the LVEDV reasonably well at lower filling pressures but as the PCWP increases

there is a weaker correlation between PCWP and preload due to the impact of pericardial restraint increasing the PCWP through an external compressive contract force without contributing to end-diastolic myocyte stretch. LV transmural pressure (LVTMP), which reflects LV preload independent of right heart congestion and pericardial restraint, can be estimated by subtracting extrinsic pericardial pressure (estimated from RA pressure) from the PCWP.[3,15−17] Determination of how much of the PCWP elevation is due to pericardial interaction as opposed to LV filling is particularly important during exercise where pericardial interaction may play an increasingly important role due to the acute heart dilation from an acute increase in venous return.

Regardless of mechanism, the risk of pulmonary congestion increases with acute increases in pulmonary venous and left-sided filling pressures. Notably, Reddy et al.[18] reported that the development of lung congestion assessed by lung ultrasound during exercise was significantly associated with exertional elevations in PCWP and left atrial (LA) stiffness in well-compensated ambulatory patients with HFpEF. On the other hand, patients with established HF often display increased LV filling pressure at rest, but the correlation between pulmonary venous pressure and lung congestion may be surprisingly weak. This is because many HF patients develop adaptations that allow them to tolerate even marked elevations of LA pressure without developing clinical or radiographic lung congestion.[19−22] The pulmonary adaptation to increased PCWP in HF is believed to be caused by reduced capillary filtration due to basal membrane thickening, enhanced alveolar fluid clearance, and increased lymphatic drainage.[23] Melenovsky and colleauges[24] demonstrated that pulmonary

FIGURE 35.1   Typical right atrial pressure (RAP; red) and pulmonary capillary wedge pressure (PCWP; black) tracings in a patient with HFpEF at rest (A) and with exercise (B) and in a control patient at respective states (C and D). *HFpEF*, heart failure with preserved ejection fraction.

FIGURE 35.2 PCWP increased to a greater extent in HFpEF compared with NCD with feet up and during exercise. PCWP returned to baseline almost immediately in recovery. *HFpEF*, heart failure with preserved ejection fraction; *NCD*, noncardiac dyspnea; *PCWP*, pulmonary capillary wedge pressure. *Figure adapted with permission from Borlaug BA, Nishimura RA, Sorajja P, Lam CS, Redfield MM. Exercise hemodynamics enhance diagnosis of early heart failure with preserved ejection fraction. Circ Heart Fail. 2010;3:588−595.*

congestion in patients with established HF is associated with increased PVR and reduced PA compliance, suggesting that lung congestion itself may contribute to PH severity in advanced HF.

Right atrial pressure

HF is characterized by neurohumoral activation and sodium retention that leads to excessive fluid accumulation in the systemic and pulmonary circulations, which coupled with abnormalities in right heart-pulmonary artery coupling results in elevation of right-sided filling pressures reflected by the RAP.[25] RAP is also a surrogate marker for pericardial pressure,[17] so when RAP and PCWP both become elevated in tandem to very high levels, this suggests that the heart has filled to the point at which the pericardium restrains further filling, and there is enhanced diastolic ventricular interaction (DVI) with the right heart and pericardium driving the PCWP elevation.[26] This is a distinct hemodynamic signature in patients with HF and a key reason for measuring RAP continuously throughout exercise testing. Patients with HF and elevated RAP are more likely to develop lung congestion during exercise, due to the combined effects of increased fluid filtration caused by high PCWP and reduced pulmonary lymphatic drainage due to central venous hypertension.[18]

Concept of pericardial restraint

The elastic pericardium exerts a compressive contact force on the surface of the myocardium that becomes more substantial when heart volume increases, as can occur in many forms of HF including HFrEF, HFpEF, and patients with pulmonary arterial hypertension (PAH).[26] Pericardial restraint plays an important role in determining hemodynamics, LV preload and ventricular function. For example, total heart enlargement and cardiomegaly in HFpEF in particular with right heart enlargement creates the substrate for increased pericardial restraint and DVI, where the right heart influences the left in parallel.[27] When DVI is enhanced, left heart filling pressures can be elevated disproportionate to the degree of LV diastolic stiffness and LVEDV is lower than expected (i.e., LVEDP and LVEDV become uncoupled), resulting in failure to augment CO through failure of Frank−Starling reserve.[28] This phenomenon is also commonly observed in patients with severe tricuspid regurgitation (TR) as well, where exertional right heart filling pressure elevation may mediate decreases in left heart filling during exercise despite increases in left-sided "filling" pressures.[15] Similar physiology has also been observed in a subset of patients with HFrEF where LV filling pressures and RAP increase in a 1:1 ratio, with no further enhancement in stroke volume (SV), owing to the restraining effects of the pericardium that prevent additional preload recruitment.[29,30]

Measurement of flow

The Fick principle

The Fick principle enables measurement of CO from directly measured O_2 consumption (VO_2) together with blood sampling to measure O_2 contents obtained from a systemic artery and PA to calculate arterial-venous O_2 content difference (AVO_2 diff). The Fick principle states that uptake of oxygen in blood by the lung (mL/min) is equal to the product of the AVO_2 diff of the oxygen and the blood flow to the lung. Therefore, if the arterial O_2 content, venous O_2 content and oxygen consumption are measured, the CO can then be calculated. A 4 Fr to 6 Fr radial arterial cannula is used to measure arterial blood pressure and allow sampling of arterial blood gases. Simultaneous PA blood samples are obtained to measure systemic and mixed venous O_2 contents ($= O_2$ saturation $\times$ hemoglobin $\times$ 1.34). AVO_2 diff is calculated from systemic arterial and PA O_2 contents. Oxygen consumption can be directly measured at the mouth at rest and during exercise using a metabolic cart. CO is calculated by using the direct Fick equation ($CO = VO_2/AVO_2$ diff). SV can be calculated as the quotient of CO and heart rate.

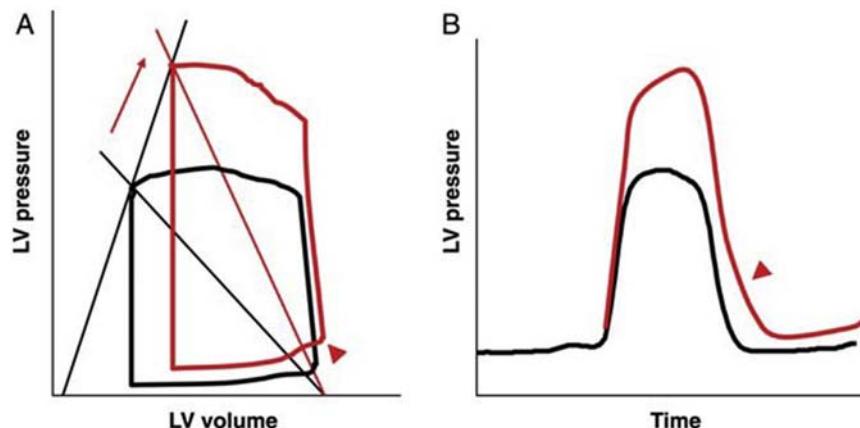
CO assessment using VO$_2$ measured versus assumed

Many clinical laboratories do not have the ability to directly measure VO$_2$, and therefore instead rely on regression equations to estimate what the directly measured VO$_2$ would be, usually based predominantly upon body size. However, these regression equations have substantial error, and with differing metabolic needs such as obesity or systemic illness, there can be great deviation from estimated VO$_2$.[31−33] Thus, use of directly measured VO$_2$ should be performed when the Fick method is utilized for CO assessment. If VO$_2$ cannot be measured, thermodilution CO is preferred.

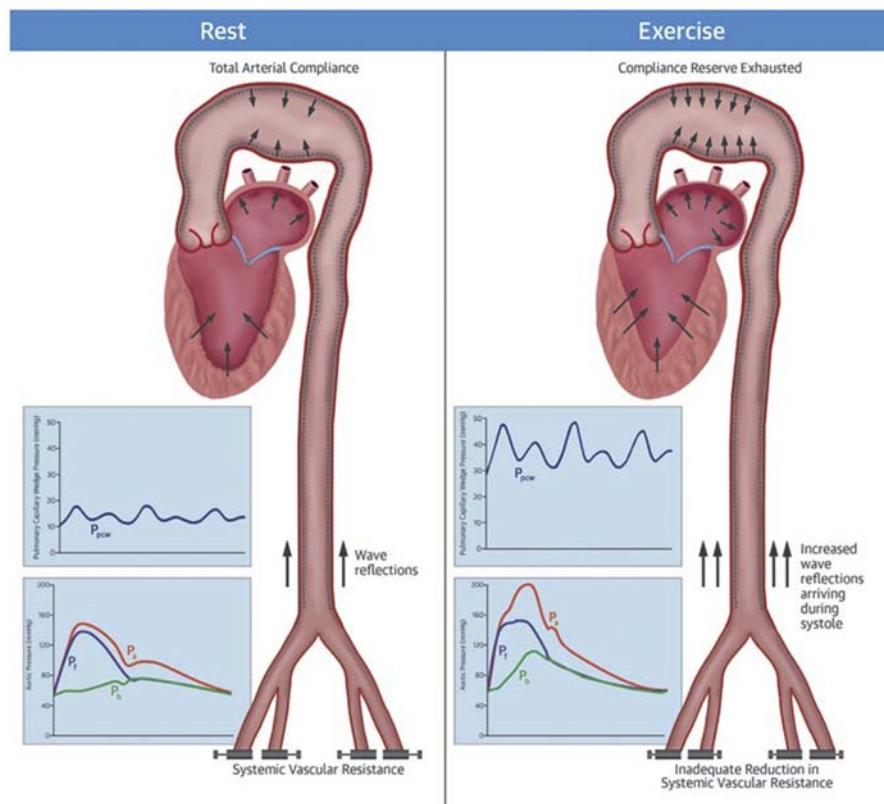
Thermodilution CO

Thermodilution is a form of the indicator dilution method, in which a bolus of cold saline is injected rapidly via the proximal port of the right heart catheter into the RA. The injectate mixes with blood and the change in temperature over time is recorded at the thermal sensor located at the distal portion of the right heart catheter. The area under this curve of change in temperature over time is calculated, which is inversely related to CO. This method can assess CO without blood gas data and expired gases analyses and therefore has advantages in the absence of directly measured VO$_2$. However, there are several limitations to thermodilution CO limiting its application compared to the direct Fick method with directly measured VO$_2$.[34] In cases with low CO, blood is rewarmed by the walls of the cardiac chambers and surrounding tissue, resulting in overestimation in CO estimation. The back and forth flow across the tricuspid valve in severe TR can result in underestimation of CO.[35] In patients with atrial fibrillation, irregular heart rates and cycle lengths can result in variability in thermodilution CO estimates. In the presence of a left to right shunt, the thermodilution CO represents the total pulmonary blood flow including the left to right shunt and therefore differs from Fick CO perfusing the systemic circulation.[36] Furthermore, errors in measuring thermodilution CO may be introduced by technical errors, such as increase injection temperature, an inappropriate injection speed, or lower injection volume. Variability may be high between injections, particularly when attempted during exercise, where Fick CO represents the preferred method.

Vascular load

The determination of vascular load of the circulatory system relies on modeling the circulation in terms of assuming steady state or pulsatile flow. Quantifying load assuming the circulation is nonpulsatile provides a measure of mean systemic vascular resistance (SVR). As discussed in Chapters 15−17, this measure of load fails to account for pulsatile loading conditions and provides an incomplete description of vascular loading.


Systemic vascular load

SVR is determined by dividing mean arterial pressure minus central venous pressure (CVP) and CO, converted to standard units. Pulsatile arterial load may be assessed in a general way by the central aortic pulse pressure (PP = systolic blood pressure-diastolic blood pressure), effective arterial elastance (Ea), and total arterial compliance (TAC). Ea is a lumped measure of the total stiffness of the arterial system, which is assessed by end-systolic central blood pressure/SV.[37] Ea is most strongly related to SVR and is also influenced by heart rate. TAC is an approximation of the pressure−volume relationship for the lumped arterial system. Although multiple methods exist to assess TAC (as detailed in Chapter 3), it is usually estimated as SV index/central PP in the catheterization laboratory.[38]


Ventricular and vascular stiffening increase with aging and comorbidity (e.g., hypertension and/or diabetes) and are abnormally elevated in patients with HFpEF. Acute afterload elevation in the setting of ventricular−arterial stiffening causes greater increase in blood pressure, which may then feedback to further impair diastolic relaxation, leading to dramatic increases in filling pressures during exercise (Fig. 35.3).[39] Many patients such as those with HFpEF may manifest arterial reserve limitations only during exercise. Reddy et al.[40] compared indices of arterial stiffness and pulsatile hemodynamics (both steady state and pulsatile load) at rest and during exercise in subjects with HFpEF and hypertensive control subjects (who themselves display vascular stiffening) to examine their relationships to cardiac hemodynamics and determine whether exertional arterial stiffening can be mitigated by inorganic nitrite. This study concluded that arterial load in HFpEF were similar to those in hypertensive control subjects at rest, but during submaximal exercise, HFpEF subjects displayed higher Ea index and reduced TAC index and at peak exercise there was greater reflected wave burden compared to control subjects. Importantly, these pulsatile arterial loads were directly correlated with higher LV filling pressures and depressed CO reserve (Fig. 35.4).[40] This pulsatile load increase appeared to be partially treatable with inorganic nitrite, as measures of wave reflection and arterial loading were improved following nitrite as compared to placebo.

Pulmonary vascular load

In patients with HF and chronic elevations in LA pressure, there may be structural vascular remodeling and changes in PA tone leading to increases in PVR and reductions in PA

FIGURE 35.3 (A) Combined ventricular−arterial stiffening in heart failure with preserved ejection fraction may lead to dramatic elevations in blood pressure with afterload increase (*red arrow*). This feeds back to increase LV end-diastolic pressures (*arrowhead*), by altering the slope or position of the diastolic pressure−volume relation, and/or (B) by prolonging LV pressure decay during isovolumic relaxation (*arrowhead*). *Figure adapted with permission from Borlaug BA, Paulus WJ. Heart failure with preserved ejection fraction: pathophysiology, diagnosis, and treatment.* **Eur Heart J.** *2011;32:670−679.*

FIGURE 35.4 At rest (left panel), the aortic pressure waveform, P_a (orange) is shown as a composite of the forward wave, P_f (blue) and reflected wave, P_b (green).Wave reflections, which develop at the points of impedance mismatch along the arterial tree, are reflected back to the aorta causing systolic pressure augmentation. Total arterial compliance, which reflects the ability of the arteries to store blood during systole without untoward elevation in pressure, is not significantly compromised, and pulmonary capillary wedge pressure (PCWP) is near normal. During exercise (right panel), venous return and cardiac output increase. Stiffening of the aorta, along with a lack of small vessel vasodilation in the periphery (inadequate reduction in systemic vascular resistance), augments pressure wave reflections, P_b (green) and pressure augmentation of the central aorta during mid to late systole. Total arterial compliance reserve becomes saturated, such that increases in stroke volume cause greater elevation in aortic pulse pressure, further augmenting left ventricular load. These changes are then correlated with pathologic increases in PCWP that promote symptoms of dyspnea, and impairment in forward cardiac output reserve, limiting oxygen transfer to the body. *Figure adapted with permission from Reddy YNV, Andersen MJ, Obokata M, et al. Arterial stiffening with exercise in patients with heart failure and preserved ejection fraction.* **J Am Coll Cardiol.** *2017;70:136−148.*

compliance. Increases in PCWP preferentially increase pulsatile RV loading by reducing compliance greater for any increase in resistance. Pulmonary vascular disease (PVD) commonly coexists with HF, can also worsen PH for any degree of LA pressure elevation. Given that the RV is highly sensitive to afterload, PH is an important contributor to RV dysfunction in HF in part due to pulsatile RV loading.[41,42]

Assessment during exercise

Normal range of resting and exercise value

In order to interpret the data from an invasive CPET, it is important to recognize the normal response to exercise. Normal ranges of resting and exercise values are shown in Table 35.1.[43] With the onset of exercise, there is an increase in venous return to the heart mediated by the combined actions of the skeletal muscle and respiratory pumps, together with sympathetic-mediated venoconstriction that shifts blood from the capacitance veins to the central circulation. The heart must cope with this increase in venous return by enhancing diastolic relaxation and suction. However, there is diastolic reserve limitation during exercise in patients with HFpEF (Fig. 35.5).[4] When venous return exceeds output, there is central congestion. This develops in the lungs in isolated left HF, and in the right heart in patients with PH in the absence of left HF or other causes of right HF. The increase in filling pressures is often exacerbated by pericardial restraint and DVI as total heart volume increases. This effect is greater in patients with obesity, right heart dilatation, and atrial fibrillation.

The duties of the LV are fundamentally to keep the lungs dry by filling to an adequate preload volume without pathologic increase in LA pressure, and to pump blood to the body at a rate commensurate with its metabolic needs, reflected by total body VO_2. This latter component is one area were invasive CPET provides an advantage against other modalities: the ability to measure both O_2 delivery and consumption in tandem. In health, studies dating back over 50 years have showed that CO increases with respect to VO_2 by a ratio of 6:1.[44,45] The lower limit of normal may be higher with supine exercise, as some studies have shown that HF-free controls have higher CO reserve with respect to VO_2.[7,46] Further study is required to define the lower limits of normal with supine exercise. By measuring the change in VO_2 (in mL/min) during exercise, one can determine what the expected change in CO should be, if the heart is adequately performing its duty as a pump.

Preforming an exercise hemodynamic study

Setup

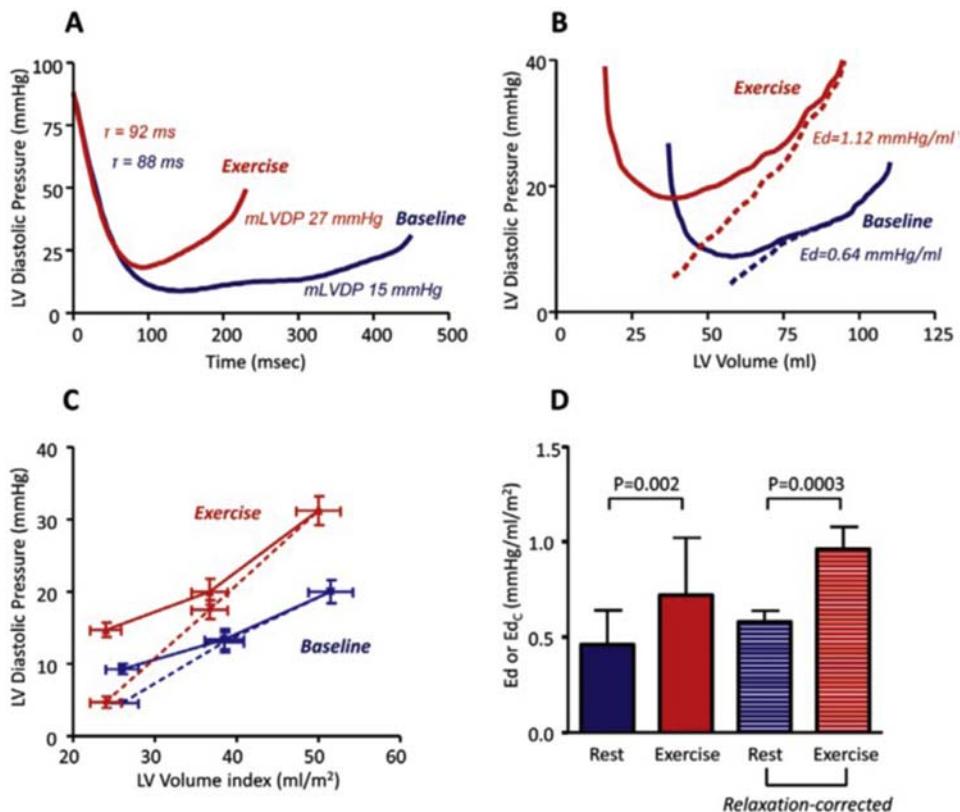
In the catheterization laboratory under mild sedation while lying supine, access is obtained in the right internal jugular vein followed by placement of a 9 Fr sheath (Arrow, Morrisville, NC). Access is also obtained in the right radial artery using a 4–6 Fr catheter. Solid state pressure transducers are leveled at mid-chest. A 7 Fr balloon-tipped catheter (Balloon wedge, Arrow, Morrisville, NC) is advanced to the RA. In our laboratory, a 2 Fr micromanometer is then advanced to the tip of the balloon-tipped catheter and balanced to the


TABLE 35.1 Normal range of resting and exercise values.[43]

	Normal resting values	Normal exercise values	Comments
RAP (mmHg)	0–6	<15	Normal range with exercise not well-defined
Mean PA (mmHg)	≤20	<30 with TPR<3 WU[a]	Often >30 above age 50 years in normal adults, but not with high TPR
PA/CO slope (mmHg/L/min)	–	<3	Less established for supine exercise
PCWP (mmHg)	<15	<25	Some references indicate normal resting values of <12 or <15; >20 during exercise may be abnormal in patients <50 years of age
PCWP/CO slope (mmHg/L/min)	–	<2	Less established for supine exercise
PVR (WU)	<2–3	<2–3	True normal <2 WU but clinical risk increases >3 WU; PVR should drop with exercise normally
CI/CO (L/min*m² or L/min)	2.2–4.0 (L/min[a]m²)	>4.8*ΔVO₂ (L/min)	Expected increase in CO is 6 mL/min for each 1 mL/min increase in VO₂[b]

[a]TPR, total pulmonary resistance, defined by mean PA pressure divided by CO.
[b]Predicted cardiac output reserve is equal to 6*ΔVO₂. Cardiac output reserve is then calculated as observed minus rest CO divided by predicted cardiac output reserve. This ratio has been referred to as the exercise factor and should be 0.8 or 80%.

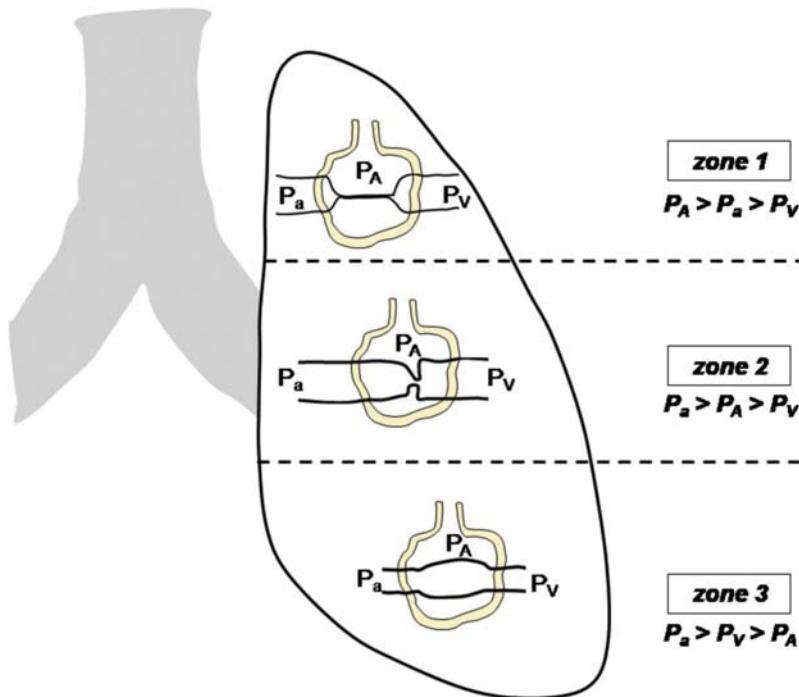
FIGURE 35.5 Diastolic reserve limitations during exercise in patients with heart failure with preserved ejection fraction (HFpEF). (A) In a typical HFpEF patient, there is dramatic elevation in mean left ventricular diastolic pressure (mLVDP) during exercise associated with limited hastening of isovolumic relaxation (reduction in the time constant of relaxation, τ). Inadequate relaxation reserve during exercise is coupled with an acute shift upward and to the left in the diastolic pressure-volume relationship, with an increase in operant diastolic elastance (Ed) as shown in an example patient (B) and in group data (C and D). The *solid lines/bar graphs* show raw unadjusted pressure-volume data and the *dashed lines/hashed bar graphs* show elastance data corrected for the effects of incomplete relaxation. *Figure adapted with permission from Borlaug BA. Mechanisms of exercise intolerance in heart failure with preserved ejection fraction. **Circ J**. 2014;78:20–32.*

mean fluid-filled catheter. The reason for the micro-manometer is the poor frequency response of the fluid-filled catheter, which becomes limiting during exercise in particular. CVP is measured continuously through the sidearm of the 9 Fr jugular sheath, taking care to assure that distal sheath pressure is equal to direct RA pressure. Transthoracic echocardiography may also be performed simultaneously with catheterization to evaluate for ventricular function, valve disease, and lung congestion. Pressures in the RA, PA, RV, and PCWP were measured at end-expiration using the mean of ≥ 3 beats. PCWP position is confirmed via appearance on fluoroscopy, characteristic waveforms, and wedge saturation $\geq 94\%$, with mean pressure taken at mid-A wave. In our laboratory, CO is determined by the Fick method from directly measured VO_2 (MedGraphics, St. Paul, MN) together with blood sampling to measure O_2 contents and pO_2 obtained from the radial artery and PA to calculate AVO_2diff. The protocol for the procedure is summarized in Box 35.1.[43]

Supine versus upright


Invasive CPET can be performed in either the supine or upright positions. While our catheter laboratory performs studies either way, our preferred approach is to utilize supine exercise, where venous return is maximized, increasing the sensitivity to detect diastolic reserve impairments. Normal ranges are also more familiar in the supine position, which is how cardiac catheterization has been performed since first introduced in the 1940s. It is important to recognize that RA, PA, and PCWP pressures are higher in the supine position as compared to upright. However, prior studies have shown that the changes with exercise are similar in both positions, as are changes in the relationships between PA and PCWP.[47,48] Of note, PVR falls more with upright exercise, particularly at low levels of exercise. With upright exercise there may be greater ringing artifact (fluctuations due to catheter movement) and catheter whip, as well as greater variability in PCWP when measured in different West zones (Box 35.2)[49] which is less relevant to supine exercise.[50]

BOX 35.1 Setup for Invasive CPET.[43]

1. Obtain access into the right internal Jugular (IJ) vein (9 Fr sheath) and right radial artery (e.g., 4 Fr monitoring line).
2. Start measurement of oxygen consumption (VO_2) for calculation of Fick cardiac output through mouthpiece or tight-fitting mask. This expired gas analysis continues throughout the remainder of the case.
3. Prepare and flush 7 Fr balloon wedge (BW) with a micromanometer (MM, 2 Fr) advanced through a sidearm.
4. Insert BW into the right atrium. Level the MM to the fluid-filled catheter and obtain right atrial pressure (RAP).
5. Transduce and record pressures from the radial arterial line, the right IJ sheath (RAP), and the BW at each stage.
6. Pass BW into the right ventricle. Verify no drift in the MM, and then record pressure.
7. Pass BW into the pulmonary artery (PA). Verify no drift in the MM and record pressures. Obtain blood gas samples from the PA, SVC (to rule out left to right shunt) and radial arterial line simultaneously. Annotate the time of blood sampling to correspond with the expired gas analysis for Fick output.
8. With flush on, advance BW in the PCWP position. Confirm PCWP position with waveform analysis, fluoroscopic appearance, and saturation >94%. Transduce pressure, verifying no drift in the MM, and record pressures.
9. Place feet into cycle ergometer pedals. After 30 s with feet up, take records while in PCWP position.
10. Begin exercise protocol (20 W). The duration of this stage is 3 min for tests without simultaneous imaging and 5 min if imaging is being performed to allow adequate time for image acquisition. After 2–4 min, pressure data and blood samples obtained as in the baseline phase.
11. Advance to next stage, in older adults with dyspnea, we generally use 20 W stage increments (3 min each) until peak.
12. Measurements of PCWP, PA, RAP, and arterial pressure tracings and arterial/PA blood samples 30 s prior to stage end for each incremental stage. Obtain Borg scores for perceived dyspnea and exertion at each stage.
13. When perceived patient effort reaches maximal tolerated effort (i.e., Borg perceived effort score >16, Borg dyspnea score >6), repeat steps 11 and 12. Confirmatory evidence of maximal effort includes respiratory exchange ratio >1.05.
14. Once all measurements obtained, stop exercise. Recovery pressure records taken at 1 min postexercise.
15. Remove patient's feet from the bike pedals and remove BW catheter from the sheath after all information obtained. Remove access sites per usual protocol.

BOX 35.2 The concept of West zones.

The lung is divided into three zones as described above. In each of zones, the magnitude of pulmonary artery pressure (P_a), pulmonary venous pressure (P_V), and alveolar pressure (P_A) are different. P_A exceeds both P_a and P_V in Zone 1. In Zone 2, where arterial exceeds alveolar but alveolar exceeds venous. Most zones in the supine position are called Zone 3, where both P_a and P_V exceed P_A. With upright exercise, venous pressure can be very low at the apex of the lungs, creating Zone 2 conditions. In that case, vascular pressure is not be measuring but rather alveolar pressure.

Measurement of pressures

End-expiration versus respiratory averaged

All pressures should be measured at end-expiration, which is when intrapleural pressure is closest to zero, lungs are at functional reserve capacity, and there is minimal airflow impacting intracardiac pressures. During exercise, some have advocated for use of pressures averaged over the entire respiratory rather than end-expiration, and this has advantages in patients with obstructive lung disease in whom intrinsic positive end-expiratory pressure (auto-PEEP) develops. For such patients where changes in intrathoracic pressure are dramatic and considered to contribute to elevated intravascular pressures, pressures averaged over the respiratory cycle may more accurately account for the effect of intrathoracic pressure and auto-PEEP compared to end-expiratory pressure. However, for the vast majority of patients without these conditions, end-expiratory values can be readily obtained and accurately reflect the transmural hydrostatic pressure in the pulmonary veins and capillaries. In these patients using pressure averaged throughout the respiratory cycle can underestimate transmural pressure due to the effect of inspiration falsely lowering measured pressures. Indeed, end-expiration PCWP was found to display a stronger relationship with the development of lung congestion as compared to PCWP averaged over the respiratory cycle.[18]

Cardiac output reserve

Invasive CPET also enables the assessment of CO reserve, which requires measurement of CO and oxygen consumption in tandem. Conventionally, CO is considered to increase by 6 mL for every 1 mL increase in whole-body oxygen consumption if the heart is adequately performing its duty as a pump as described above. Thus, if VO_2 increases from 250 mL per minute at rest to 1250 mL per minute at peak exercise (1000 mL/min), a 6 L per minute increase in CO is expected. Values <80% of this level are considered to indicate impairment in CO reserve, which is frequently observed in both HFrEF and HFpEF.[7,46,51,52] Subtle abnormalities in resting contractility in patients with HFpEF become dramatic during stress because of the inability to enhance systolic function that attenuates the increase in SV during exercise to limit CO reserve. Although resting LV ejection fraction (LVEF), SV, and CO are generally normal in HFpEF, the ability to enhance those with exercise relative to metabolic needs is impaired.

Added value of simultaneous exercise echocardiography

Exercise echocardiography provides valuable information including assessments of ventricular and valve structure and function. It is particularly useful to discriminate causes of the prominent V wave in the PCWP tracing that is commonly observed in patients with HF, which may be related to poor LA compliance or worsening mitral regurgitation. In the absence of significant mitral regurgitation, it suggests that the large V wave would be more a reflection of increased LA stiffness, as is commonly observed in patients with HF.[53] Furthermore, one advantage of echocardiography is the ability to perform simultaneous lung ultrasound, which enables evaluation of increases in pulmonary congestion during exercise.[18] Echocardiography with short axis imaging also allows determination of the degree of pericardial restraint with LV underfilling which can be estimated from the degree of LV collapse and eccentricity index resulting in a more D-shaped LV and septum. A higher eccentricity index and more collapsed LV for a given PCWP elevation reflects a greater degree of pericardial restraint. For these reasons, we often perform concurrent echocardiography during invasive CPET. Echocardiography also allows for the measurement of time-resolved blood flow velocity across the LV outflow tract, which in tandem with estimated central aortic pressures, can provide comprehensive assessments of arterial properties and ventricular—arterial interactions (as detailed in Chapters 3 and 17).

Clinical utility in the evaluation of suspected heart failure

HFpEF

Diagnostic uncertainty

In contrast to HFrEF, the diagnosis of HFpEF is challenging because ejection fraction is normal, cardiac congestion is difficult to evaluate noninvasively, and many patients display hemodynamic abnormalities only during exercise.[1,3,18] Despite normal resting hemodynamics, HFpEF patients develop cardiac injury and an impairment in myocardial function that worsen with exercise, leading to marked elevation in pulmonary vascular pressures that causes lung congestion, altered breathing mechanics and dyspnea.[5]

To diagnose HFpEF, clinical history, physical examination, and imaging tests are essential, but in patients with stable HFpEF or early stage HFpEF, current measures are poorly sensitive (Table 35.2).[54] Regarding blood tests, plasma natriuretic peptide levels increase in response to elevations in cardiac wall stress, which is related to chamber dimension and distending pressure. However, compared with patients with HFrEF, patients with HFpEF have lower wall stress owing to a smaller cavity size and thicker ventricular walls.[55] Many patients with HFpEF have normal distending cardiac pressures at rest and increased distending pressures only during exercise when the patient becomes symptomatic. Therefore, resting plasma natriuretic peptide levels are substantially lower in patients with HFpEF than in patients with HFrEF and are indeed often normal. For these reasons, the diagnosis of HFpEF can be often challenging.

TABLE 35.2 Clinical, laboratory and imaging predictors of HFpEF.[54]

Parameters	Odds ratio	C-statics	Sensitivity (%)	Specificity (%)	P value
Clinical					
Age >60 years	6.20	0.704	80	60	<.0001

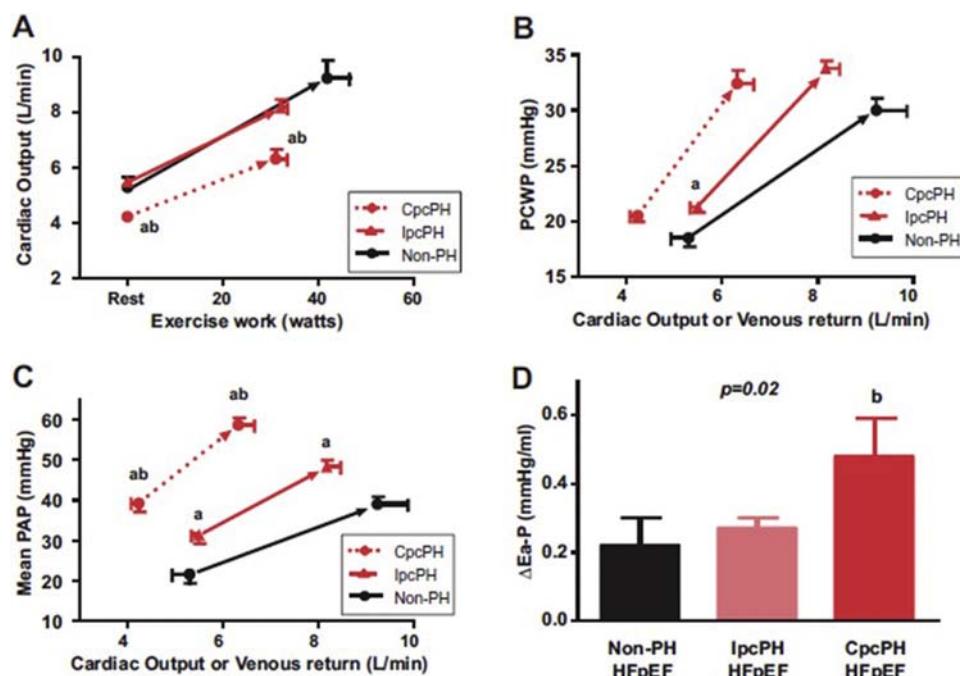
Evaluation of specific phenotypes


HFpEF is a heterogeneous syndrome. Clinical trials to date have not identified a treatment that improves the prognosis of people with HFpEF,[5,56] but phenotyping patients into pathophysiologically homogeneous groups may enable better targeting of treatment.[57]

Obesity has reached epidemic proportions worldwide and is a common finding in people with HFpEF (60% −75%).[5] Obesity has many deleterious effects on the cardiovascular system, mediated by changes in volume status, cardiac loading, energy substrate utilization, tissue metabolism, and systemic inflammation, which are believed to promote disease progression such as HFpEF. Several studies have reported that obesity was associated with more adverse hemodynamic measures, poorer RV function, increased volume retention, greater ventricular interaction, reduced exercise capacity and efficiency, greater symptom severity, increased vulnerability to kidney dysfunction, and poorer quality of life.[58−62] Furthermore, obesity is related to reduced natriuretic peptide levels in plasma as a result of increased clearance via natriuretic peptide receptors in adipocytes[63] as well as with a reduction in cardiac chamber distention owing to heightened pericardial restraint.[59] These distinctions suggest that obesity may be considered as a specific HFpEF phenotype. Exercise testing is often

necessary not only to unmask the diagnosis of HFpEF in these individuals but also can identify unique pathophysiological impairments including enhanced DVI and increased pulmonary vascular burden which may have therapeutic implications.

PH is common and contributes to increased morbidity and mortality in patients with HFpEF. Lam and colleagues demonstrated that echo-estimated PH was very common in HFpEF, present in greater than 80% of stable outpatients. For each 10 mmHg increase in estimated systolic PA pressures, there was a 30% increased risk of death.[64] PH in HFpEF may be caused by high downstream PCWP, increased impedance to flow through the pulmonary vessels, or both. The former has been termed isolated postcapillary PH (IpcPH) and the latter combined post- and precapillary PH (CpcPH).[65]

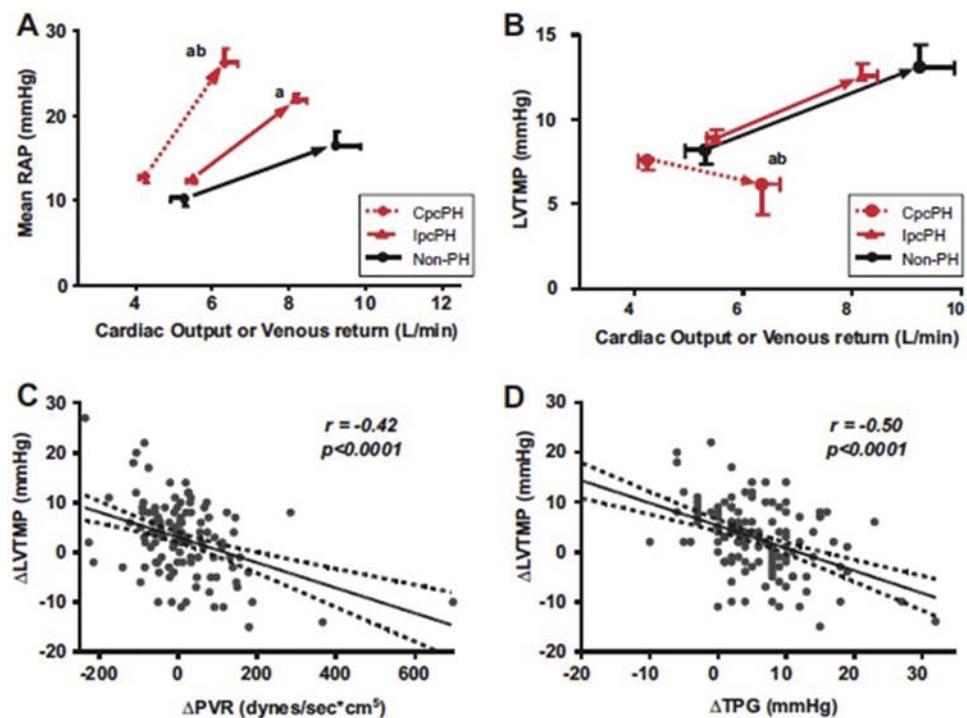
Gorter et al.[28] evaluated and compared cardiovascular structure, function, and reserve capacity in patients with non-PH-HFpEF, IpcPH-HFpEF, and CpcPH-HFpEF by performing invasive hemodynamic CPET. Exercise capacity was reduced in HFpEF patients with PH, evidenced by lower workload achieved and decreased peak VO$_2$. CO increased similarly with exercise in non-PH and IpcPH-HFpEF but was lower for any exercise workload in CpcPH-HFpEF (Fig. 35.6A). While all groups displayed


FIGURE 35.6   (A) Baseline and peak exercise for cardiac output. (B−C) PCWP and mean PAP and as a function of venous return. (D) As compared to both non-PH- and IpcPH-HFpEF, CpcPH-HFpEF patients displayed greater increase in pulmonary arterial elastance (Ea) during exercise a $P < .05$ versus non-PH-HFpEF; and b $P < .05$ versus IpcPH-HFpEF. *CpcPH*, combined post- and precapillary pulmonary hypertension; *HFpEF*, heart failure with preserved ejection fraction; *IpcPH*, isolated postcapillary pulmonary hypertension; *PAP*, pulmonary artery pressure; *PCWP*, pulmonary capillary wedge pressure; *PH*, pulmonary hypertension. *Figure adapted with permission from Gorter TM, Obokata M, Reddy YNV, Melenovsky V, Borlaug BA. similar absolute increases in PCWP with exercise, PCWP elevation occurred at lesser CO in CpcPH-HFpEF (Fig. 35.6B). Pulmonary artery pressures increased in all groups with exercise, but the greatest increases were observed in the CpcPH group, with higher pressures relative to blood flow (Fig. 35.6C). Patients in the CpcPH-HFpEF group experienced greater reduction in PA compliance on exercise along with higher exercise PVR and pulmonary artery elastance, in keeping with impaired pulmonary vascular reserve (Fig. 35.6D). Furthermore, recent studies reported that many patients with HFpEF also have coexisting PVD, which could also contribute to worsen PVR.[28,66–69] Patients with HFpEF and PH display worse pulmonary vascular load with impaired RV reserve, which is associated with poorer exercise capacity and worse clinical outcomes.[28,69] In patients with early stages of HFpEF, this may become manifest exclusively by abnormal pulmonary vasodilation during exercise. It has been proposed that these patients with HFpEF represent a unique HFpEF phenotype with enhanced ventricular interaction and pericardial restraint with LV underfilling and limited SV reserve during exercise (Fig. 35.7). HFpEF patients with this phenotype may share biological overlap with PAH,[70,71] which is defined by high PA pressure but normal PCWP.

The LA plays a key role in HFpEF progression. In the early stage of HFpEF, it may compensate for LV diastolic dysfunction through its booster function as an important barrier between the LV and the pulmonary circulation, but with prolonged LV dysfunction, there is LA dilatation, resulting in LA mechanical failure.[56] LA strain assessed by speckle tracking globally reflects atrial function, remodeling and distensibility components that become progressively more impaired in the setting of chronic LV diastolic dysfunction, as in patients with HFpEF. Notably, a previous study[53] showed that LA reservoir strain and LA compliance allow for discrimination of HFpEF from noncardiac dyspnea with similar or greater accuracy as compared to commonly used echocardiographic parameters of diastolic function. Therefore, LA volume contraction or failure to dilate could contribute to pulmonary venous hypertension and unfavorable symptoms in patients with HFpEF.

FIGURE 35.7 Ventricular interdependence with exercise in heart failure with preserved ejection fraction and pulmonary vascular disease. (A) Increase in venous return during exercise was associated with more dramatic increase in RAP in CpcPH-HFpEF compared to the other HFpEF groups. (B) While patients with non-PH-HFpEF and IpcPH-HFpEF displayed an increase in LVTMP, CpcPH-HFpEF patients developed a paradoxical decrease in LVTMP as venous return to the right heart increased during exercise. (C−D) The reduction in LVTMP was increased as exercise pulmonary vascular resistance and TPG increased, indicating that left heart underfilling was directly related to the severity of pulmonary vascular disease. a $P < .05$ versus Non-PH-HFpEF; and b $P < .05$ versus IpcPH-HFpEF. *CpcPH*, combined post- and precapillary pulmonary hypertension; *IpcPH*, isolated postcapillary pulmonary hypertension; *LVTMP*, left ventricular transmural pressure; *PH*, pulmonary hypertension; *PVR*, pulmonary vascular resistance; *RAP*, right atrial pressure; *TPG*, transpulmonary gradient. *Figure adapted with permission from Gorter TM, Obokata M, Reddy YNV, Melenovsky V, Borlaug BA. FIGURE 35.8 Diagnostic Approach for HFpEF. In the patient with unexplained dyspnea, assessment of the pretest probability that HFpEF is present is first performed via clinical, echocardiographic, and laboratory testing. Two scoring systems have been developed for this purpose: the H_2FPEF score[54] (left) and the HFA−PEFF[72] (right). With either system, patients deemed at high and low probability are generally diagnosed as having or not having HFpEF, respectively, without further testing. In patients with intermediate probability of HFpEF, hemodynamic exercise testing is needed, which can be performed using cardiac catheterization or stress echocardiography. *BNP*, B-type natriuretic peptide; *LAVI*, left atrial volume index; *LVMI*, left ventricular mass index, *NT-pro BNP*, N-terminal pro-B-type natriuretic peptide. *Figure adapted with permission from Borlaug BA. Bayesian approach can guide decision to refer for invasive assessment

In the patient with unexplained dyspnea, assessment of the pretest probability of HFpEF is first performed by clinical, echocardiographic, and laboratory testing. In the past two years, two scoring systems have been developed approaches for the diagnostic work-up of HFpEF: the H_2FPEF score[54] and the HFA−PEFF score[72] (Fig. 35.8). With either system, patients deemed at high and low probability are generally diagnosed as having or not having HFpEF, respectively, without further testing. In patients with intermediate probability of HFpEF, hemodynamic exercise testing is needed, which can be performed using cardiac catheterization or stress echocardiography. If exercise Doppler echo is clearly negative test, no further testing would be required, but its result is positive or equivocal, we need to consider invasive exercise test for diagnosis.[3]

HFrEF

Value in determining cardiac component of limitation

In patients with HFrEF undergoing evaluation for advanced therapies, bringing the sophisticated expired gas analysis techniques of CPET together with invasive exercise hemodynamics evaluation can determine the severity of the cardiac component of limitation compared to peripheral abnormalities beyond the heart. A previous study[46] reported that both CO response to exercise and peak exercise VO_2 were independently associated with worse clinical outcome in ambulatory patients with chronic HF who had been referred for cardiac transplantation. In contrast, there are a well-characterized subset of HFrEF patients where peripheral abnormalities are prominent,[73] and conceptually such patients may have relatively preserved CO reserve and likely derive less benefit from advanced HF therapies such as transplantation.[74] Invasive CPET may provide greater insight into the selection for potential heart transplantation candidates, although the conventional selection criteria of candidates for cardiac transplantation had limited by resting hemodynamics, echocardiography, and NYHA functional classification so far. Thus, invasive CPET has been expected to be used as a robust method to determine cardiac component of limitation even in HFrEF.

Degree of pulmonary hypertension, RV dysfunction

PH in HFrEF is initially felt to be a reflection of passive elevation in downstream PCWP, but in some patients, sustained elevation PCWP leads to pulmonary vascular remodeling and changes in pulmonary arterial tone leading to increases in PVR and reductions in PA compliance. In an

invasive hemodynamics assessment, Schwartzenberg et al[8] showed that PA mean pressure and PCWP were similar in subjects with HFpEF and HFrEF. Exercise markedly elevates RV afterload through increases in downstream PCWP and PA mean pressures. RV preload also increases by exercise via greater increases in CO and venous return from peripheral. In this study, PA mean pressure and resistance were largely reversible with intravenous sodium nitroprusside, suggesting that there is a substantial reactive component.

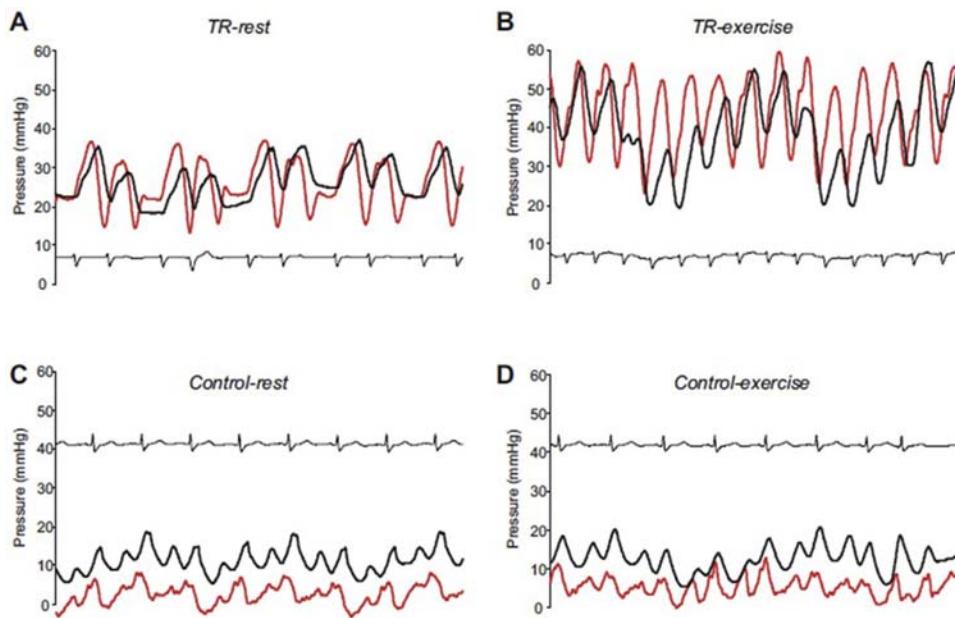
RV dysfunction from increased RV afterload is a major cause of morbidity and mortality in all HF cohorts. The pulmonary circulation and the afterload are very different from the systemic circulation. PH and pulmonary fibrosis do not significantly change the hyperbolic dependence between PVR and compliance.[42] This fixed relationship helps explain the difficulty of reducing total RV afterload by therapies that have a modest impact on mean PVR. Higher PCWP appears to enhance net RV afterload by elevating pulsatile, relative to resistive load and may contribute to RV dysfunction.

PAH

Utility in atypical PAH

The term PH is sometimes confused with what used to be called PAH, defined by high PA pressure but normal LV filling pressure. This is now referred to by consensus as Group 1 PH.[65] Group 1 PH is different disorder than HFpEF with IpcPH, but increasing evidence suggests that it has many similarities to HFpEF with CpcPH.[68,70,75] Recently, Opitz and colleagues identified a group out of registry patients with special characteristics who have hemodynamic criteria for PAH as well as more than three risk factors of clinical features of HFpEF.[71] They named this group as "atypical PAH." This group of patients responded less well to pulmonary vasoactive therapy when compared with Group 1 PH (PAH), but better than the registry patients who met criteria for HFpEF with PH. As such, the authors suggested that "atypical PAH" exists as part of a disease continuum between Group 1 PH (PAH) and PH associated with HFpEF. Further support for this disease continuum hypothesis, comes from Assad and colleagues, who recently reported that subjects with CpcPH display genes and biological pathways in the lung known to contribute to "PAH" pathophysiology.[70] Exercise testing uncouples occult left heart disease in these subjects with atypical PAH many of whom have risk factors for HFpEF, and such identification may help predict possible response to therapy.

Valve disease

Paradoxical LG AS


Severe aortic stenosis (AS) is usually diagnosed on the basis of both an aortic valve effective orifice area (EOA) $\leqq 1.0$ cm^2 (or $\leqq 0.6$ cm^2/m^2 converted to standard units) and a mean transvalvular pressure gradient $\geqq 40$ mmHg. However, low CO (e.g., SV index <35 mL/m^2) may lead to an important reduction in transvalvular pressure gradients even if the stenosis is very severe. There are some patients with severe AS on the basis of EOA might develop a restrictive physiology, resulting in low CO and lower than expected transvalvular pressure gradients despite the presence of a preserved LVEF (e.g., LVEF $>50\%$), what is called "Paradoxical LG AS." Paradoxical LG AS accounts for 10%−25% of patients with severe AS and is characterized by pronounced LV concentric remodeling, small LV cavity size, and a restrictive physiology leading to impaired LV filling pressure, altered myocardial function and is associated with poor prognosis.[76−81]

A recent study found that paradoxical LG AS display elevated arterial afterload (lower total arterial compliance and greater effective arterial elastance) compared with patients with high gradient severe AS and moderate AS.[82] In this study, nitroprusside reduced afterload and reducing LV filling pressures in patients with paradoxical LG severe AS. Furthermore, an inverse relationship between baseline SV index and change in SV index with afterload reduction was observed, which could reclassify to moderate AS in 25% of patients. The findings suggest that heightened sensitivity to afterload is a significant contributor to LG AS pathophysiology. Reduction of afterload might be a useful method to increase flow and distinguish between true severe and pseudo severe AS in patients with paradoxical LG AS. The importance of arterial low in LG AS is discussed in more detail in Chapter 37.

Severe TR with pericardial restraint

TR is a common valvular lesion that is usually caused by ventricular and annular dilation. Patients with TR are often asymptomatic, but with more advanced disease, patients complain of exertional fatigue, edema, and anorexia. The cause of exercise intolerance in patients with TR is complex. To clarify the cause of impaired exercise tolerance in patients with TR, invasive CPET is a robust method. Andersen et al.[15] demonstrated that impaired exercise capacity in patients with TR who had no evidence of left heart disease and PVD was related to an inability to adequately increase CO relative to metabolic needs, coupled with elevated systemic and pulmonary venous pressures assessed by invasive CPET. This impairment in perfusion is coupled with abnormal increases in PCWP that is related to right heart congestion and DVI rather than a primary left heart lesion because LVTMP dropped with exercise, consist with inadequate LV preload, despite elevated left-sided filling pressure (Fig. 35.9).[3,15−17] When RV and pericardial pressures are low, LVEDP (and PCWP) accurately reflects true LV preload (LVEDV). However, when there is right heart overload and pericardial restraint, LVEDP and LVEDV become uncoupled. This phenomenon is commonly observed in HF patients, wherein

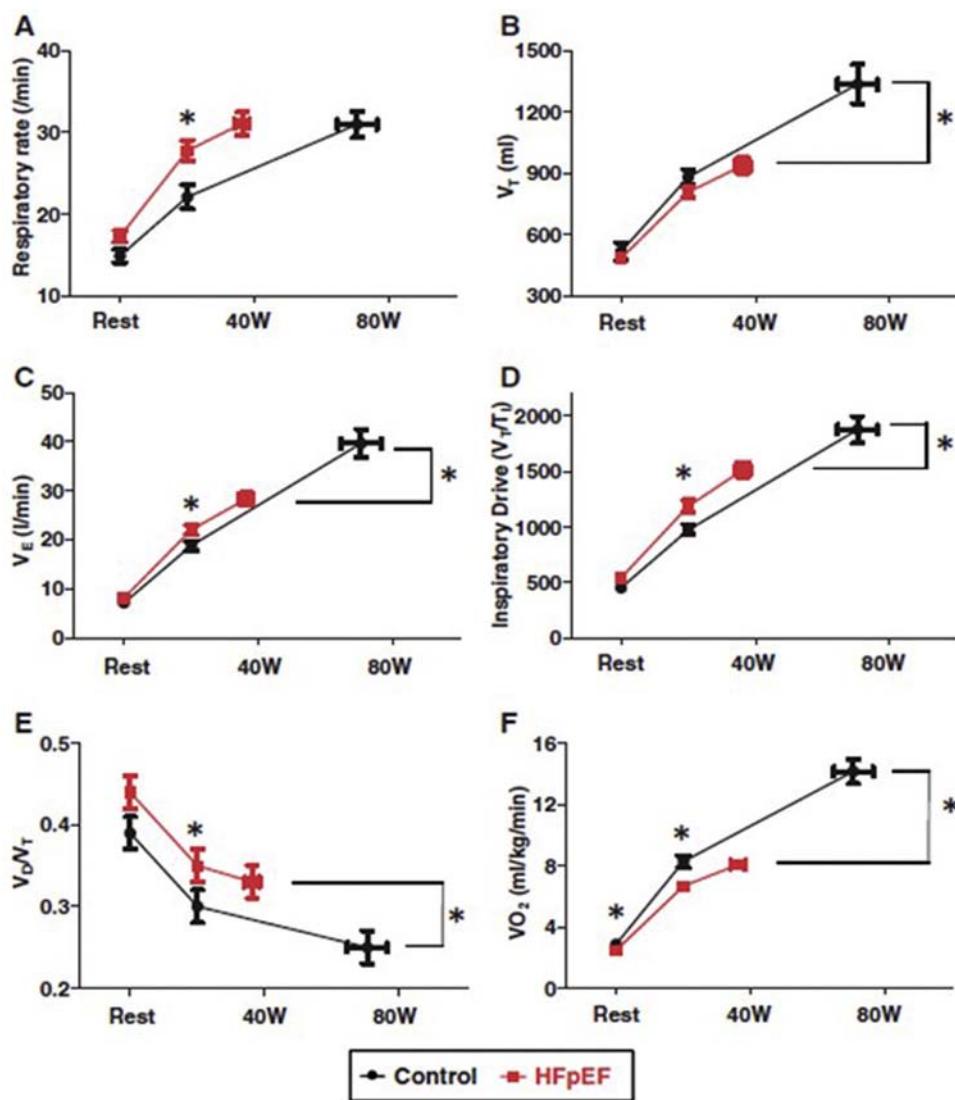
FIGURE 35.9   Typical RAP (red) and PCWP (black) tracings in a patient with severe TR at rest (A) and with exercise (B) and in a control patient at respective states (C and D). Note the prominent C−V waves with absent × descent (ventricularized waveforms) and near-equalization of right and left heart pressures in the TR patient. During inspiration, there is no drop in RAP (Kussmaul sign) despite reduction in PCWP associated with the drop in intrathoracic pressure, such that the transmural pressure gradient becomes transiently negative. In the control patient, PCWP and RAP are normal at rest and with exercise, and PCWP consistently exceeds RAP. *PCWP*, pulmonary capillary wedge pressure; *RAP*, right atrial pressure; *TR*, tricuspid regurgitation. *Figure adapted with permission from Andersen MJ, Nishimura RA, Borlaug BA. The hemodynamic basis of exercise intolerance in tricuspid regurgitation.* **Circ Heart Fail.** *2014;7:911−917.*

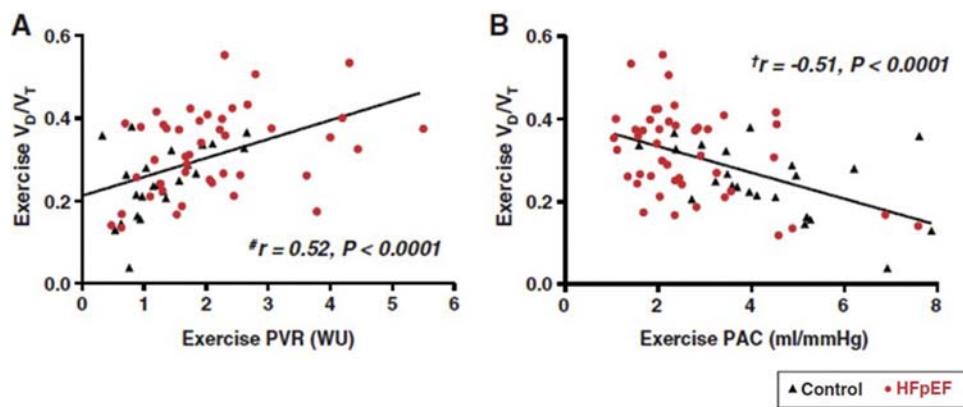
reduction in right-sided venous return may increase LV stroke work.

More advanced assessment

Peripheral O_2 utilization

Peak VO_2 is limited in equal parts by peripheral O_2 utilization (AVO_2 diff) as well as CO.[83] As such, enhanced peripheral O_2 distribution, utilization, and extraction (i.e., AVO_2 diff reserve) during exercise plays an equally important role as CO reserve in maximizing achieved VO_2. Although the heart increases its output during exercise, this enhanced flow needs to be distributed to tissues where perfusion is most needed, which is achieved by regional vasodilation in skeletal muscle and vasoconstriction in nonexercising regions such as the skin, splanchnic beds, and kidneys.[4] In patients with HF, there are some who are predominantly limited by peripheral factors, even when the EF is low. Accordingly, combining expired gas analysis techniques of CPET together with invasive exercise hemodynamics evaluation and direct arterial and venous blood sampling provides the direct method to evaluate both CO and peripheral O_2 utilization (AVO_2 diff), which can detect these causes for exercise intolerance.

Ventilation and expired gas analysis


Breath-by-breath VO_2, carbon dioxide production (VCO_2), tidal volume (V_T), minute ventilation (V_E), respiratory rate, minute ventilation ($V_E = V_T \times$ respiratory rate), and inspiratory time (T_I) can be measured throughout the invasive CPET to quantify functional capacity. Objective effort is estimated by the respiratory exchange ratio ($RER = VCO_2/VO_2$). Ventilatory efficiency is assessed by the slope of V_E to VCO_2, and ventilatory drive is assumed by the ratio of V_T to T_I. Pulmonary dead space (V_D) is the volume that does not participate in gas exchange, and the sum of anatomical dead space (conduit airways such as the mouth and trachea) and alveolar dead space. The ratio of dead space ventilation to tidal volume (V_D/V_T) is determined from the modified alveolar gas equation. Obokata et al.[13] demonstrated that elevation in left heart filling pressure with exercise is correlated with worse symptoms, greater ventilatory drive, more tachypneic breathing, impaired ventilation, and worse exercise capacity in HFpEF (Figs. 35.10 and 35.11).


Conclusion

Invasive CPET combines the robust expired gas analysis capabilities of CPET with the definitive assessments of pressure, flow, and resistance from cardiac catheterization, providing the most robust evaluation of exertional intolerance available in clinical practice. This chapter summarizes the performance and proper interpretation of invasive CPET, which relies upon careful integration of pressure waveforms, blood gas data, expired gas analysis, and assessments of O_2 transport. Given the comprehensive nature

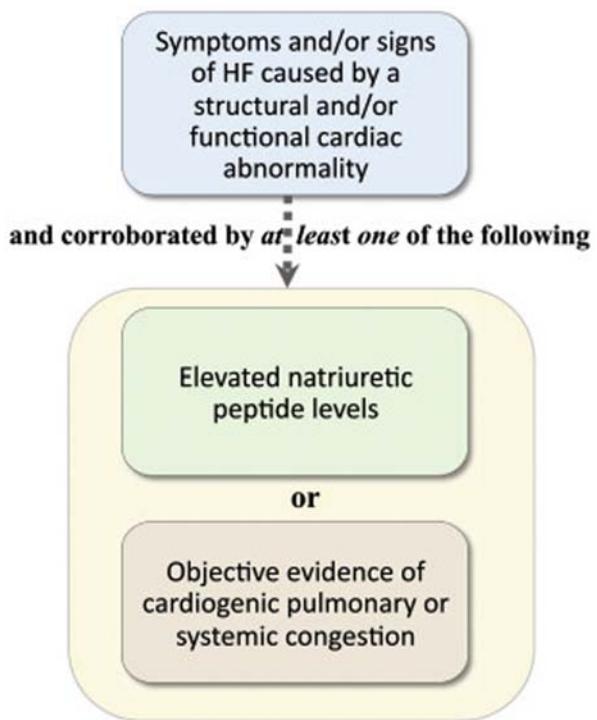
Chapter 36

Arterial stiffness and pulsatile hemodynamics in heart failure

Julio A. Chirinos[1,2]

[1]*University of Pennsylvania Perelman School of Medicine, Hospital of the University of Pennsylvania and Perelman Center for Advanced Medicine, Philadelphia, PA, United States;* [2]*Ghent University, Ghent, Belgium*

Introduction

Heart Failure (HF) is an important clinical and public health problem in developed countries. In the United States, HF affects ∼6 million American adults ≥20 years of age[1] and is associated with high mortality, poor quality of life, and important societal costs.[2]


Given the growing burden of HF, understanding mechanistic abnormalities that contribute to the pathophysiology of HF and that can be targeted with therapy is important.[3,4] Arterial load exerts a profound impact on left ventricular (LV) structure and function. Assessments of pulsatile arterial hemodynamics have provided important insights into the pathophysiology of LV remodeling and fibrosis, myocardial dysfunction, and failure. Moreover, pulsatile arterial load may interact with the distal microvasculature, promoting microvascular dysfunction and impaired oxygen delivery to peripheral skeletal muscle, all of which contribute to exercise intolerance in HF. Arterial pulsatile hemodynamic mechanisms likely contribute to the frequent presence of HF comorbidities, such as chronic kidney disease and dementia (see Chapters 40 and 41), particularly in patients with HF with preserved ejection fraction (HFpEF).

Arterial load, particularly increased late systolic load from arterial wave reflections, represents an increasingly recognized mechanistic abnormality with an established causal link to LV maladaptive remodeling and dysfunction in experimental models. Similarly, prominent arterial wave reflections have been shown to correlate with LV remodeling (both hypertrophy and fibrosis), LV and left atrial (LA) dysfunction, and incident HF risk in humans. Wave reflections may be susceptible to modification by pharmacologic interventions, which could have important implications for HF prevention and treatment. This chapter is largely based on recent reviews of the topic by the author and collaborators,[5−8] and discusses our current knowledge of the role of pulsatile arterial hemodynamics in HF, including HF with reduced ejection fraction (HFrEF) and HFpEF. This chapter does not deal with pulmonary arterial load and its role in pulmonary hypertension and right ventricular dysfunction, which are discussed in detail in Chapters 55−58.

Heart failure: definition and classification

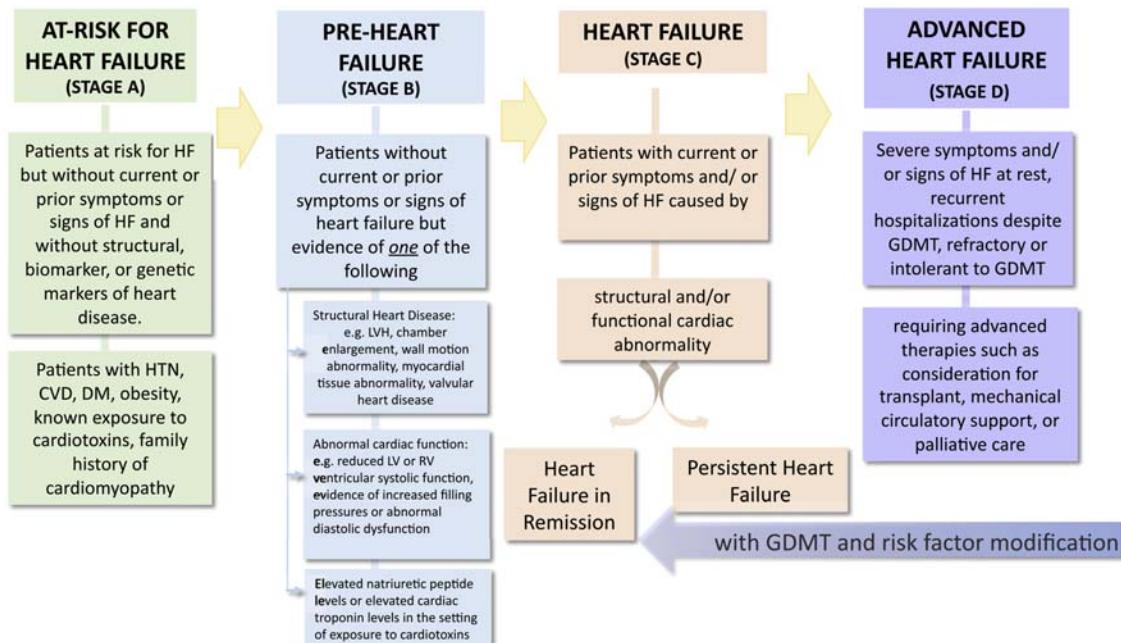
HF has classically been defined according to its pathophysiology as a syndrome resulting from an inability of the heart to pump enough blood to meet the body's needs or to do so at the expense of elevated LV filling pressures. Such definition, although conceptually attractive, has a number of theoretical and practical limitations.[9] Similarly, operational HF case definitions used in epidemiologic and clinical research are highly varied and can be discordant. Recently, the Heart Failure Society of America (HFSA), the HF Association of the European Society of Cardiology (HFA-ESC), and the Japanese HF Society (JHFS) released a document proposing a Universal Definition and Classification of HF.[9] The proposed universal definition of HF (Fig. 36.1) is based on symptoms and or signs of HF caused by a structural and/or functional cardiac abnormality, as determined by an EF of <50%, abnormal cardiac chamber enlargement, early diastolic atrioventricular inflow to annular tissue velocity ratio (E/e′) >15 (a marker of elevated ventricular filling pressures), moderate/severe ventricular hypertrophy, or moderate/severe valvular obstructive or regurgitant lesion. This should be corroborated by at least one of the following:

FIGURE 36.1 **Universal definition of heart failure according to the** Heart Failure Society of America (HFSA), the HF Association of the European Society of Cardiology (HFA-ESC), and the Japanese HF Society (JHFS). *Reproduced from reference Bozkurt B, Coats A, Tsutsui H. Universal definition and classification of heart failure.* **J Card Fail**. *2021.*

(1) Elevated natriuretic peptide levels, or;
(2) Objective evidence of cardiogenic pulmonary or systemic congestion by diagnostic modalities, such as imaging (e.g., by chest radiograph or elevated filling pressures by echocardiography) or hemodynamic measurements (e.g., right heart catheterization, pulmonary artery catheter) at rest or with provocation (e.g., exercise).

HF can be classified according to several different criteria, including the stage of the disease continuum, the severity of symptoms or functional limitation, its etiology (for example, ischemic/nonischemic, valvular, hypertensive, infiltrative, peripartum, viral myocarditis chemotherapy-induced cardiomyopathy), or the LV EF category. The recent HFSA/HFA-ESC/JHFS document also standardized the definition and subclassification of HF according to EF categories and provided a revised classification of the stages of HF (Fig. 36.2).[9] Briefly, the revised stages of the HF continuum include:

- Stage A ("at risk" for HF): Patients at risk for HF, but without current or prior symptoms or signs of HF and without structural cardiac changes or elevated biomarkers of heart disease (particularly, natriuretic peptide levels). This category includes patients with

hypertension, atherosclerotic cardiovascular disease, diabetes, obesity, known exposure to cardiotoxins, a positive family history of cardiomyopathy or genetic cardiomyopathy.
- Stage B (Pre-HF): Patients without current or prior symptoms or signs of HF, but who exhibit at least one of the following: structural heart disease (such as LV hypertrophy, cardiac chamber enlargement, ventricular wall motion abnormalities, myocardial tissue abnormalities, or valvular heart disease), abnormal cardiac function such as reduced left or right ventricular systolic function, diastolic dysfunction and/or evidence of increased filling pressures, elevated natriuretic peptide or cardiac troponin levels (especially in the setting of exposure to cardiotoxins).
- Stage C HF: Patients with current or prior symptoms and/or signs of HF caused by a structural and/or functional cardiac abnormality.
- Stage D (Advanced) HF: Severe symptoms and/or signs of HF at rest, recurrent hospitalizations despite guideline-directed medical therapy, refractory or intolerant to guideline-directed medical therapy, requiring advanced therapies such as consideration for cardiac transplantation, mechanical circulatory support, or palliative care.


The document also endorses the widely used New York Heart Association (NYHA) functional classification to characterize the symptoms and functional capacity of patients with symptomatic (Stage C) or advanced (Stage D) HF. The NYHA functional classification system categorizes HF on a scale of I to IV, as follows:

- Class I, no limitation of physical activity.
- Class II, slight limitation of physical activity.
- Class III, marked limitation of physical activity.
- Class IV, symptoms occur even at rest and discomfort with any physical activity.

Finally, the document also proposed a revised classification of HF according to LV EF, as follows:

- HF with reduced EF (HFrEF): HF with LV EF $\leq 40\%$.
- HF with mildly reduced EF (HFmrEF): HF with LV EF of $41\%-49\%$.
- HF with preserved EF (HFpEF): HF with LV EF $\geq 50\%$.
- HF with improved EF (HFimpEF): HF with a baseline LV EF $\leq 40\%$, a ≥ 10-point increase from baseline LV EF, and a second measurement of LV EF of $>40\%$.

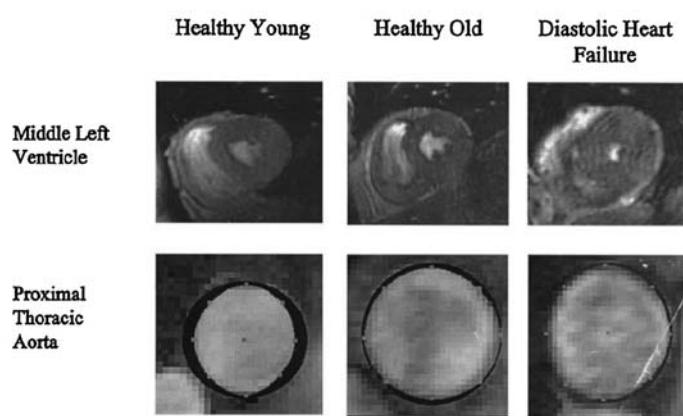
This chapter deals predominantly with studies of arterial stiffness and pulsatile hemodynamics in stage C–D HF (typically including patients with NYHA classes II–IV). We will also discuss the role of increased large artery stiffness and adverse pulsatile hemodynamics in promoting

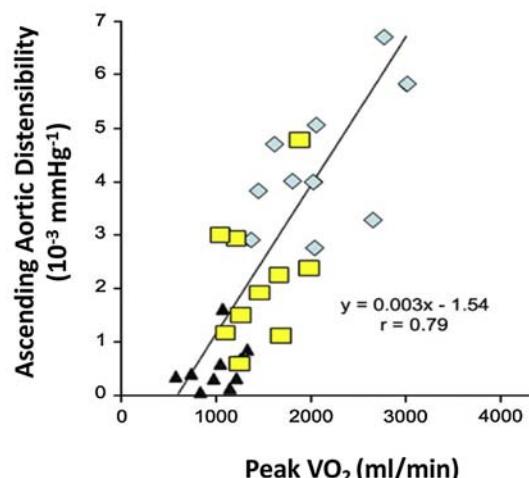
FIGURE 36.2 Stages in the development and progression of HF. *CVD*, cardiovascular disease; *DM*, diabetes mellitus; *HTN*, hypertension. *Reproduced from reference Bozkurt B, Coats A, Tsutsui H. Universal definition and classification of heart failure.* **J Card Fail**. *2021.*

LV remodeling and dysfunction prior to the onset of HF symptoms (i.e., stage B HF). Discussions regarding large artery stiffness and pulsatile hemodynamics in conditions that define Stage A HF (i.e., conditions placing patients at risk for HF, such as diabetes, hypertension, obesity, and atherosclerotic cardiovascular disease) are discussed in Chapters 29, 30, 38, 39, 49, and 52−54. Regarding the proposed classification by LV EF, we will largely focus on HFpEF and HFrEF, since the literature regarding arterial stiffness and pulsatile hemodynamics in HFimpEF and HFmrEF is very limited at present.

The arterial tree in HF

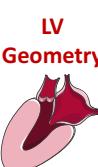
For didactic purposes, the chapter discusses the role of the aorta first, followed by the more distal muscular arteries (in the context of the role of arterial wave reflections) and finally, the microvasculature, in HF. We will then briefly discuss the therapeutic implications of pulsatile load in patients with HFrEF and HFpEF.

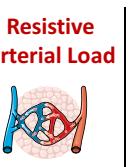
The aorta in HF


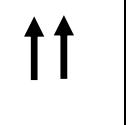


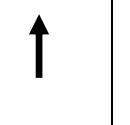
As described throughout this book, the aorta plays an important hemodynamic role. The proximal aortic geometry and wall material properties determine the aortic root characteristic impedance (Zc), which in turn represents the arterial pulsatile load to the LV in the absence of wave reflections, as discussed in detail Chapters 1, 3, 10 and 17.

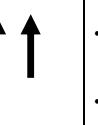
Aortic Zc is a dominant factor as a determinant of pulsatile load in early systole, prior to the arrival of wave reflections originating in more distal arterial segments.[5,8,10−14] A small aortic diameter, a stiff aortic wall, or both, can determine an increased Zc and pulsatile load from the aortic root. Moreover, an increased aortic wall stiffness causes an increased aortic pulse wave velocity (PWV) which leads to a premature arrival of wave reflections to the LV during mid-to-late systole, as will be discussed in more detail in later sections of this chapter.

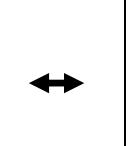
The aorta in HFpEF


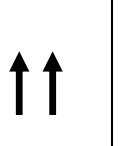


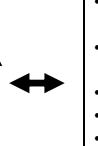












It has long been known that proximal aortic stiffness is increased in HFpEF. Hundley et al. demonstrated that patients with HFpEF exhibit a significant reduction in the cardiac cycle-dependent change in ascending aortic area and distensibility, assessed with magnetic resonance imaging (MRI), compared to young or old control healthy participants (Fig. 36.3A). Moreover, thoracic aortic distensibility was strongly correlated with aerobic exercise capacity measured as peak exercise oxygen consumption (VO$_2$; Fig. 36.3B).[15] This correlation persisted after adjustment for age and sex. Patients with HFpEF also exhibited increased ascending aortic wall thickness in this study.

More recently, Weber et al.[16] assessed pulsatile arterial function and invasively measured aortic PWV among patients with dyspnea and a preserved LV ejection fraction.

FIGURE 36.3 (A) Short-axis magnetic resonance images of the left ventricle (LV) acquired at the midpapillary muscle level at end systole (top row) and the magnitude component of the phase-contrast images of the ascending thoracic aorta (bottom row) from a participant in each of the three patient groups (healthy young, healthy old and HFpEF (i.e., "diastolic heart failure"), in the study by Hundley et al.[15] The myocardium is gray, and the blood pool within the cavity is white in the images of the LV. The blackened silhouettes on the images of the aorta represent the difference in aortic area between end-diastole and end-systole. Cardiac cycle-dependent changes in aortic area and aortic distensibility decreased with advancing age and were most reduced in older participants with HFpEF. (B) Relation between peak volume of oxygen (VO₂) and proximal thoracic aortic distensibility (vertical axis) for healthy young participants (blue diamonds), healthy old participants (yellow squares), and patients with HFpEF (black triangles). *Modified from reference Hundley WG, Kitzman DW, Morgan TM, et al. Cardiac cycle-dependent changes in aortic area and distensibility are reduced in older patients with isolated diastolic heart failure and correlate with exercise intolerance.* **J Am Coll Cardiol**. 2001; 38:796–802.

In this study, the presence or absence of HFpEF was established based on invasively derived filling pressures and natriuretic peptide levels. Pulse pressure, aortic PWV, and measures of arterial wave reflections were higher in patients with HFpEF. Moreover, this study suggested that adding measures of aortic stiffness and pulsatile arterial hemodynamics can improve the diagnosis of HFpEF in this clinical setting, although the latter point requires further validation.

Whereas the above studies in HFpEF indicate an overall increase in aortic stiffness in this population, it is important to remember that there is substantial phenotypic heterogeneity among patients with HFpEF, some of which may be driven by specific comorbidities. Chirinos et al. assessed the role of diabetes mellitus on LV and arterial structure and function in patients with established HFpEF.[17] It was demonstrated that, despite few differences in clinical characteristics, diabetic participants with HFpEF exhibited a much greater LV mass index and indexed extracellular volume measured by T1 mapping MRI (a measure of diffuse LV interstitial expansion), as well as pronounced aortic stiffening, as demonstrated by a markedly increased carotid-femoral PWV and proximal aortic Zc, relative to nondiabetic HFpEF participants. Diabetic participants also exhibited other features of adverse pulsatile hemodynamics, including increased forward wave amplitude, backward wave amplitude, and oscillatory power.

Interestingly, adverse pulsatile hemodynamics were also evident in 24-h ambulatory monitoring in the diabetic group, despite the absence of significant differences in 24-h systolic blood pressure between the groups.

Another comorbidity that may impact the arterial HFpEF phenotype is chronic obstructive pulmonary disease (COPD). Jain et al.[18] compared key cardiovascular phenotypes between patients with COPD, HFpEF, or both, using MRI and arterial tonometry to assess cardiac structure and function, pulsatile hemodynamics, and thoracic aortic stiffness. Participants with HFpEF and COPD demonstrated a more concentric LV geometry, a greater LV mass, and LV extracellular volume, as well as greater thoracic aortic PWV and aortic Zc. These results indicated that individuals with comorbid HFpEF and COPD have a greater degree of systemic large artery stiffening, LV remodeling, and LV fibrosis than those with either condition alone.

Although diabetes and COPD are common comorbidities in HFpEF, a wide range of relevant demographic and comorbidity factors can affect the phenotypic heterogeneity of the HFpEF population. These factors include older age, female sex, history of hypertension, obesity, atrial fibrillation, and coronary artery disease, among others.[19,20] Patients with HFpEF also have highly variable underlying cardiac structural and functional abnormalities.[21] Therefore, more formal approaches to characterizing the

phenotypic heterogeneity in HFpEF are advantageous to discern specific mechanistic abnormalities in various subgroups of patients. A useful approach is cluster analysis, which applies empirical statistical and/or machine learning techniques designed to detect naturally occurring subgroups of patients, maximizing within-group similarities and between-group differences on the basis of multiple measurable characteristics.[22−25] Clustering approaches can provide a potentially valuable way to identify discrete subphenotypes (or "phenogroups") of HFpEF patients, and have been applied in various studies.[23−25] Cohen et al. recently assessed large artery stiffness and related phenotypes in HFpEF phenogroups identified among participants enrolled in the Treatment of Preserved Cardiac Function Heart Failure With an Aldosterone Antagonist Trial (TOPCAT). Using latent class analysis, a well-established clustering technique, the study identified three distinct clinical phenogroups, which exhibited clear differences in clinical features, circulating biomarker profiles, cardiac structure and function, large artery stiffness (assessed via carotid-femoral PWV in a subgroup of participants), prognosis, and response to randomized spironolactone therapy, as follows (Fig. 36.4):

- Phenogroup 1 ("Younger with mild symptoms") exhibited younger age, higher smoking prevalence, preserved functional class, and the least evidence of LV hypertrophy and large artery stiffening. It is unclear if phenogroup 1 constituted individuals with genuine HFpEF, or whether it was composed predominantly by individuals with noncardiac causes of dyspnea. A noncardiac cause of dyspnea (such as lung disease) was supported by the observation that phenogroup 1 exhibited the highest prevalence of smoking and highest levels of MMP-9 (a protein involved in respiratory tract remodeling and known to be elevated in individuals with asthma and COPD).[26]
- Phenogroup 2 ("Older with stiff arteries, small LVs, and AF") was characterized by the oldest mean age and the highest prevalence of female sex and atrial fibrillation. This phenogroup also exhibited normotrophic or even hypotrophic concentric LV remodeling, LA enlargement, and markedly increased large artery stiffness. Phenogroup 2 demonstrated the highest levels of several markers of innate immunity, which have been previously associated with vascular injury as well as aging.[27] This phenogroup also exhibited the highest

FIGURE 36.4 Summary of biomarker, echocardiographic, vascular, and clinical differences across the three identified HFpEF phenogroups. *Afib*, atrial fibrillation; *CKD*, chronic kidney disease; *NAFLD*, nonalcoholic fatty liver disease; *NYHA*, New York Heart Association. *Modified from reference Cohen JB, Schrauben SJ, Zhao L, et al. Clinical phenogroups in heart failure with preserved ejection fraction: detailed phenotypes, prognosis, and response to spironolactone.* **JACC Heart Fail.** *2020; 8:172−184.*

levels of osteoprotegerin, which is a regulator of tissue calcification that has been linked with increased large artery stiffness, independent of atherosclerotic disease.[28]

- Phenogroup 3 ("Obese, diabetic with advanced symptoms") demonstrated a very high prevalence of obesity and diabetes, as well as chronic kidney disease, concentric LV hypertrophy, echocardiographic signs of high LV filling pressures, high renin, and biomarkers of tumor necrosis factor-alpha-mediated inflammation, liver fibrosis, and tissue remodeling. This phenogroup demonstrated evidence of increased large artery stiffness and pulsatile load, but not of resistive arterial load (i.e., microvascular resistance). This phenogroup exhibited the greatest functional impairment and most severe symptoms, with the highest risk of the primary endpoint of cardiovascular death, HF hospitalization, or aborted cardiac arrest. Interestingly, spironolactone randomized therapy appeared to selectively benefit participants in phenogroup 3.

Overall, these findings suggested distinct disease mechanisms across clinical phenogroups of HFpEF, which may benefit from targeted therapeutic interventions. Further studies are required to characterize more detailed measures of aortic stiffness and pulsatile arterial load in various HFpEF phenogroups.

The aorta in HFrEF

Increased aortic stiffness is also important in HFrEF. Pepine et al. reported an increase in invasively measured aortic Zc, among patients with nonischemic cardiomyopathy compared to age-matched control participants.[29] In this study, evidence of increased wave reflections was also found among HFrEF participants. Rerkpattanapipat et al.[30] examined patients with HFrEF as well as age matched and younger control participants. The investigators measured aortic distensibility using MRI and quantified aerobic exercise capacity (VO_2) using ergometry with expired gas analysis. In this study, patients with HFrEF exhibited a markedly decreased distensibility of the ascending aorta and increased aortic wall thickness. Aortic distensibility was strongly and significantly correlated with peak VO_2, and the correlation remained after adjusting for age and LV ejection fraction.[30] Reduced abdominal aortic distensibility was also reported by Giannattasio et al. among patients with HFrEF compared to age- and sex-matched controls.[31]

Interestingly, although aortic stiffening clearly has the potential to contribute to systolic LV dysfunction, some data support a bidirectional relationship, by which LV dysfunction may also result in secondary aortic abnormalities leading to increased pulsatile load. In a canine model of LV dysfunction induced by rapid pacing, Eaton et al. demonstrated that aortic Zc increased in response to LV

systolic dysfunction and this preceded changes in systemic vascular resistance.[32] In another study using a similar canine model, Khan et al. demonstrated that the aortic changes in response to a reduced LV systolic function were due to a change in geometry (smaller diameter and thicker wall), rather to changes in the material properties of the wall (stress-strain stiffness), suggesting that under-expansion of the aorta by a reduced stroke volume may play an important role.[33] This phenomenon may partially explain the reduced distensibility and increased aortic wall thickness reported in humans with HFrEF by Rerkpattanapipat et al.[30]

Large artery stiffness as a predictor of incident HF

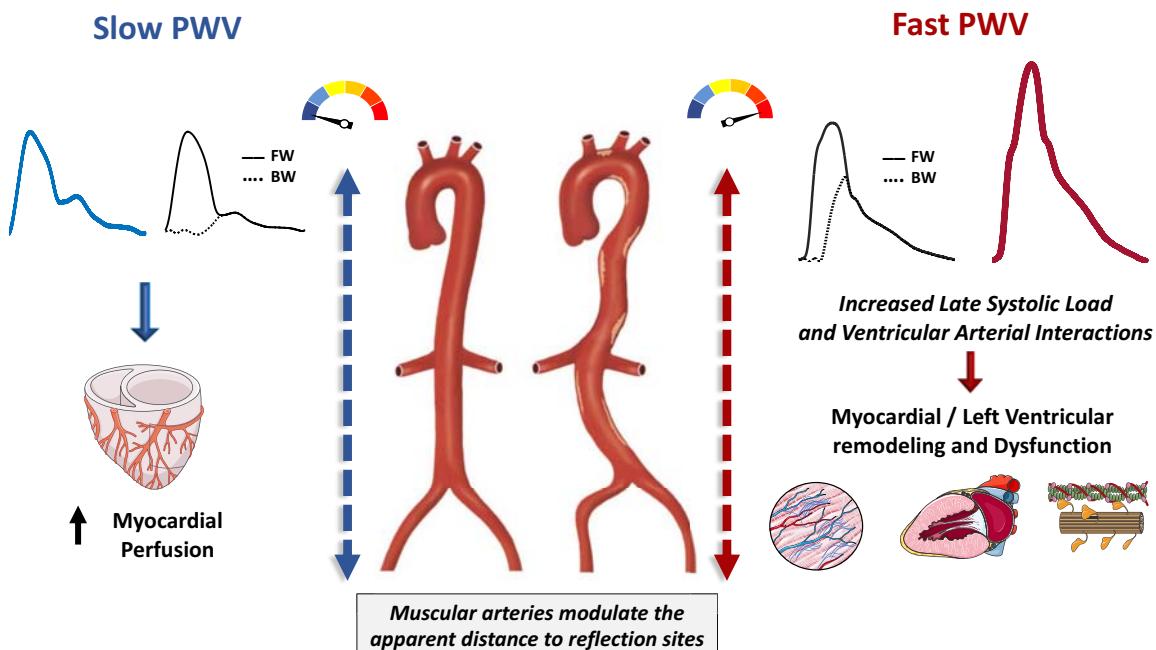
Large artery stiffness predicts the incidence of new-onset HF. In the Framingham cohort, carotid-femoral PWV was associated with an increased risk of incident HF over approximately 10 years, and was associated with both incident HFpEF and HFrEF.[34] In the recent CAVI-J study, which included 2932 participants aged 40−74 years in Japan, an increased cardio-ankle vascular index (a metric strongly influenced by large artery stiffness) was associated with HF hospitalization over a ∼5 year follow-up period.[35] Although the direct causal contribution of aortic stiffening on HF risk remains to be quantified in humans, multiple mechanisms link aortic stiffening to the pathogenesis of LV dysfunction and HF. Whether reducing aortic stiffness using specific therapeutic interventions can reduce the risk of HF remains to be determined.

Large artery stiffness as a predictor of outcomes in established HF

In advanced HFrEF, a lower pulse pressure can be associated with a worse prognosis. In these patients, a low pulse pressure is due to a very poor LV function and small stroke volume. In patients with less severe HFrEF, the relationship may become direct, since in these patients, pulse pressure is more reflective of arterial stiffness and increased pulsatile afterload. In HFpEF, the relationship between pulse pressure and outcomes tends to be direct (a higher pulse pressure being associated with a worse prognosis). In some studies, patients with the lowest pulse pressure also have a worse prognosis, likely due to a small stroke volume, despite a preserved EF due to pronounced concentric remodeling and a small LV cavity.

Given the important confounding effect of LV structure and function on pulse pressure, more direct measurements of large artery stiffness are likely to be informative. An increase in carotid-femoral PWV, aortic PWV or brachial-ankle PWV has been shown to be related to the risk of HF hospitalization, CV, and all-cause mortality in HF patients, regardless of EF.[36,37]

Arterial wave reflection in heart failure

Every beat, the LV generates a pulse wave that travels forward in the arteries and gets partially reflected at sites of impedance mismatch, such as points of branching or changes in wall diameter or material properties along the arterial tree. Innumerable reflections merge into a discrete reflected wave, which travels back to the heart.[12,13,38] Of note, the source of wave reflections is not necessarily the same as the resistance microvasculature, which determines mean arterial pressure.[12,13,38] Therefore, it is possible to modify wave reflections without affecting mean pressure, and vice versa. Important sources of wave reflection include arterial bifurcations, the tapering of the aorta, sites of tortuosity or focal wall stiffening, and/or narrowing in conduit arteries, as well as more distal arterial segments.[12,13,38]


The time of arrival of the reflected wave to the proximal aorta is strongly dependent on the PWV of conduit vessels, particularly the aorta, which transmits forward and backward traveling waves from and toward the LV, respectively.[38–41] Stiffer aortas, which exhibit greater PWV, conduct forward and backward traveling waves at greater velocities and therefore promote an earlier arrival of wave reflections to the LV (Fig. 36.5).[10,12,38,42,43] As a consequence of the aortic stiffening that occurs with aging

and various disease states, the hemodynamic effects of wave reflections shift from diastole to systole, with prominent effects during mid-to-late systole in older adults,[38,42] particularly in women[12,13,42,44–47] and in patients with HFpEF.[16,48,49] In these conditions, wave reflection can have a substantial impact on the LV loading sequence (increasing mid/late relative to early systolic load), as discussed in detail in Chapter 16.

Despite the key role of the aorta as a determinant of reflected wave transit time, it is useful to consider the role of wave reflection along with muscular artery function, given that the latter can modulate the timing and magnitude of wave reflection for any given aortic PWV (Fig. 36.5). Moreover, muscular arterial function represents a readily modifiable target for pharmacologic interventions. However, it should be emphasized that, as mentioned above, wave reflections occur throughout the arterial tree, including the aorta, intermediate-sized conduit arteries, and more distal arterial segments.

Wave reflection and LV hypertrophy

As discussed in various other sections of this book, exaggerated mid-to-late systolic pulsatile load from arterial wave reflections can lead to LV remodeling. For any given level of systolic (peak) blood pressure, prominent

FIGURE 36.5 Cardiac Consequences of Arterial Stiffening and premature wave reflection. Earlier arrival of wave reflections favor a loss of coronary perfusion pressure on one hand, and increased mid-to-late systolic load on the other, due to a shift of wave reflection arrival from diastole to systole. In populations with stiff aortas, muscular artery function may become a key determinant of the apparent distance to reflection sites and thus the effects of wave reflections on the central aorta, for any given PWV. *BW*, backward wave; *FW*, forward wave; *PWV*, pulse wave velocity. *Reproduced from Chirinos JA, Segers P, Hughes T, Townsend R. Large-artery stiffness in health and disease: JACC state-of-the-art review.* **J Am Coll Cardiol**. *2019; 74:1237−1263.*

mid-to-late systolic loading has been shown to exert deleterious effects on LV structure and function in animal models and has been associated with LV hypertrophy in humans, as discussed in more detail in Chapter 16.[38,50,51] Aortic constriction studies in rats[50] that induced early versus late systolic load demonstrated a causal effect of late systolic loading on LV hypertrophy and fibrosis, despite identical peak LV pressure levels. In humans, changes in wave reflection magnitude occurring during antihypertensive therapy predicted regression of LV mass independently of blood pressure reduction.[52] A relationship between reflection magnitude (approximated from measured pressure and an assumed physiologic flow waveform) and LV mass has been reported in large community-based studies that included normotensive and hypertensive individuals.[45,53] Finally, in patients with repaired aortic coarctation, reflection magnitude estimated from the ascending aortic distension waveform and measured aortic flow using MRI was independently associated with LV hypertrophy.[54] When interpreted in the context of available animal data, available human studies support a role for wave reflections in the development of LV hypertrophy, independent of absolute blood pressure levels. Also consistent with animal data implicating wave reflection in the development of LV fibrosis, a relationship between reflection magnitude and LV diffuse interstitial fibrosis has been reported in patients with severe aortic stenosis undergoing aortic valve replacement.[55] Whether this relationship is present in other forms of severe LV pressure overload (i.e., in the absence of aortic stenosis) in humans remains unclear.

Effect of mid-to-late systolic load on LV diastolic dysfunction

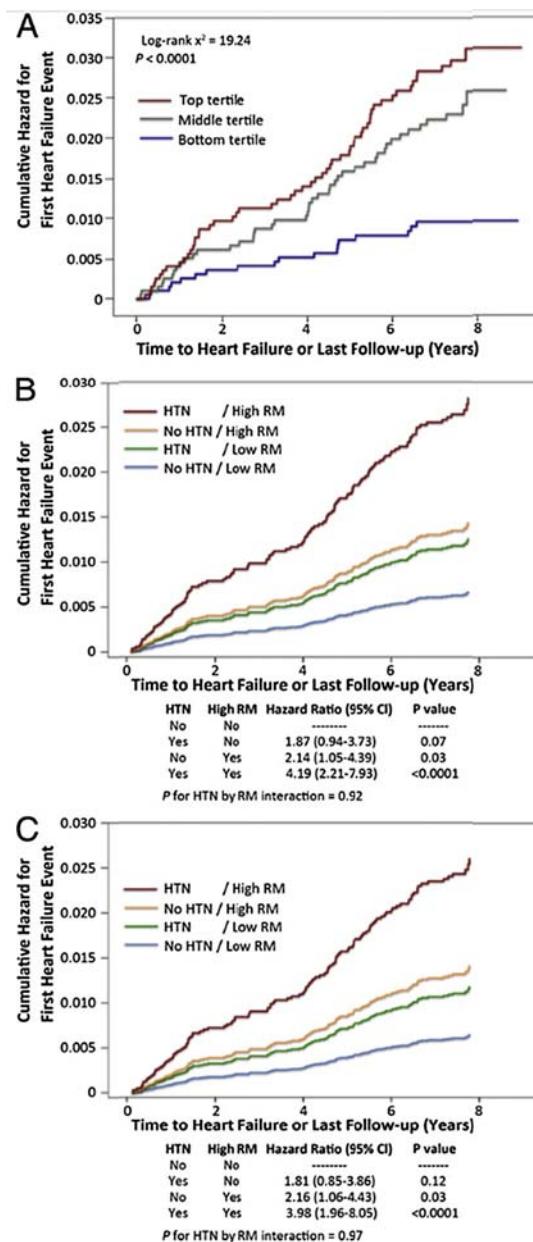
Multiple animal studies have demonstrated the deleterious effect of mid-to-late systolic load on LV relaxation.[51,56−60] Hori et al. used a canine model of aortic clamping and demonstrated that, for a given increase in peak systolic LV pressure, mid-to-late systolic loading interventions prolonged the time constant of diastolic LV relaxation much more than early loading. Gillebert et al.[51] studied the effect of the timing of systolic load in a canine model using rapid balloon inflations in the ascending aorta at different times during ejection (inducing either early systolic load or mid-to-late systolic load), demonstrating that, for a given increase in peak systolic LV pressure, mid-to-late systolic loading prolonged *tau* much more than early systolic inflation.[51] These results are consistent with several other animal studies[57−62] as discussed further in Chapter 16.

Consistent with available animal studies demonstrating a cause-effect relationship between mid-to-late systolic load and impaired LV relaxation, human studies have shown that indices of wave reflections and/or mid-to-late systolic

myocardial wall stress (MWS) are independently associated with diastolic dysfunction,[48,61,63−72] LA remodeling and dysfunction,[65,73,74] decreased longitudinal LV systolic function (despite preserved EF),[67,75] and elevated brain natriuretic peptide levels.[66,71,76,77]

The effect of mid-to-late systolic load on LV relaxation and remodeling may relate to differential cellular processes in different phases of ejection. During early ejection, active development of fiber cross-bridges occurs in the electrically activated myocardium and peak MWS develops,[78] which is followed by a transition from contraction to relaxation.[67,69,78−80] Before this transition, active cross-bridge formation takes place and loading increases the number of interacting cross-bridges (cooperative activity), a physiological mechanism that favors matching of the number of cross-bridges with systolic load.[51,81] However, when increased load occurs after the onset of myocardial relaxation, the number of interacting cross-bridges can no longer adapt, resulting in a mismatch between the number of cross-bridges and load, increasing the stress on individual cross-bridges and decreasing cross-bridge cycling. However, more complex interplays between cross-bridge recruitment, cooperative activity, cross-bridge inactivation, and cross-bridge cycling rate are likely at play.[69,70,79,81]

As discussed in detail in Chapter 16, under normal conditions MWS rapidly decreases during mid-systole as a result of the geometric reconfiguration induced by early systolic LV ejection, resulting in a shift of the LV pressure-stress relation that favors lower MWS levels for any given LV pressure.[78] This shift protects the cardiomyocytes against late systolic load, but may be impaired in LV hypertrophy or LV systolic dysfunction. The resulting mismatch between early and late systolic load may result in impaired shortening-deactivation in cardiomyocytes.[69] The phenomenon of shortening-deactivation (which is associated with reduced calcium sensitivity of the contractile apparatus) decreases force development after early systolic rapid shortening, and increases the relaxation rate of muscle.[69,70] This represents a perfect "match" to the normal physiology (i.e., markedly reduced MWS in mid-to-late systole), because sustained myocardial force development in this period is unnecessary to preserve fiber shortening and LV ejection against the load imposed by wave reflections. However, in the presence of contractile abnormalities that compromise early ejection, the mid-systolic dynamic geometric reconfiguration of the LV that favors a reduced MWS relative to pressure is impaired. In these conditions, shortening-deactivation does not operate fully, such that force development continues or increases in mid-to-late systole.[69,70] However, much remains to be learned about the molecular pathways that mediate malignant effects of late systolic load at the cellular level, and this should be the focus of future research.

Arterial wave reflection and the risk of incident HF


Wave reflection magnitude has been shown to strongly predict new onset HF among 5934 participants in the Multiethnic Study of Atherosclerosis (MESA), who were free of clinically apparent cardiovascular disease at baseline (Fig. 36.6). During 7.61 years of follow-up (and after adjustment for systolic and diastolic blood pressure, age, gender, body mass index, diabetes, ethnicity, antihypertensive medication use, total and HDL-cholesterol, current smoking, heart rate, and glomerular filtration rate), reflection magnitude strongly predicted HF (Hazard ratio per 10% - increase = 2.69; 95% CI = 1.79−4.04; $P < .0001$) and was a stronger predictor than blood pressure and all other modifiable risk factors listed above. When we stratified the population based on the presence or absence of hypertension and the presence or absence of high reflection magnitude (Fig. 36.6B and C), we found that, compared to nonhypertensive subjects with low reflection magnitude (lowest risk category), hazard ratios for hypertensive subjects with low reflection magnitude, nonhypertensive subjects with high reflection magnitude and hypertensive subjects with high reflection magnitude were 1.81 (95% CI = 0.85−3.86), 2.16 (95% CI = 1.04−4.43), and 3.98 (95% CI = 1.96−8.05), respectively.

Furthermore, we assessed the strength of the association between reflection magnitude and incident HF using multiple parameters. Reflection magnitude was associated with the largest Wald statistic of all predictors (including age), the greatest reduction in Akaike's information and Bayesian information criteria (indicating improvement in model fit). With the exception of age, a nonmodifiable risk factor, reflection magnitude was associated with the greatest net reclassification improvement for prediction of HF. Therefore, reflection magnitude was a robust and strong predictor of incident HF in this cohort after adjustment for other known predictors. In the same population, systemic vascular resistance, total arterial compliance, and effective arterial elastance (E_A) did not predict HF.[83] A limitation of this study is the utilization of a synthetic flow approach that approximates reflection magnitude. Further studies are required to assess the association between reflection magnitude and incident HFpEF versus HFrEF.

Hemodynamic role of the microvasculature in HF

The microvasculature as a determinant of LV load

The resistive load imposed by small arterioles throughout the body is the main determinant of the so called "effective arterial elastance" (E_A), which represents the arterial load in the pressure−volume plane (see Chapter 15). Whereas

FIGURE 36.6 (A) Cumulative hazard for heart failure among subjects stratified according to tertiles of reflection magnitude (RM). (B) Hazard function for incident of heart failure in subjects stratified according to the presence or absence of hypertension (prevalence: 45%) or reflection magnitude above ("high" RM) or below ("low" RM) the 55th percentile (prevalence of "high" RM: 45%), adjusted for other significant heart failure predictors. effective arterial elastance is a misnomer (since it bears little relation with arterial stiffness or pulsatile arterial load), E_A does impact the LV EF for any given LV
end-systolic stiffness (the gold-standard load-independent parameter of LV contractility). For an in-depth discussion of ventricular–arterial coupling in the pressure–volume plane, please refer to Chapter 15.

In the setting of marked reductions in LV contractility and LV end-systolic stiffness (as occurs in HFrEF), a high E_A can contribute to an impaired energetic efficiency of the ventricular–arterial system. In this setting, substantial reductions in SVR, with consequent reductions in E_A with the use of arteriolar vasodilators can improve ventricular–arterial coupling, stroke volume, and the energetic state of the failing LV.

In HFpEF (which by definition is accompanied by a normal LV EF and a normal to high LV end-systolic stiffness), the pressure–volume plane is much less informative regarding the variability in energetic aspects of ventricular–arterial coupling, but it does provide some insights into ventricular–arterial interactions. In particular,

in the setting of a high E_A, increased LV systolic stiffness can be necessary to preserve the ejection fraction (thus being implicit in HFpEF), but this results in increased blood pressure lability.[84] In the setting of increased LV end-systolic stiffness, a given reduction in E_A (which as mentioned above is primarily influenced by systemic vascular resistance) will lead to a proportionally greater blood pressure decrease versus a stroke volume increase (Fig. 36.7). Furthermore, an increased LV systolic stiffness at rest will impair the LV chamber contractile reserve (and stroke volume reserve) during exercise. This is particularly problematic in this condition because patients with HFpEF demonstrate an impaired microvascular vasodilatory reserve during exercise, which thus limits the exercise-induced reduction in E_A.[85–88]

This constellation of abnormalities presents a unique challenge for vasoactive therapeutic strategies in HFpEF because important reductions in systemic vascular

FIGURE 36.7 Role of microvascular hemodynamic function in hemodynamics at rest and during exercise. At rest (left panels), the ventricular–arterial system of patients with HFpEF is characterized by increased LV systolic stiffness (i.e., increased E_{ES}, upper left panel, red line). Therefore, any therapeutic intervention that reduces vascular resistance at rest (black curved arrow) (which is the key arterial determinant of "effective arterial elastance," represented in green lines) will induce a large pressure decrease (blue arrow) relative to the increase in stroke volume (orange arrow). Furthermore, given the presence of stiff conduit arteries and premature wave reflections that augment systolic, rather than diastolic aortic pressure, a reduction in mean arterial pressure may decrease diastolic arterial pressure excessively (left lower panel), leading to a reduction of perfusion pressure in key organs. During exercise (right panels), however, a reduction in vascular resistance is essential. A combination of vasoconstriction in most vascular beds (splanchnic vasculature, nonexercising muscle, etc) along with vasodilation in exercising muscle (local functional sympatholysis) is key for the optimization the cardiac output distribution and oxygen supply-demand matching in the periphery. In addition, the lack of reduction in SVR during exercise increases LV load and contributes to the limitation in cardiac output reserve. Microvascular function is also essential for enhancing coronary perfusion during exercise. However, pulsatile hemodynamics also affect myocardial oxygen demand (workload) and supply (diastolic perfusion pressure) during exercise (see text). *DBP*, diastolic blood pressure; *MAP*, mean arterial pressure.

resistance in this population may result in important side effects (such as dizziness and hypotension). However, enhancing vasodilatory reserve (i.e., a selective reduction in systemic vascular resistance with exercise) is a logical goal to enhance aerobic capacity, as discussed below.

Effects of peripheral microvascular function on exercise capacity

In addition to the role of vasodilatory reserve on arterial load and ventricular—arterial interactions during exercise, an abnormal vasodilatory response has profound implications for peripheral oxygen delivery and utilization (Fig. 36.7). Vasodilatory responses during exercise mediate the peripheral redistribution of blood flow to working muscle tissue, which is a key component of the normal hemodynamic response to exercise,[89] and depends on local vasodilatory mechanisms within locomotive muscle, allowing it to advantageously compete with other vascular beds for the available cardiac output.[89] This is a highly suitable adaptive response to balance oxygen supply and demand, given the marked increase in metabolic demands imposed by active skeletal muscle contraction.[89,90] Skeletal muscle vasodilation during exercise allows the local vasculature to overcome humoral and reflex-mediated vasoconstriction.[89] In particular, exercise is accompanied by systemic sympathetic activation, and "functional sympatholysis" must occur in exercising muscle to overcome the intense systemic sympathetic vasoconstrictive response. Based on these principles and experimental evidence, it follows that impaired microvascular responses within skeletal muscle can have important adverse consequences for oxygen extraction, creating a marked imbalance between oxygen delivery and demand in muscle, ultimately resulting in a large oxygen deficit, accentuated intracellular metabolic perturbations, and enhanced glycogenolysis even at low levels of activity.[89]

The importance of flow distribution *within* muscle should also be noted, given that blood flow within active muscles is not homogeneous, but greater in highly oxidative muscles, which require greater vasodilatation.[91,92] Hypoxic vasodilation favors preferential vasodilation in tissues with high oxidative capacity, which seems important to optimize the matching of oxygen supply and demand.[89,90] Finally, microvascular vasodilation in skeletal muscle during exercise is important to washout metabolites (such as hydrogen ions), preventing an excessive afferent stimulus for metaboreflex responses which result in sympathetic activation and vasoconstriction.

Given the important role of the peripheral microvasculature in HF, various studies have assessed exercise-induced vasodilatory responses in HFrEF and HFpEF, as discussed below.

- *Peripheral vasodilatory reserve in HFrEF*: Sullivan et al.[93] compared hemodynamic and metabolic responses to maximal upright bicycle exercise between participants with HFrEF and healthy controls. In this study, mean arterial pressure was not different between the two groups at rest or at matched submaximal work rates, whereas leg vascular resistance was higher in patients compared with normal subjects at rest, submaximal, and maximal exercise. Patients with HFrEF also demonstrated increased leg oxygen extraction and lactate production accompanied by a decreased leg oxygen consumption during exercise. These findings were consistent with impaired local vasodilation leading to leg hypoperfusion in HFrEF, which was associated with decreased leg oxygen utilization (despite increased leg oxygen extraction) and anaerobic skeletal muscle metabolism. Barrett-O' Keefe et al.[94] compared the hemodynamic responses to small muscle mass exercise (static-intermittent handgrip and dynamic single-leg knee-extension) between HFrEF patients and age-matched control subjects. These exercise interventions induce activation of a small amount of muscle mass that does not provoke significant central cardiopulmonary stress, thus better isolating peripheral responses. The investigators demonstrated that despite similar increases in mean arterial pressure during exercise, HFrEF patients exhibited an attenuated increase in arm and leg blood flow. Whereas the former was evident only at high workloads, the latter was present across all work rates, albeit with more substantial attenuations at higher intensities. Wilson et al.[95] reported that the impaired local vasodilatory reserve may be limited to HFrEF patients with a markedly reduced aerobic capacity, whereas impaired cardiac output reserve is a contributor to reduced blood flow in HFrEF, regardless of aerobic capacity. Although the majority of available studies indicate an attenuation in exercising limb perfusion attributable to impairments in peripheral vasodilatory capacity in HFrEF, some data argue against the presence of impaired peripheral vasodilation in this condition.[96] This may be related to a small sample size and/or the heterogeneity in the etiology or severity of HFrEF in different studies.

- *Peripheral vasodilatory reserve in HFpEF*: Although an impaired systemic vasodilatory reserve in HFpEF was reported long ago by Borlaug et al.,[87] thus providing indirect evidence of impaired local vasodilation in exercising muscle, few studies have specifically assessed local skeletal muscle vasodilatory reserve in this condition. Using cardiovascular magnetic resonance imaging during submaximal exercise, Punta-wangkoon et al. reported a reduction in superficial

femoral artery blood flow upon cessation of supine cycling exercise in HF patients (including both HFpEF and HFrEF) compared to healthy controls, despite similar flow in the ascending and descending aorta. These differences, consistent with an impaired blood flow distribution attributable to reduced local conductance (the inverse of resistance) in exercising skeletal muscle in HF, persisted after adjustment for LV EF. Lee et al.[97] compared leg blood flow during dynamic, single leg knee-extensor exercise between HFpEF patients and healthy controls and reported a lower leg vascular conductance at high but not low workloads in HFpEF, which resulted in reduced local blood flow despite similar mean arterial pressure between the groups. Similarly, Ratchford et al.[98] concomitantly evaluated brachial artery blood flow during progressive intermittent handgrip exercise (at 15%, 30%, and 45% of maximal voluntary contraction) among individuals with HFpEF and control overweight individuals with hypertension. In this study, systemic stroke volume and cardiac output were not different between groups across exercise intensities, whereas forearm blood flow was significantly lower ($\sim 20-40\%$) in individuals with HFpEF at higher exercise intensities (30% and 45% of maximum voluntary contraction), and forearm vascular conductance was $\sim 20\%$ lower in HFpEF only at the highest exercise intensity. Overall, these studies support the presence of an attenuation in the vasodilatory response in muscle during exercise in HFpEF, particularly at higher exercise intensities, which is sufficient to induce hypoperfusion of skeletal muscle and is likely to contribute to exercise intolerance in this condition.

The relationship between microvascular dysfunction and adverse central pulsatile hemodynamics remains unclear. On one hand, it is possible that long-term adverse central pulsatile hemodynamics may contribute to microvascular damage in skeletal muscle, although this is less likely than in other organs given the relatively high vascular resistance of the skeletal muscle microvasculature at rest. On the other hand, common risk factors and biochemical pathways may impact vasodilatory responses and pulsatile arterial hemodynamics, and these may represent both mechanistic links between macrovascular and microvascular dysfunction in HFpEF and suitable targets for therapy, as will be discussed later in this chapter. Regardless of whether mechanisms leading to microvascular and macrovascular dysfunction in HFpEF are interrelated, it is clear that both can contribute to the syndrome in general and to impaired exercise capacity in particular, given the important role of pulsatile arterial load on the LV at rest and during exercise.[5,7,99]

Role of the coronary microcirculation

Abnormalities of the coronary microcirculation are increasingly recognized determinants of myocardial function.[100-103] Myocardial blood flow must increase during exercise to match the metabolic demands of the myocardium. Myocardial blood flow occurs predominantly in diastole given the compression of the coronary microvasculature that occurs during systolic myocardial contraction. Impaired myocardial microvascular reserve may impair diastolic myocardial perfusion during exercise, worsening myocardial function and exercise intolerance. Resting myocardial blood flow and flow reserve in response to various stimuli are determined by a complex set of factors, including myocardial tissue architecture, coronary microvascular resistance, and importantly, aortic root pulsatile hemodynamics (see Chapter 18).[5,6]

In patients with a normal LV ejection fraction, normal epicardial perfusion, and risk factors for HFpEF, a decreased myocardial flow reserve is associated with diastolic dysfunction, increased LV filling pressures, and abnormal LA function.[104] Moreover, patients with established HFpEF exhibit myocardial microvascular rarefaction and impaired coronary flow reserve.[100,103,105] Kato et al. assessed coronary flow reserve responses to adenosine among 163 HFpEF patients and found that an impaired response was associated with the risk of all-cause death and hospitalization due to HF exacerbation during a median follow-up of 4.1 years.[106]

Inflammation has been proposed as a key determinant of coronary microvascular dysfunction in HFpEF, but a direct causal link remains to be proven.[107,108] Moreover, microvascular dysfunction in the coronary bed likely represents a component of systemic microvascular dysfunction. More research is required to understand the determinants and the implications of coronary microvascular dysfunction in HFpEF. Finally, the relative role of microvascular rarefaction, abnormal vasodilatory responses in small vessels, and aortic pulsatile hemodynamics as determinants of abnormal coronary flow reserve in HFpEF requires further study.

Coronary flow reserve also seems to be important in HFrEF. Canneti et al. demonstrated an impairment in coronary blood flow reserve in response to adenosine among patients with idiopathic dilated cardiomyopathy despite normal epicardial coronary arteries.[109] Similarly, Morales et al. demonstrated that myocardial blood flow reserve in response to dipyridamole was depressed in patients with idiopathic dilated cardiomyopathy even the in absence of overt HF.[110]

An important aspect neglected by the studies mentioned above is the role of aortic root pulsatile hemodynamics. As discussed in detail in Chapter 18, the diastolic pressure-time integral is a key determinant of coronary blood flow,

given that it represents the driving pressure promoting perfusion across the coronary microvascular bed. Coronary blood flow is directly related to the aortic diastolic pressure-time integral, for any given coronary microvascular resistance and coronary sinus/right atrial pressure. Therefore, coronary flow reserve (assessed via coronary sinus flow measurements) or myocardial flow reserve (assessed via perfusion techniques such as positron emission tomography or MRI perfusion imaging) cannot be equated to coronary microvascular dilatory reserve. Adverse aortic pulsatile hemodynamics can clearly impact the diastolic pressure-time integral and therefore reduce coronary blood flow independently of microvascular rarefaction or vasodilation. Specifically, large artery stiffening and low total arterial compliance will determine a steep pressure decay during diastole,[111] as the arterial volume decreases due to diastolic blood flow to the venous circulation across the systemic capillary bed. Similarly, wave reflections that shift from diastole to systole as a result of a short reflected-wave transit time, fail to augment diastolic pressure and thus coronary perfusion. Despite the importance of these hemodynamic factors as determinants of coronary blood flow, available studies have not separated them from true coronary microvascular resistance and vasodilatory coronary reserve. The extent to which aortic root hemodynamics versus coronary microvascular function are involved in the abnormal coronary/myocardial flow reserve abnormalities in HFpEF described above remains to be determined, but it should be recognized that increased large artery stiffness and wave reflections may conspire with coronary microvascular dysfunction to impair coronary flow, particularly during exercise (in which diastolic duration is shortened). Optimizing aortic root pulsatile hemodynamics may thus represent a suitable therapeutic approach to improve myocardial oxygen supply and demand in HF. A detailed discussion regarding the role of aortic root pulsatile hemodynamics as a determinant myocardial blood supply can be found in Chapter 18.

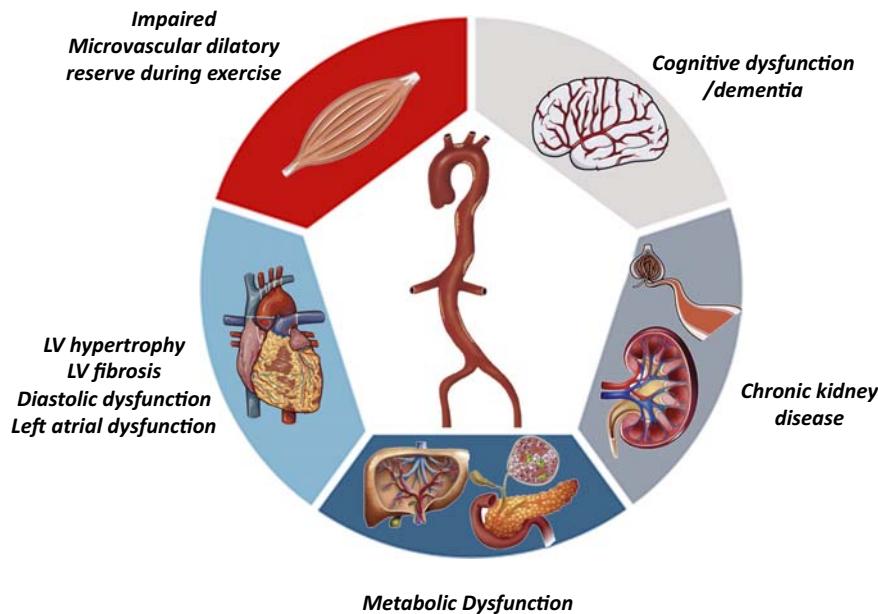
Macrovascular-microvascular cross-talk: role of large arterial pulsatile hemodynamics in microvascular dysfunction and HFpEF comorbidities

There is an increasing recognition of the role of large artery stiffness and abnormal arterial pulsatile hemodynamics on microvascular disease, which is relevant for the damage of target organs such as the brain, the kidney, and possibly, the liver, and endocrine pancreas.[43,112−116] Cognitive dysfunction/dementia, renal dysfunction, and diabetes are highly prevalent in HFpEF, and can significantly influence prognosis.[117−121]

Aortic stiffening and increased wave reflections have important adverse consequences on microvascular pressure and flow. Conduit arteries normally exert a powerful cushioning function, which results in nearly steady flow in the microvasculature despite the intermittent LV ejection. Aortic stiffening results in a loss of this cushioning function and promotes increased pulsatility in the microvasculature. Peripheral vascular resistance, largely imposed by small arteries, governs the amount of mean capillary flow for any given mean arteriovenous pressure gradient (which in turn, depends mostly on mean arterial pressure). Given that mean pressure varies minimally throughout the arterial system, differences in vascular resistance primarily determine the vastly different flow rates seen in various vascular beds. Since resistance is highly correlated with arteriolar tone, it is thought that in low-resistance, high-flow vascular beds, a low precapillary arteriolar tone allows for greater transmission of proximal pulsatility into the capillaries, resulting in increased pulsatile pressure (barotrauma) and pulsatile flow (with excessive pulsatile shear forces). In contrast, the high arteriolar tone in high-resistance vascular beds uncouples the proximal pulsations from the distal capillaries, which are more effectively protected from excessive pulsatility.

Consistent with these principles, accumulating evidence links cerebral microvascular disease and renal disease with increased aortic stiffness.[43,112,114,115] Similarly, the pancreatic islets exhibit very high flow per gram of tissue, and thus low-resistance high-flow physiology.[122] Recent evidence indeed suggests a role for large artery stiffening in the development of diabetes, although a causal link remains speculative at present.[123−125]

Vascular beds with increased resistance (such as skeletal muscle) are relatively (but not entirely) protected from increased central pulsatility. Increased large artery stiffness is also associated with impaired microvascular dysfunction (postischemic vasodilation) in the forearm vascular bed.[113] As discussed above, axial skeletal muscle microvascular function (vasodilatory reserve) is key for exercise-induced vasodilation, flow redistribution, and oxygen extraction during exercise, and is impaired in HFrEF and HFpEF, although its mechanistic link with large artery hemodynamics remains unclear.

Wave reflections are also important for microvascular dysfunction. Wave reflections from the lower body increase central (aortic) pressure pulsatility and thus promote microvascular pulsatility in target organs such as the brain. A more controversial issue is the role of local wave reflection at the aortic-carotid interface, which has been suggested to protect the brain. This is based on the observation that aging is associated with a disproportionate increase in aortic stiffness relative to muscular arterial


stiffness, promoting impedance matching and a reduction in wave reflection in first-order arterial bifurcations in older adults.[114] Loss of wave reflection proximal to target organs (such as at the aorta-carotid interface) has thus been proposed as a mechanism for excessive pulsatile power transmission to the distal circulation. However, impedance matching is not only dependent on wall stiffness, but strongly dependent on vessel size.[126] Therefore, despite substantial differences in PWV between the aorta and muscular arteries, optimization of the size ratio between parent and daughter vessels in the arterial tree[126] optimizes impedance matching in individual first order bifurcations even before the aorta stiffens with age and disease. The configuration of parent and daughter arterial branches, which appears perfectly designed to favor forward energy transmission, is also responsible for the fact that reflections at single bifurcations tend to be quite small, relative to the composite reflected wave arising from the sum of millions of tiny reflections elsewhere. For example, it has been reported that 90% of reflection coefficient values at the aorta-carotid interface were between 0% and 15%,[114] corresponding to power transmission coefficients as high as 97.75%−100%, indicating that such reflections return as little as 0%−2.75% of the pulsatile energy to the parent branch. It is also worth noting that reflections at a single interface tend to increase pulse (and systolic) pressure in the distal branches, which is in principle, deleterious to target organs.

Despite these considerations, some investigators propose an important role of discrete reflections at the entry of low-resistance vascular beds, which requires serious consideration and further study. A recent study by Haidar et al. indicated that a reduced impedance gradient between the proximal aorta and the common carotid arteries leads to a predominant increase in the local flow transmission coefficient despite the low overall reflection coefficient of the bifurcation. Another important factor suggested to play a key role in energy penetration to the brain is the relative impedances of the parent branch (proximal aorta), carotid branches, and distal aortic segments, coupled with distal carotid bed reflections and re-reflections.[127] Interestingly, this study indicated that reflections arising from the distal carotid circulation and re-reflection of these waves at the carotid origin can reduce pulsatile power transmitted into the cerebral vasculature. This is due to the fact that re-reflections at the carotid origin are "open" reflections; that is, reflections arising from the distal carotid circulation, travel down the common carotid in a retrograde direction, and encounter a high-to-low impedance change at its origin from the arch. Open reflection changes the sign of waves and thus results in compression waves being re-reflected at the interface as forward-traveling suction waves that reduce pulsatile pressure and flow (see Chapters 1, 3 and 11).

Despite the potential protective role of local reflections at the aortic-carotid interface and within the cerebral vasculature, it is also important to note that most wave reflections arise from locations distal to the upper body first-order bifurcations and in fact, the larger reflected wave returning from arterial locations distal to the aortic arch penetrates the carotid artery as a "forward" wave (thus increasing pressure and flow in the carotid bed).[43,128] The innumerable reflections from arterial locations distal to the aortic arch form a larger composite reflected wave, which thus demonstrates a larger reflection coefficient, and carries a larger amount of reflected power than the single reflection at the aorta-carotid interface. Furthermore, impedance matching at the aortic-carotid interface may paradoxically promote the penetration of the reflected wave returning from the lower body into the carotid territory. Interestingly, arteries upstream of the cerebral microvasculature appear to attenuate high-frequency flow pulsations (such as those contained in the early systolic carotid flow peak produced by the initial cardiac contraction), much more effectively than low-frequency oscillations (such as those contained in the reflected wave returning from the lower body).[43,128] Therefore, the pulsatile energy from reflected waves arising in the lower body appears to more effectively penetrate into the cerebral microvasculature.[43,128]

Clearly, wave reflections cannot be simply categorized as benign or malignant events for target organs such as the brain, but its origin and interaction with local hemodynamics must be carefully considered. However, the preponderance of evidence suggests that the bulk of systemic wave reflections arising in places other than target organs themselves can be deleterious to target organs via their effects on central pressure pulsatility. Interestingly, vasodilators that reduce wave reflection (such as calcium channel blockers) have been shown to reduce cognitive decline in older adults with systolic hypertension.[43,112,129] This effect on cognitive function is not true for all antihypertensive agents, and is likely independent on the effects of these drugs on brachial blood pressure.

Aortic stiffness and abnormal pulsatile arterial hemodynamics are also deleterious for the kidney, as discussed in detail in Chapter 40. The loss of renal autoregulation (because of altered myogenic tone) is a feature of aging, hypertension, and diabetes,[130−133] all of which are commonly present in patients with HF. Loss of autoregulation favors the transmission of higher pulsatile pressure and flow to the renal microcirculation, leading to glomerulosclerosis. Available data suggest that systemic wave reflections are also deleterious to the kidney, which is expected to the degree that they increase aortic pressure pulsatility.[134] Measures of wave reflection have been shown to predict a poor prognosis in patients with established renal disease.[135,136] Similarly, augmentation index is positively associated with a faster progression of

FIGURE 36.8   Role of arterial hemodynamic dysfunction in HF and HF comorbidities. Abnormal macrovascular and microvascular hemodynamic dysfunction promotes LV diastolic dysfunction, LV maladaptive remodeling (hypertrophy, fibrosis), and causes a reduced vasodilatory reserve during exercise, which in turn impairs coronary flow, peripheral flow redistribution, oxygen delivery, and extraction in exercising muscle. Abnormal pulsatile arterial hemodynamics also contribute to microvascular disease in the brain and the kidney (dementia, chronic kidney disease, which are frequently encountered comorbidities in HF, particular older patients with HFpEF).

established kidney disease,[137,138] and backward wave amplitude is independently associated with a lower glomerular filtration rate[139] and with faster renal function decline over time in the general population, even after adjustment for forward wave amplitude.[140] Furthermore, measures of wave reflection correlate positively with renal resistive index (a measure of renal microvascular dysfunction).[141]

In summary, a host of arterial hemodynamic abnormalities may play a role into the pathophysiology of LV remodeling, dysfunction, abnormal myocardial oxygen supply and demand, exercise intolerance, and the frequent presence of some comorbidities (Fig. 36.8). The arterial tree, therefore, represents an important therapeutic target in patients with HF.

Therapeutic implications

Although modifying aortic wall stiffness represents a high priority goal, the chronic material changes in the aortic wall, including elastin breakdown and degradation, collagen and elastin cross-linking, fibrosis and calcification, impose a formidable challenge for substantial modifications of aortic wall stiffness with short-term pharmacologic interventions. Implantable mechanical interventions to modify arterial pulsatility represent an interesting area of investigation that could be applied in HF, but these are currently in early stages of preclinical development.[142]

Relatively few studies have assessed the impact of pharmacologic interventions on aortic wall stiffness and pulsatile hemodynamics in HF, as discussed below.

Spironolactone

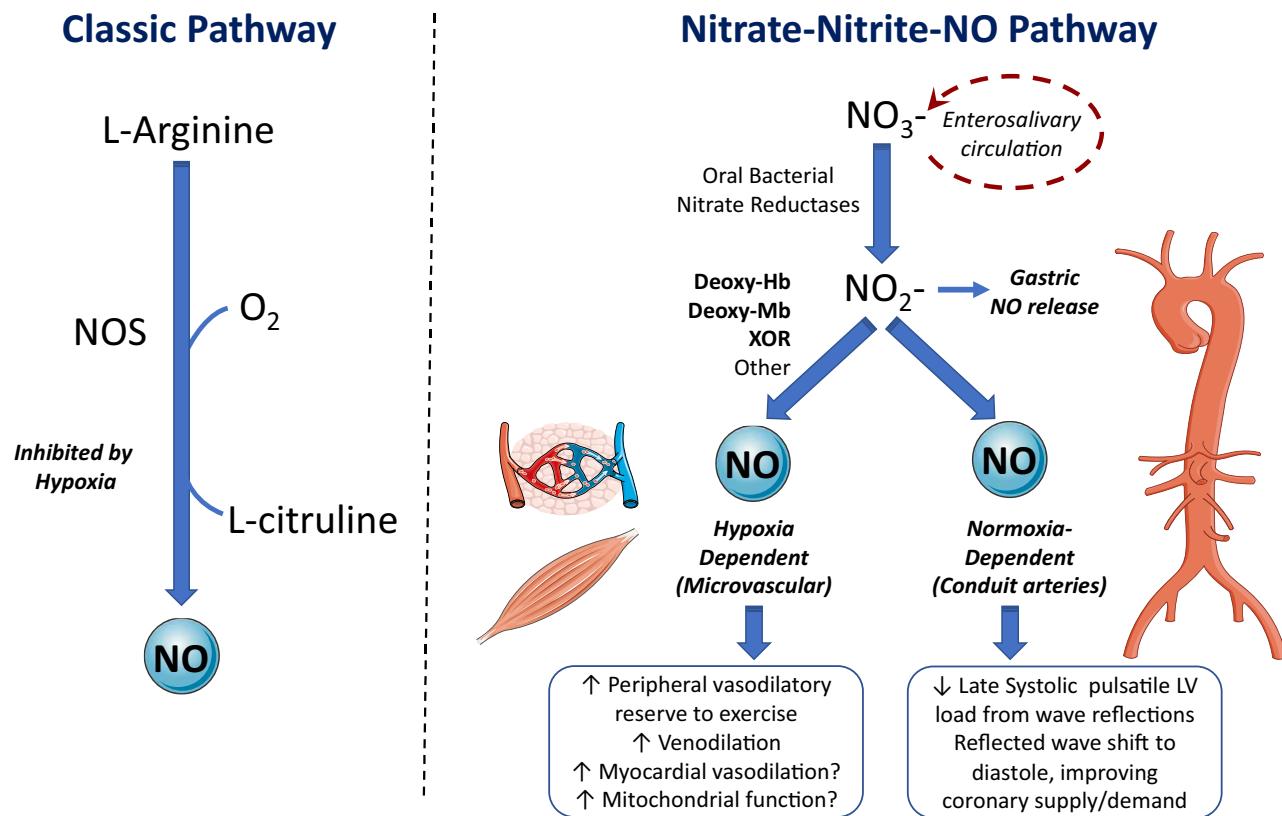
Spironolactone has been studied in both HFpEF and HFrEF. In a randomized controlled trial comparing spironolactone (25 mg/d) versus placebo in elderly patients with stable HFpEF and controlled blood pressure, Upadhya et al. demonstrated that spironolactone therapy for nine months reduced BP but did not improve exercise capacity, quality of life, LV mass, or large artery stiffness.[143] Interestingly, this contrasts with earlier findings by Edwards et al. in a population of patients with chronic kidney disease and LV hypertrophy but not established HF, in which randomized spironolactone therapy (25 mg/d for 40 weeks) significantly reduced carotid-femoral PWV and ascending aortic distensibility.[144] However, it is unclear to what extent the latter results were related to the reduction in mean arterial pressure observed in that trial. Among TOPCAT HFpEF participants enrolled in the Americas, the rates of the primary outcome (a composite of cardiovascular death, aborted cardiac arrest, or hospitalization for the management of HF), as well as individual secondary outcomes (cardiovascular death, and hospitalization for HF) were significantly reduced by spironolactone.[145] However, spironolactone has multiple systemic effects and it is

unclear to what extent any potential benefit of this intervention is mediated by effects on the arterial tree. Similarly, although mineralocorticoid receptor antagonism is clearly beneficial in stage C HFrEF,[146] the extent to which this benefit is mediated by arterial effects is unknown. A more detailed discussion of the effects of mineralocorticoid receptor antagonists on arterial stiffness can be found in Chapter 50.

Vasodilators

The important role of muscular arteries in modulating wave reflection and pulsatile load to the LV suggests that targeting muscular arteries may be a viable therapeutic strategy in HF. Nitric oxide (NO) is an endogenous regulator of wave reflection. Unfortunately, most exogenous NO donors and vasoactive agents exhibit nonselectivity for muscular arteries, producing predominant reductions in arteriolar tone and thus SVR. As described above, this can be beneficial in HFrEF due to the reduced LV end-systolic stiffness, which coupled with a high E_A can contribute to an impaired energetic efficiency of the ventricular—arterial system. In this setting, reductions in SVR, with consequent reductions in E_A induced by arteriolar vasodilators, can improve ventricular—arterial coupling, stroke volume, and the energetic state of the failing LV without markedly affecting mean arterial pressure.[5,8,11] Indeed, various agents that have shown beneficial effects in HFrEF (hydralazine, organic nitrates, angiotensin converting enzyme inhibitors, angiotensin receptor blockers) exert arteriolar vasodilatory effects and may reduce wave reflection, although it is unclear to what extent their beneficial effects are due to various hemodynamic versus neurohormonal factors, particularly for the case of renin-angiotensin-aldosterone system antagonists. A more detailed discussion regarding the effects of commonly used vasodilators on arterial stiffness and arterial hemodynamics can be found in Chapter 49.

In contrast to HFrEF, in which arteriolar vasodilation coupled with effects on muscular arteries can be beneficial, the arterial hemodynamic characteristics of HFpEF dictate a set of much more specific "ideal" characteristics for a hemodynamic intervention, namely, one that: (1) Reduces wave reflections and mid-to-late systolic load at rest (which could improve diastolic function and exert long-term, "disease-modifying" effects on LV maladaptive remodeling); (2) Does not significantly reduce mean arterial or systemic vascular resistance at rest, avoiding hypotension; (3) Enhances exercise-induced vasodilation (reduction in SVR) to reduce LV afterload during exercise; (4) Has selectivity for enhancing local vasodilation in hypoxic/acidotic environments, in order to match blood flow to metabolic demands (i.e., directing blood flow to exercising muscle); (5) Does not vasodilate low-resistance

microvascular beds (target organs), due to their vulnerability to the prominent central pulsatility seen in this older population.


NO donors

NO is a key regulator of various cardiac and peripheral physiologic adaptations to exercise. Two major pathways exist for the production of NO in the cardiovascular system: the classic, NO-synthase dependent pathway, and the more recently recognized nitrate-nitrite-NO pathway (Fig. 36.9).[147]

In the classic pathway, NO synthases (NOSs) catalyze the formation of NO from L-arginine and molecular oxygen. In the nitrate-nitrite-NO pathway, inorganic nitrate (derived from dietary ingestion or from the oxidation of endogenous NO) undergoes a regulated two-step reduction process (nitrate→nitrite→NO). Nitrate (NO_{3-}) is actively concentrated and secreted by the salivary glands and subsequently absorbed in the gastrointestinal tract with high bioavailability (>90%). With each enterosalivary cycle, a small proportion of nitrate is reduced to nitrite (NO_{2-}) by oral cavity commensal bacteria. Some reduction of nitrite to NO occurs in the acid pH of the stomach, with the remainder nitrite undergoing systemic absorption. Circulating nitrite is an immediate precursor to NO.

Nitrite reduction to NO occurs under particular conditions: (a) via hypoxia-dependent reduction, catalyzed by deoxy-hemoglobin, deoxy-myoglobin, xanthine oxidoreductase, and other nitrite reductases; (b) via a more recently described normoxia-dependent reduction pathway that operates in the wall of conduit muscular systemic arteries[148] (Fig. 36.9). Therefore, the nitrate-nitrite-NO pathway mediates a series of effects via normoxic vasodilation of conduit muscular arteries[148] (which thus operates both at rest and during exercise and reduces wave reflection)[99,148–150] in combination with selective microvascular dilation in hypoxic/acidotic conditions (such as occurs in exercising muscle)[147,149,151,152] that seem ideal to improve the prevalent arterial hemodynamic abnormalities in HFpEF. Moreover, inorganic nitrate, in contrast to organic nitrate, does not significantly vasodilate the cerebral vasculature or increase the amount of hydraulic energy transmitted into the carotid artery in HFpEF.[151,153]

Interestingly, two separate studies have recently demonstrated that patients with HFpEF exhibit a reduced circulating NO metabolite pool[154,155] (composed largely of nitrate and to a lesser extent, nitrite), which may limit the activity of this pathway. Exogenous inorganic nitrate supplementation is being investigated as a therapeutic approach in HFpEF. However, there are significant challenges related to the pharmacokinetic and side effect profile of various preparations. Whereas the administration of nitrite (the main "active" NO donor in this pathway) is

possible, nitrite has a very short half-life ($\sim$35−40 min), potentially leading to important waxing and waning of hemodynamic effects, which may activate counter-regulatory responses. In the INDIE HFpEF trial, inhaled inorganic nitrite administered thrice daily for four weeks failed to improve peak oxygen consumption, daily activity levels assessed by accelerometry, quality of life, functional class, cardiac filling pressures assessed by echocardiography, or NT-pro brain natriuretic peptide levels.[156] In contrast to the very short half-life of inorganic nitrite, oral inorganic nitrate has a half-life of $\sim$5−8 h, allowing for steady-state pharmacokinetics with thrice daily adminstration.[151,153] Small trials have demonstrated acute or short term effects of inorganic nitrate on peak exercise capacity and submaximal exercise endurance in HFpEF.[149,153,157] In the single-dose study by Zamani et al., the reduction in measures of wave reflection correlated with the improvement in peak VO$_2$. The main disadvantage of oral nitrate is the variable activation to nitrite by mouth bacteria. An ongoing trial (KNO$_3$CK OUT HFpEF) is assessing the potential efficacy of orally administered potassium nitrate in HFpEF. A more detailed discussion of the nitrate-nitrite-NO pathway can be found in Chapter 51.

Interestingly, organic nitrates do not share the ideal vasoactive characteristics exhibited by inorganic nitrate. In contrast to inorganic nitrate, organic nitrates in HFpEF: (1) induce a less consistent reduction in wave reflection; (2) can markedly reduce mean arterial pressure at rest; (3) lack the selective vasodilatory effect during exercise in exercising muscle; (4) exert prominent cerebrovascular vasodilatory effects, which account for the high incidence of headaches (and may also expose the already susceptible cerebrovascular microvasculature to excessive pressure and flow pulsatility); (5) induce tolerance or pseudotolerance; (6) increase oxidative stress.[151,158,159] In a recent multi-center trial, isosorbide mononitrate reduced outpatient activity in a dose-dependent manner in this population.[160] In another trial,[161] isosorbide dinitrate, with or without hydralazine, failed to improve wave reflections, LV remodeling or the 6-minute walk distance in HFpEF. Furthermore, in the isosorbide dinitrate-hydralazine arm, an increase in wave reflections at 24 weeks was seen, which was associated with worsened 6-minute walk distance and an increased myocardial T1 (assessed by MRI T1 mapping), suggesting adverse interstitial remodeling/fibrosis. In both trials, organic nitrates were poorly tolerated. This is in contrast with available studies with inorganic nitrate which suggest a better tolerability profile.[147,149,151,153,157,162−164]

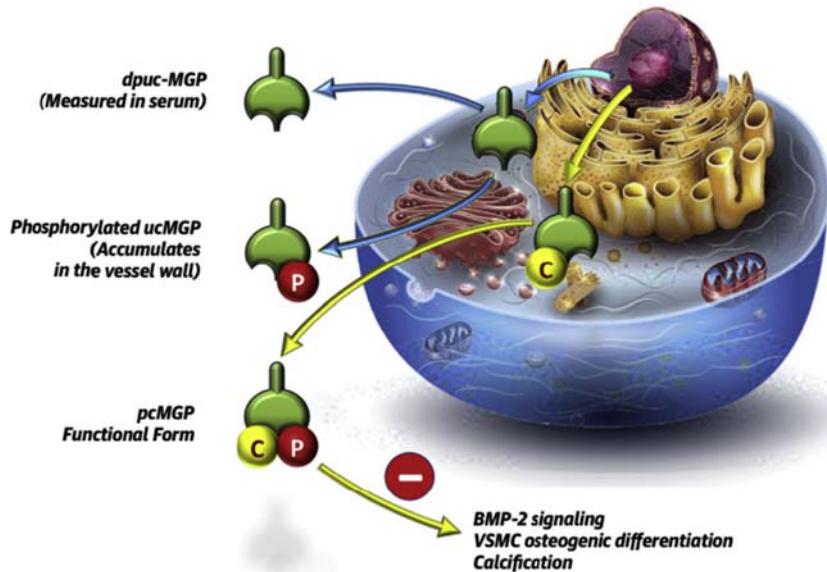
Inorganic nitrate may also have therapeutic potential in HFrEF.[165] It has been shown to increase skeletal muscle

power[166] and to improve exercise tolerance[167] in two previous studies in nonischemic cardiomyopathy, as well as a trial in patients with predominantly nonischemic cardiomyopathy,[168] whereas Hirai et al.[169] reported no effect on exercise capacity in a male population of predominantly ischemic cardiomyopathy. Further research and larger trials are necessary to determine the potential efficacy and therapeutic role of inorganic nitrate in HFrEF.

Soluble guanylate cyclase stimulators/activators

The binding of NO to soluble guanylate cyclase (sGC) (the primary acceptor and sensor of NO) boosts the enzymatic activity of sGC to catalyze the conversion of guanosine triphosphate into inorganic pyrophosphate and cyclic guanosine monophosphate. The latter then acts on downstream effectors, to regulate multiple physiological processes in the cell.[170] The VICTORIA trial demonstrated that vericiguat, a novel oral soluble guanylate cyclase stimulator, reduced the risk of death from cardiovascular causes or hospitalization for HF in patients with HF and an LV EF <45%, although formal evaluations of the effect of this medication on central hemodynamics in humans are lacking.[171] A recent study assessed the central pulsatile hemodynamic effects of vericiguat in hypertensive dogs.[172] It was found that vericiguat did not exert significant effects on mean arterial pressure or diastolic blood pressure. In contrast, parameters of arterial wave reflection exhibited significant reductions starting from the first hour of administration. Significant dose-dependent reductions in reflection magnitude and augmentation index were seen, with minimal effects detected on forward wave amplitude (which changed only with high doses). This study demonstrates that sGC stimulation can reduce wave reflection even at doses that do not reduce blood pressure, likely via effects on muscular arteries rather than resistance arterioles. The extent to which this effect mediates its benefits in HFrEF remains unknown.

Importantly, sGC stimulators (including vericiguat) have not proven effective in improving quality of life or peak aerobic exercise capacity in HFpEF.[173,174] Whereas the recent study in hypertensive dogs mentioned above suggests that sGC stimulation can produce some of the desirable hemodynamic effects for the HFpEF population (1 and 2 above), it is unlikely that sGC stimulators exhibit exercise-induced selective effects that may be key to improve exercise hemodynamics. sGC stimulators are discussed in more detail in Chapter 51.

Neprilysin inhibitors


Neprilysin inhibitors represent another important drug class with relevant hemodynamic effects in HF, which work by blocking the action of neprilysin, a membrane metallo-

endopeptidase that cleaves natriuretic peptides, glucagon, glucagon-like peptide-1, bradykinin, substance P, neurotensin, oxytocin, enkephalins, angiotensin I, endothelin-1, adrenomedullin, amyloid β, and others. Sacubitril/valsartan (formerly called LCZ696) consists of an ARB, valsartan, and a neprilysin inhibitor, sacubitril, in a 1:1 molecular ratio.[174] The PARADIGM Heart Failure trial demonstrated that sacubitril/valsartan was superior to enalapril in reducing the risk of death and hospitalization for HF in HFrEF.[175] In contrast, the PARAGON trial demonstrated that sacubitril-valsartan did not reduce the risk of hospitalization for HF and death from cardiovascular causes among patients with HF and an LV EF ≥ 45%. However, in prespecified subgroup analyses, there was suggestion of heterogeneity with possible benefit with sacubitril-valsartan in patients with lower EF (45%−57%) and in women. Interestingly, in the latter trial, pulse pressure was significantly lower in the sacubitril/valsartan group compared with the valsartan group one year after randomization. Moreover, pulse pressure was an independent predictor of cardiovascular events in this trial.

The EVALUATE-HF study was specifically designed to compare the effect combined angiotensin-neprilysin inhibition with sacubitril-valsartan versus enalapril on changes in central aortic stiffness in patients with HFrEF, and demonstrated no significant difference in the primary end point of change from baseline to 12 weeks in ascending aortic Zc.[176,177] In a subsequent analysis of the data which examined effects of treatment on aortic Zc at 4 and 12 weeks after randomization, treatment with sacubitril-valsartan was associated with a greater acute (postdose) reduction in aortic Z_c compared to enalapril. The investigators also found evidence of effect modification by LV EF, such that in the lower LV EF group (LV EF<40%), there was evidence of an acute, postdose reduction in Z_c in the sacubitril-valsartan group, with no evidence of effect modification by sex, which was proposed as a possible contributor to the favorable clinical outcomes seen in the PARADIGM-HF study. In the higher LV EF group (LV EF ≥ 40%), there was evidence of effect modification by sex, with evidence for a reduction in Z_c in women only, which persisted throughout the dosing interval and remained significant after further adjustment for baseline and change in mean pressure, consistent with a pressure-independent favorable effect of sacubitril-valsartan on aortic Z_c. Importantly, however, the high LV EF group in this study is unlikely to represent true HFpEF, but more likely HF with midrange EF or recovered LV EF. Finally, none of these analyses reported effects on wave reflection, which is a key phenotype in both HFpEF and HFrEF.

The matrix gla protein pathway

Matrix gla protein (MGP) is a small secretory protein produced by chondrocytes and vascular smooth muscle

FIGURE 36.10 Vitamin K-dependent Matrix Gla protein (MGP) maturation. MGP maturation requires vitamin K and leads to the formation of pc-MGP (phosphorylated, carboxylated MGP), which is a strong inhibitor of vascular calcification via inhibition of bone morphogenetic protein 2 (BMP-2) signaling and vascular smooth muscle cell (VSMC) osteogenic-differentiation. Vitamin K deficiency in the vascular wall leads to the formation of uncarboxylated (uc-) MGP (which accumulates in the vessel wall) and dephosphorylated, uncarboxylated (dpuc-)MGP, which can be measured in serum. *MGP*, matrix gla protein.

cells (VSMCs).[178] Its inactive form, dephospho-uncarboxylated MGP (dp-ucMGP), must undergo serial posttranslational carboxylation and phosphorylation to become active (Fig. 36.10). Active MGP is a potent inhibitor of arterial calcification by inhibiting bone morphogenetic protein-2-induced osteogenic differentiation of VSMCs, and via calcium phosphate scavenging. Carboxylation of MGP is dependent upon the availability of vitamin K in the vascular wall.[178] Vascular vitamin K deficiency appears to occur at lower thresholds of severity than those leading to coagulopathy and can be completely unapparent on standard clinical testing. Since dp-uc-MGP (inactive MGP) is secreted into the circulation, it represents a circulating biomarker of vascular vitamin K availability/deficiency. An increase in circulating dp-uc-MGP has been shown to be independently associated with increased large artery stiffness in various populations, including the general population,[179,180] adults with diabetes,[181] hypertension,[182] chronic kidney disease,[183] and HF with preserved or reduced ejection fraction.[184] It has been shown that warfarin inhibits MGP carboxylation/activation and is a potent promoter of vascular calcification in animal models. Hasmath et al. demonstrated that warfarin is associated with increased large artery stiffness in HF, and this relationship was dependent on the relationship between warfarin use and dp-uc-MGP.[184] With the current availability of novel oral anticoagulants that, in contrast to warfarin, do not interfere with vitamin K-dependent carboxylation, it may be possible to target MGP with vitamin K2

supplementation in HF. Whether this will represent a useful approach to improve outcomes in this patient population remains to be determined.

Conclusions

Compelling evidence from animal and human studies strongly suggest that large artery stiffness and pulsatile arterial hemodynamics (particularly increased and/or premature wave reflections) represent key phenotypes and relevant therapeutic targets in HF. In addition to their impact on the LV, increased aortic stiffness and abnormal pulsatile hemodynamics are linked to microvascular disease in the brain, the kidney, and other extracardiac organs, and are thus relevant for common HF comorbidities that impact the clinical course of HF. Reductions in large artery stiffness and/or improvements in pulsatile hemodynamics may be involved in the benefit seen with various available agents in HF. However, comprehensive hemodynamic profiling in large studies or randomized trials has been rather limited to date, and should be more widely applied in future studies.

Chapter 37

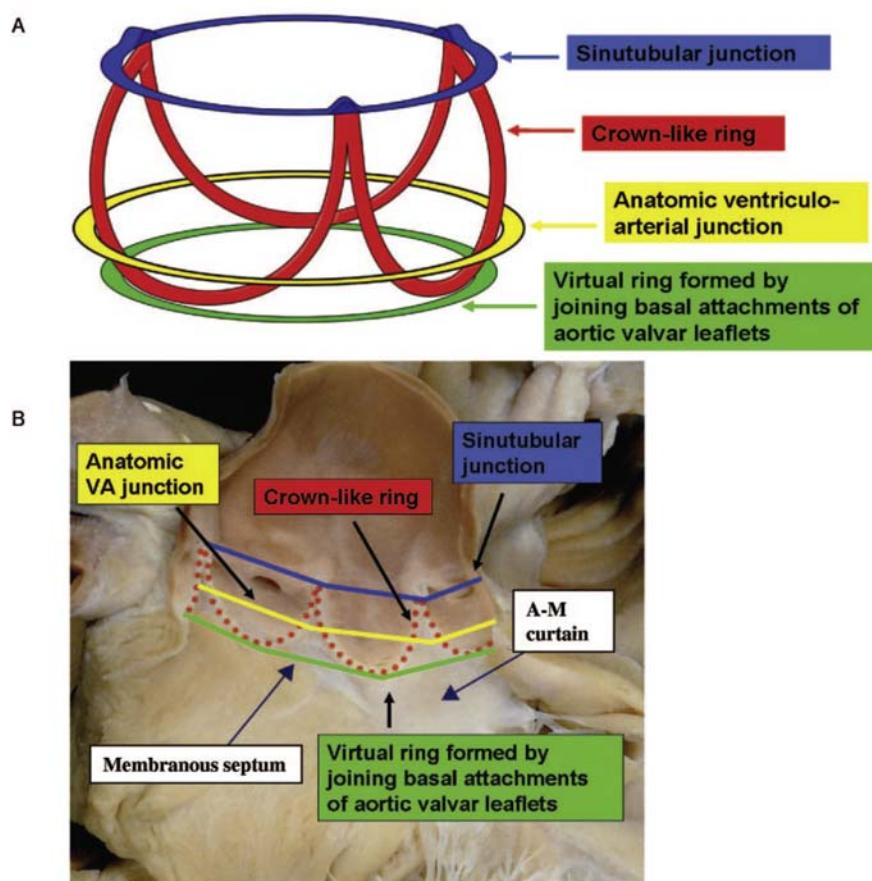
Ventricular–arterial coupling and arterial load in aortic valve disease

Ezequiel Guzzetti, Nancy Côté, Marie-Annick Clavel and Philippe Pibarot
Institut Universitaire de Cardiologie et de Pneumologie de Québec / Québec Heart & Lung Institute, Laval University, Québec City, QC, Canada

Introduction

A harmonious anatomical and functional interrelation between the left ventricle (LV), the aortic valve, and the aorta is key to ensure both adequate blood flow and driving pressure to ensure perfusion to all body organs.[1] Any abnormality—congenital or acquired—of the LV myocardium, LV outflow tract, aortic valve, aortic root, or arteries may compromise the complex anatomical and functional coupling between these components which, ultimately, may lead to heart failure and death. In recent years, there has been important progress in noninvasive advanced cardiovascular imaging (Doppler echocardiography, multidetector computed tomography [MDCT], and cardiovascular magnetic resonance [CMR]), which coupled with hemodynamic modeling, will allow for detailed assessments of ventriculo–valvular–arterial coupling in both health and disease. The purpose of this chapter is to describe the morphological and functional interplay between the LV, the aortic valve, and the aorta and its implications with regards to the diagnosis and treatment of aortic valve disease.

Anatomical interaction between the LV, aortic valve, and aortic root

Anatomical interrelation between the LV outflow tract, aortic valve, and aortic root


The aortic valve is composed of three semilunar leaflets that are attached to the aortic root. Thus, the aortic root can be divided by the semilunar attachment of the leaflets into supravalvular and subvalvular components (Fig. 37.1).[2] The supravalvular component is represented by the three sinuses of Valsalva, two of which host a coronary ostium. The flow vortices created in the sinuses reduce mechanical stress on the aortic leaflets and support coronary blood flow.[3] Hence, effacement of the sinuses may impair coronary flow and increase the mechanical stress and ensuing structural degeneration of aortic valve leaflets.

The subvalvular component consists in the LV outflow tract, which is surrounded by both myocardium and fibrous tissue. Under each commissure of the leaflets lies one of the three interleaflet triangles, which are, in fact, extensions of the LV outflow tract and reach the level of the sinotubular junction in the area of the commissures. The triangle between the left and noncoronary sinuses forms a part of the mitro-aortic curtain that leads to the anterior mitral leaflet. The triangle between the right and noncoronary sinuses forms part of the membranous septum.[4] This area is of particular importance during aortic valve procedures (especially transcatheter aortic valve replacement [TAVR]), as injury at this level can lead to conduction abnormalities, which may require the implantation of a permanent pacemaker.[5]

Due to their semilunar configuration, the leaflets of the aortic valve are attached in crown-like fashion with a basal ring at the bottom of leaflet insertion, i.e., the aortic "annulus" and an upper ring at the level of the sinotubular junction (Fig. 37.1). The aortic annulus that is measured clinically by echocardiography, MDCT, or CMR for diagnostic or therapeutic purposes (e.g., selection of valve size for transcatheter aortic valve implantation) corresponds to the circle at the base of the crown formed by the leaflets.[6] However, the aortic annulus is not a real and distinct anatomic entity, as it does not correspond to the basal contour of the aortic valve, which is not circular but rather has a tripoint crown shape. Furthermore, the aortic annulus is a dynamic structure, with larger and more circular cross-sectional area during systole than diastole.[7] Ultimately, the aortic annulus represents the landing zone of most TAVR devices, and thus its accurate measurement is essential to determine the size of the prosthetic valve to be implanted.[6]

Bicuspid aortic valve and aortopathy

The normal architecture of the aortic valve is a 3-cusp (tricuspid or trileaflet) configuration. However, some subjects may have a bicuspid, unicuspid, or quadricuspid configuration. Bicuspid aortic valve (BAV) is the most common congenital heart defect, affecting 1%–2% of the population and three men for one woman.[8,9] All combination of cusps fusion with and without raphe are theoretically possible, but the most common types are fusion of the right and left coronary leaflets (60%) and fusion of the right and the noncoronary leaflets (35%) (Fig. 37.2).[10] Despite the evidence of an autosomal dominant pattern of BAV inheritance with variable expression and incomplete penetrance in families, the genetic determinants of BAV are far from being elucidated.[11,12] Patients with BAV have a high risk of developing aortic valve dysfunction, i.e., stenosis and/or regurgitation, and show a higher rate of progression of aortic stenosis (AS) than those with trileaflet (tricuspid) aortic valves.[13] The lifetime risk of aortic valve replacement for AS in subjects with BAV is about 50%.

BAV has been associated with other congenital defects, and in particular aorta dilation, aneurysm, and dissection.[9]

The link between BAV and aorta dilation/aneurism is likely multifactorial with a genetic basis and a possible impact of flow pattern induced by BAV type (Fig. 37.3, – A).[14] The eccentric aortic blood flow generated by the BAV increases the radial forces and thus the stress on the aortic wall, thus causing a dilation of the aortic root.[12,15] This phenomenon is more pronounced in patients with BAV and AS (Fig. 37.3, Panel B).[12] On the other hand, the genetic basis for aortic dilation is supported by the fact that aortopathy is often present in relatives of patients with BAV. The structural support and elasticity of the aorta are achieved by alternating layers of elastic lamellae and smooth-muscle cells (Fig. 37.3, Panel C). In subjects with a trileaflet aortic valve, the smooth-muscle cells in the aorta are secured to the adjacent elastin and collagen matrix by fibrillin 1 microfibrils. The aorta of subjects with a bicuspid valve may be deficient in fibrillin 1, which causes a disruption of the histological architecture of the aortic wall whereby smooth muscle cells detach, leading to weakened structural integrity and reduced elasticity of the aorta.[12] Disruption of the histologic architecture of the aortic wall has also been observed in subjects with bicuspid valves in the absence of any identifiable genetic or mechanical explanation.

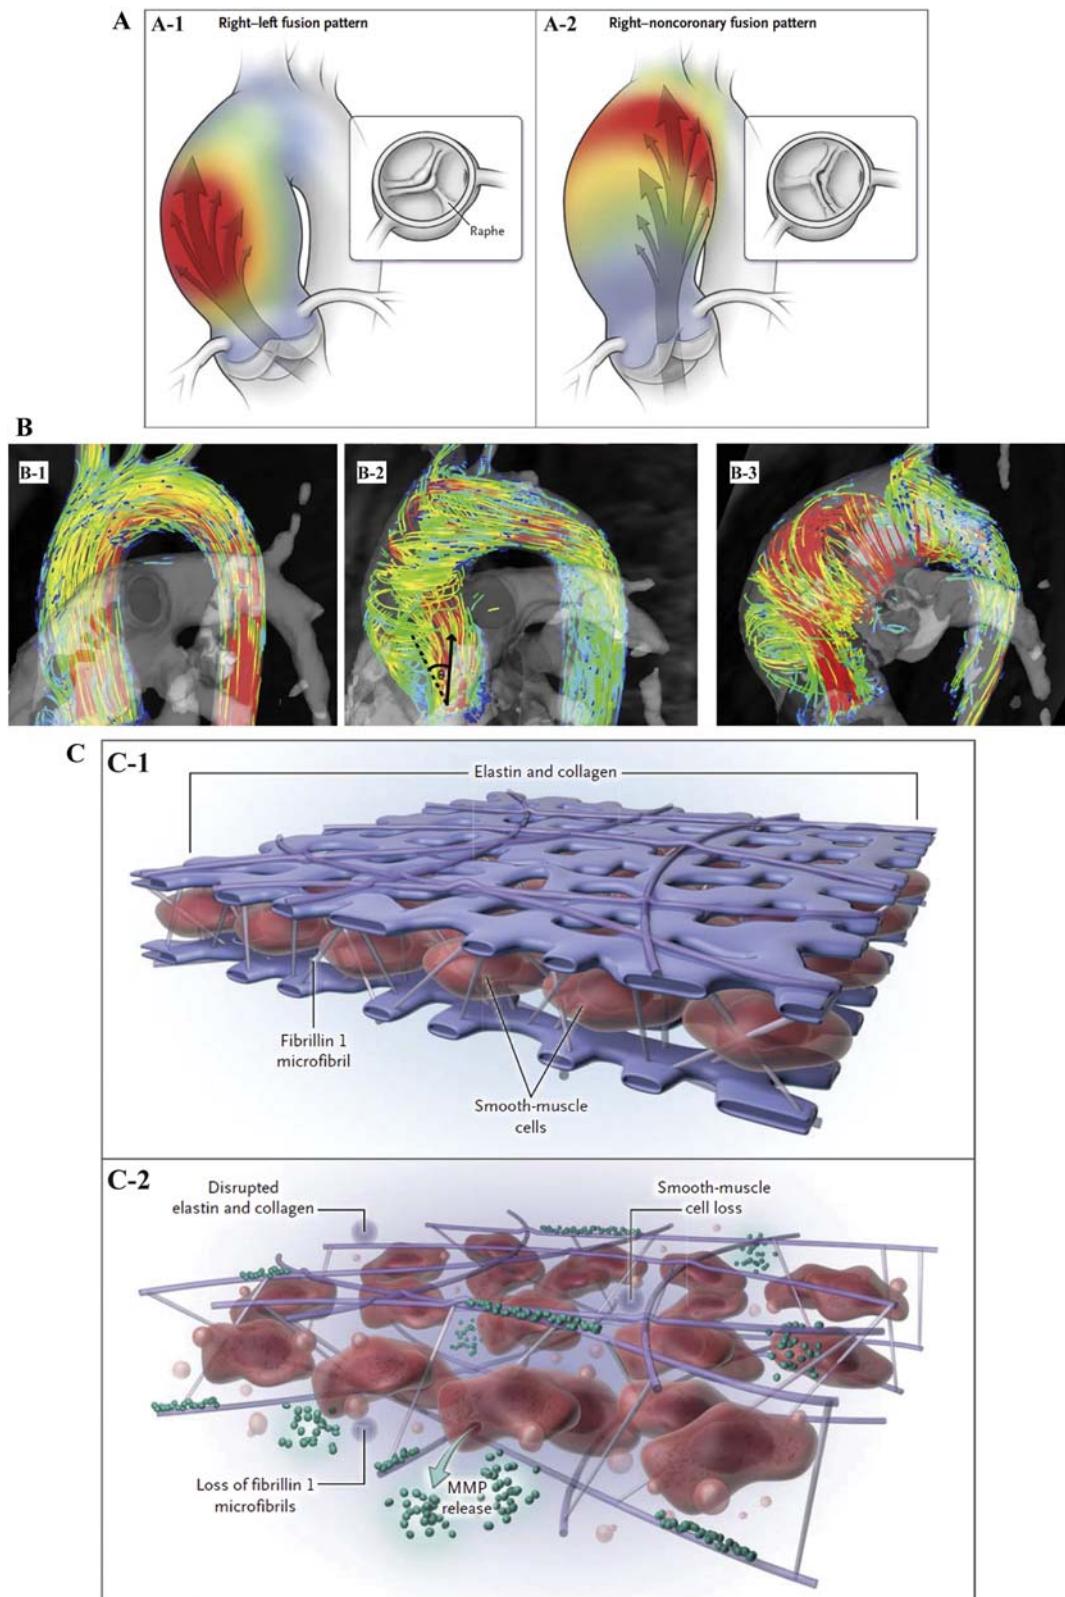
Functional interaction between the left ventricle, aortic valve, and aorta

Ventriculo−valvulo−arterial coupling


The dynamic interaction between the heart and the systemic circulation allows the cardiovascular system to be efficient in providing adequate cardiac output and arterial pressures to ensure adequate organ perfusion in different physiological conditions, such as rest and exercise. The cardiovascular system indeed works better when the heart and the arterial system are coupled.[16] The ventriculo−arterial coupling is achieved by the continuous modulation of the arterial system compliance and resistance with respect to LV systolic performance, and this physiological process is key to maintain adequate LV stroke volume and cardiac output.[17] Because LV stroke volume depends on myocardial contractility and loading conditions (i.e., preload and afterload), any myocardial, valvular, and arterial dysfunction can lead to ventriculo−arterial decoupling with resulting decrease in LV myocardial contractility, stroke volume, cardiac output, and organ perfusion,[16,18,19]

One approach to quantify ventriculo−arterial coupling is via the ratio of the effective arterial elastance (Ea) to the ventricular elastance (Ees) measured on the LV pressure−volume loop (Fig. 37.4, panel A).[17,20] Ea is calculated as the ratio of the end-systolic pressure to the LV stroke volume and is usually considered a measure of the arterial hemodynamic load imposed on the LV. Ees describes the maximal pressure that can be developed by the ventricle at any given LV volume. Ees is an index of myocardial contractility that is relatively insensitive to changes in preload, afterload, and heart rate. The Ea/Ees ratio is useful to evaluate the mechanical efficiency of the cardiovascular system and the interaction between cardiac performance and systemic vascular function. An unbalance between Ea and Ees as reflected by an increase or decrease in the Ea/Ees ratio may lead to heart failure. The main limitation of this approach to assess ventriculo−arterial coupling is that Ea is merely a function of systemic vascular resistance and heart rate and is insensitive to pulsatile arterial load.[21,22] Hence, Ea is not an optimal and comprehensive metric of true arterial load. Assessment of ventricular−arterial coupling in the pressure−volume plane is discussed in detail in Chapter 15.

Impact of aortic stenosis on ventriculo−arterial coupling

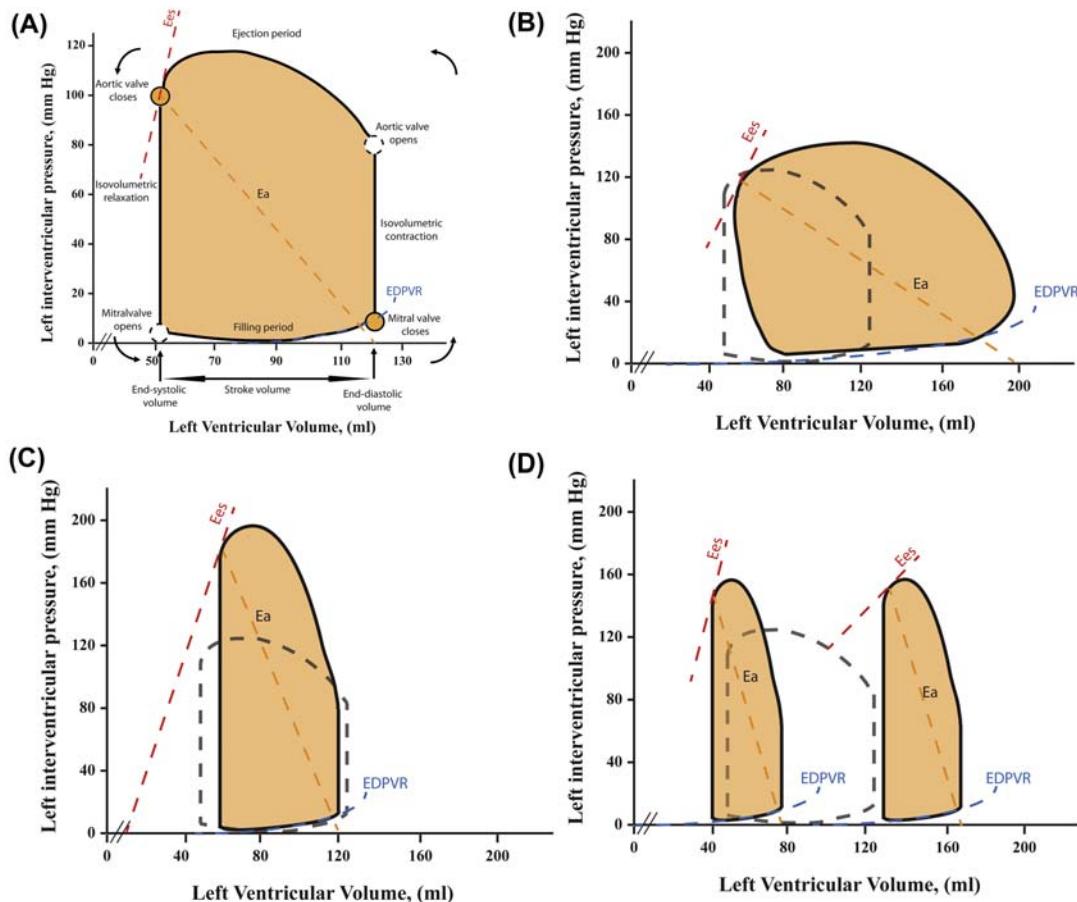
AS is the most common disease of the aortic valve. In AS, the LV afterload is increased and as a consequence, the LV stroke volume is reduced and the LV peak systolic pressure

FIGURE 37.3   Morphological and pathophysiological features of aortopathy in subjects with a bicuspid aortic valve. Panel A shows the fusion configuration of the aortic-valve cusps lays the foundation for changes in aortic wall shear stress and the resultant flow pattern. In the right—left fusion pattern (A-1), the jet is directed toward the right anterior wall of the ascending aorta, where it travels in a right-handed helical direction to promote

and end-diastolic pressures are increased (Fig. 37.4, panel C). The stroke work, which is the area enclosed within the LV pressure—volume loop, is increased. With advanced severity of AS, Ea increases and Ees decreases resulting in a marked augmentation of the Ea/Ees ratio and ventriculo—arterial "decoupling." A ratio >1.0 is a marker for the development of heart failure.

Ea is calculated from the LV end-systolic pressure and therefore is influenced by arterial load but does not include the valvular load per se. This valvular load is negligible in patients with a normal aortic valve but is markedly increased in patients with severe AS. To estimate the true total (i.e., arterial + valvular) hemodynamic load that the LV is facing in patients with AS, one can calculate the valvulo—arterial impedance, which is the ratio of the LV peak systolic pressure to the stroke volume index (Figs. 37.5B and 37.6).[23,24] The LV systolic pressure can be estimated noninvasively by Doppler echocardiography by adding the mean transvalvular gradient to the systolic blood pressure. The rationale for using the stroke volume index rather than the unindexed stroke volume as in the Ea is that a small-size subject may have a much smaller stroke volume than a large-size subject but nonetheless similar arterial and LV pressures. The valvulo—arterial impedance represents the valvular and arterial factors that oppose ventricular ejection by dissipation of the mechanical energy developed by the LV. As opposed to Ea, this parameter also includes the valvular load (i.e., the mean transvalvular gradient) and it accounts for the interindividual variability in body size. Valvulo—arterial impedance values > 4.5 mmHg/ml m^2 have been shown to provide incremental value to predict symptoms, heart failure, and mortality in patients with AS.[24,25]

The stroke volume index is a good surrogate marker of the ventriculo—arterial coupling and of the overall performance of the cardiovascular system in patients with AS (Fig. 37.6). Several studies and metaanalyses reported that a low flow state defined as a stroke volume index <35 mL/ m^2 (or <40 mL/m^2 in men and <32 mL/m^2 in women[26]) is a powerful predictor of outcomes in patients with AS both before and after aortic valve replacement.[27,28] Although

from a mechanistic standpoint, it may be interesting to measure Ea, Ees, and Ea/Ees ratio in patients with AS, from a practical standpoint, however, it may be preferable and easier to measure the valvulo—arterial impedance (i.e., a marker of the true total LV hemodynamic load) and the stroke volume index (i.e., a downstream marker of ventriculo—arterial decoupling). These two parameters can easily be measured in the echocardiography laboratory and have shown to correlate well with invasive measurements.[29]


Impact of aortic regurgitation on ventriculo—arterial coupling

Aortic valve regurgitation (AR) causes a volume overload in the LV as well as in the arterial system. In patients with AR, the LV end-diastolic volume is markedly increased due to the enhanced ventricular filling. In the compensated phase of the disease, the LV contractility increases as a result of the increased preload and the Frank—Starling mechanism and the LV end-systolic volume is only slightly increased (Fig. 37.4, panel B).[30] As a consequence, the LV stroke volume, LV stroke work, and LV systolic pressure increase. The Ea/Ees ratio is decreased compared to normal. In the decompensation phase of the disease, the LV end-systolic volume increases markedly, the LV contractility drops, and thus the LV stroke volume and systolic pressure fall. Furthermore, the arterial load (Ea) is increased. As a consequence, the Ea/Ees ratio increases and there is ventriculo—arterial decoupling.

Interaction between LV outflow tract and aortic valve

When the blood flow passes through the aortic valve, there is a contraction of the flow and for that reason, the valve anatomic orifice area (AOA) is always larger than the valve EOA, which represents the cross-sectional area of the vena contracta (i.e., smallest section) of the transvalvular flow jet (Fig. 37.5, panel A; Fig. 37.6).[31,32] In the situation of a normal aortic valve, there is no or minimal flow contraction

---

dilatation predominantly of the ascending aorta. In the pattern with fusion of the right and noncoronary cusps (A-2), the jet is directed toward the posterior wall of the aorta, whereby the pattern of wall shear stress it causes may promote aortic dilatation within the proximal arch. Panel B shows the flow patterns in bicuspid aortic valve disease. (B-1) Normal flow pattern, (B-2) right-handed helical flow, and (B-3) left-handed helical flow. The systolic flow angle (θ) is demonstrated in B-2: the angle between the aortic midline (dashed) and the instantaneous mean flow vector at peak systole (*arrow*). Panel C shows the structural support and elasticity are afforded to the aorta by means of alternating layers of elastic lamellae and smooth-muscle cells. At the histologic level, the smooth-muscle cells in the aorta in persons with tricuspid valves are secured to the adjacent elastin and collagen matrix by fibrillin 1 microfibrils (C-1). The aorta in persons with bicuspid valves may be deficient in fibrillin 1. This deficiency culminates in a disrupted architecture whereby smooth muscle cells detach, accompanied by a surge in local levels of matrix metalloproteinases (MMPs), leading to loss of integrity in the extracellular matrix and the accumulation of apoptotic cells. These events may lead to an aorta with weakened structural integrity and reduced elasticity (C-2). *Panels A and C Reproduced with permission from Verma S, Siu SC. FIGURE 37.4   (Central Figure): Ventriculo—valvulo—arterial coupling, assessed in the pressure—volume plane, in normal condition, aortic regurgitation, and aortic stenosis. This figure shows the LV pressure—volume loops for different situations including normal condition (A), severe aortic regurgitation (B), severe aortic stenosis with high gradient (C), paradoxical (preserved LV ejection fraction) and classical (reduced LV ejection fraction) low-flow, low-gradient aortic stenosis (C). The dashed pressure—volume loop on Panels B—D represents the loop in normal condition. *AS*, aortic stenosis; *Ea*, arterial elastance; *EDPVR*, end-diastolic pressure—volume relationship; *Ees*, ventricular elastance (end-systolic pressure—volume relationship).

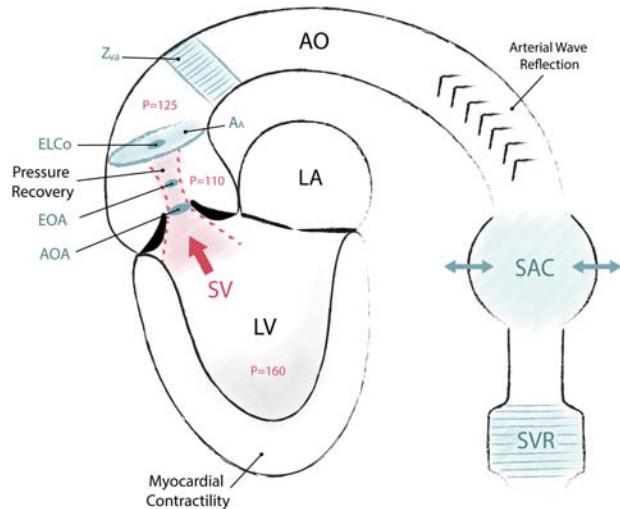
at the level of the aortic valve and thus the EOA is almost equal to the AOA. In this situation both the AOA and EOA are normal and there is no or minimal pressure drop and thus energy loss across the aortic valve. However, in the presence of AS, the AOA is reduced because of the fibro-calcific remodeling of the valve leaflets and the EOA is further reduced compared to the AOA because of significant flow contraction that occurs downstream of the valve orifice. The transvalvular pressure gradient and thus the LV pressure overload are essentially determined by the EOA and the smaller the EOA the larger are the gradients and, ultimately, the LV pressure overload (Fig. 37.6). The accurate assessment of the hemodynamic severity of the valvular stenosis is crucial for clinical decision-making in patients with AS. The severity of AS is generally determined by measuring the pressure gradient across the valve or, preferably the EOA, since it is less flow-dependent (Fig. 45.5B). The EOA can be measured either by Doppler echocardiography with the use of the continuity

equation or by left heart catheterization with the Gorlin formula.[33] The AOA can be measured by planimetry of the valve orifice visualized by echocardiography, MDCT, or CMR.


The main factors that influence the flow contraction coefficient, i.e., the ratio of EOA/AOA, are the shape and size of the LVOT and the magnitude of the LV outflow (Fig. 37.5, panel A; Fig. 37.6). A decrease in stroke volume and transvalvular flow results in more pronounced flow contraction and thus in a smaller EOA relative to the AOA.[34] A larger LVOT cross section and/or an LVOT shape with abrupt transition from LVOT to AOA (i.e., flat valve inflow shape) are associated with greater flow contraction.[31,35,36] On the other hand, smaller LVOT size or funnel-shaped LVOT allows more progressive convergence of the flow toward the valve orifice and thus less flow contraction downstream of the valve. Interestingly, in up to 75% of patients with AS LVOT has an hourglass (i.e., diameter at the annulus higher than 5—10 mm below) and

FIGURE 37.5 **Flow contraction and pressure recovery at the level of the aortic valve.** Panel A shows the flow contraction that occurs downstream of the aortic valve. The flow contraction is more pronounced when the valve aperture angle θ is larger and so the valve inflow is flatter (A-1) compared to smaller angle and funnel shape inflow (A-2 and A-3). The flow contraction coefficient (CC = EOA/AOA) is close to 0.6 and so the effective orifice area is much smaller than the anatomic orifice area when θ is close to 90 degrees and it increases up 1.0 when θ is < 20 degrees. In such case, there is little flow contraction and the EOA is similar to the AOA. Hence, for the same AOA (i.e., size of aortic valve orifice), the EOA (minimal cross section of the transvalvular flow) and thus the transvalvular pressure gradient and LV pressure overload may vary significantly depending on the valve inflow shape. *LVOT*, Left ventricular outflow tract. Panel B shows the evolution of blood flow and pressure across the LVOT, aortic valve, and ascending aorta during systole. When the blood flow contracts to pass through a stenotic orifice (i.e., the anatomic orifice area [AOA]), a portion of the potential energy of the blood, namely, pressure, is converted into kinetic energy, namely, velocity, thus resulting in a pressure drop and acceleration of flow. Downstream of the vena contracta (i.e., the effective orifice area [EOA]), a large part of the kinetic energy is irreversibly dissipated as heat because of flow turbulences. The remaining portion of the kinetic energy that is reconverted back to potential energy is called the "pressure recovery" (PR). The global hemodynamic load imposed on the left ventricle results from the summation of the valvular load and the arterial load. This global load can be estimated by calculating the valvulo—arterial impedance. In patients with medium or large size ascending aorta, the impedance can be calculated with the standard Doppler mean gradient in place of the net mean gradient. *AA*, cross-sectional area of the aorta at the level of the sinotubular junction; ΔP_{max}, maximum transvalvular pressure gradient recorded at the level of vena contracta (i.e., mean gradient measured by Doppler); ΔP_{net}, net transvalvular pressure gradient recorded after pressure recovery (i.e., mean gradient measured by catheterization); *LVOT*, left ventricular outflow tract; P_{LVOT}, pressure in the LVOT; *SBP*, systolic blood pressure; *SVi*, stroke volume index; *Vpeak*, peak aortic jet velocity; *Zva*, valvuloarterial impedance. Panel C shows the pressure recovery phenomenon in prosthetic heart valves in patients with large aorta diameter (I, minimal pressure recovery) and small aorta diameter (II, significant pressure recovery). *Panel A Adapted from Garcia D, Kadem L. What do you mean by aortic valve area: geometric orifice area, effective orifice area, or gorlin area?* **J Heart Valve Dis**. *2006; 15:601—608; Panel B Reproduced with permission from Pibarot P, Dumesnil JG. this has a significant impact on SVi and AVA estimations.[37] Depending on the conditions of LV flow and LVOT size and shape, the contraction coefficient may vary between 0.6 and 1.0 and thus major differences may be observed between AOA and EOA.[31,34—36] Hence, it is preferable to use the EOA rather the AOA to assess the hemodynamic severity of the aortic valve stenosis. In the clinical setting, the EOA can be measured either by Doppler echocardiography with the use of the continuity equation or by left heart catheterization with the Gorlin formula. CMR provides unique capabilities to measure flow using phase-contrast imaging[38,39] without doing geometric (such as a circular LVOT which is known to be elliptic) or fluid dynamics (such as a flat flow profile which in practice is skewed) assumptions as compared to continuity equation by echocardiography. The underlying principles of

FIGURE 37.6 Ventriculo—arterial coupling and valvulo—arterial load in aortic valve disease. This figure illustrates the interplay between the left ventricular, valvular, and arterial anatomic and hemodynamic factors in the context of aortic valve stenosis. The flow ejected by the left ventricle during systole contracts to pass through the stenotic aortic valve. This flow contraction occurs, in large part, within the LV outflow tract but increases further downstream to the valve. This is why the effective orifice area (EOA, i.e., cross section of the vena contracta of the transvalvular flow) is smaller than the anatomic orifice area (AOA) at the level of the valve. The EOA is the main determinant of the pressure loss or pressure gradient (50 mmHg in this case) that occurs between the LV outflow tract and the vena contracta and that results in a pressure overload ($P = 160$ mmHg in this case) on the left ventricle. Downstream to the vena contracta, a portion of the kinetic energy of the flow jet is, however, reconverted into potential energy, i.e., pressure. This pressure recovery phenomenon is more important when the ratio between the EOA and the cross-sectional area of the ascending aorta (AA) is high because in this context, there is less flow turbulences downstream to the valve and thus less energy (pressure) loss. Because of the pressure recovery (+15 mmHg in this case), the blood pressure in the ascending aorta (125 mmHg) is higher than at the level of the vena contracta (110 mmHg). The systemic arterial compliance (SAC) is in large part determined by the compliance of the aorta and large arteries, whereas the systemic vascular resistance (SVR) is mainly determined by the small arteries. A reduction in SAC causes a faster reflection of arterial waves from the periphery, which may contribute to increase the aortic and then the LV systolic pressure. Hence, reduced SAC and increased SVR contribute to increase the pulsatile (SAC) and steady (SVR) components of the arterial impedance and thus of the afterload imposed on the LV. In patients with aortic stenosis and concomitant hypertension, the LV is facing a double load, i.e., a valvular load because of the valve stenosis and an arterial load because of the reduced SAC and/or increased SVR. The valvulo—arterial impedance (Zva) encompasses these factors and reflects the overall hemodynamic burden imposed by the aortic valve, the aorta, and the arterial system on the LV. The increase in LV afterload related to the increase in Zva leads to reduced myocardial contractility and ventricular—arterial uncoupling, which, in turn, cause a reduction in stroke volume (SV).

through-plane phase-contrast MRI relies on the acquisition of flow-sensitizing bipolar gradients. Flow volume is measured by the acquisition of a cross-sectional image of the vessel or area of interest. Fluid velocity can then be calculated for every pixel covering the region of interest, which in turn represents a voxel of a given thickness (often 5 mm or more). The flow corresponds to the product of every pixel fluid velocity multiplied by every pixel area. Total flow is derived by the summation of all pixel flow covering the area of interest.[40,41] Though phase-contrast CMR can be considered the noninvasive gold standard for stroke volume estimations, a recent study by our group showed that Doppler echocardiography provides comparable stroke volumes versus phase-contrast CMR.[37] However, phase-contrast CMR is known to underestimate velocity—time integrals and peak velocities. This is due to its lower temporal resolution in relation to Doppler, difficulties in finding the exact perpendicular through plane (position and angle) of the vena contracta and voxel averaging of flow velocity.[38] Thus, even though some studies have shown the feasibility of AVA calculation by CMR,[42,43] a recent metaanalysis has confirmed that CMR estimation of effective orifice area cannot be compared to that of Doppler echocardiography.[44] Time-resolved three-directional velocity encoded phase-contrast-CMR (i.e., 4D-flow)[45,46] can overcome many of these limitations and has a promising role in assessing blood flow and blood—vessel interactions, such as energy loss, kinetic energy, and shear stress.[45—47] Therefore, CMR (and especially 4D flow) will represent an important step toward improving the understanding of the complexities of ventriculo—valvulo—arterial coupling.[48] The main limitations of 4D flow phase-contrast MRI are the long acquisition times need to encode velocities in three dimensions, and its temporal resolution, which remains limited even with very long acquisition times.

Interaction between aorta and aortic valve in aortic valve disease

Aortic stenosis

Effacement of sinotubular junction

The size and geometry of the aortic root and ascending aorta may have an impact on the aortic valve mechanics and hemodynamics. In particular, a recent study reported that effacement of the sinotubular junction is independently associated with faster AS progression.[49] Indeed, this abnormality of the aortic root geometry may increase mechanical stress of aortic valve leaflets and disturb the flow pattern at the aortic surface of the valve leaflets, which may, in turn, alter the mechanobiology of the valve and promote disease initiation or progression.

Pressure recovery

When the blood flow contracts to pass through a stenotic orifice, a portion of the potential energy of the blood, i.e., pressure, is converted into kinetic energy, i.e., velocity,

thus resulting in a pressure drop and acceleration of flow (Figs. 37.5B and 37.6). Downstream of the vena contracta, the flow jet reexpands and decelerates. Given that the total energy must remain constant, the kinetic energy is converted back into potential energy, i.e., blood velocity decreases, whereas blood pressure increases. However, this energy conversion is not complete in the context of an abrupt obstruction such as an aortic valve stenosis because the sudden expansion of the flow jet downstream of the vena contracta generates flow turbulences. As a result of these turbulences, a large part of the kinetic energy is irreversibly dissipated as heat. The remaining portion of the kinetic energy that is reconverted back to potential energy is called the "pressure recovery" (Figs. 37.5B and 37.6). The extent of this pressure recovery essentially depends on the relationship between the size of the valve orifice and the size of the aorta.[50–52] The smaller the valve EOA relative to the size of the aorta, the more flow turbulences will occur and the less energy will be available to be recovered as pressure. Hence, the extent of pressure recovery generally becomes clinically relevant in patients with smaller aortas, i.e., with an aorta diameter at the sinotubular junction ≤ 30 mm, and especially in those with mild, moderate, or moderate-to-severe AS.[50–54] Patients with a large aneurysm of the ascending aorta have no pressure recovery and therefore have a larger energy loss for a given valve EOA. Congenital bicuspid AS is often associated with dilation of the ascending aorta, which may reduce the extent of pressure recovery and thereby increase the energy loss at the level of the aortic valve/root. The same considerations should be taken into account in the case of aortic prostheses (Fig. 37.5C).[55]

Doppler-echocardiographic measurements rely on the maximum velocity or gradient measured across the aortic valve at the level of the vena contracta (Fig. 37.5B). On the other hand, catheterization measurements are generally performed at a few centimeters downstream of the valve, where the pressure is fully recovered. As a result, the pressure gradient recorded by catheterization, which corresponds to the "recovered" or "net" pressure gradient, is generally lower than the Doppler gradient, which corresponds to the maximum gradient recorded at the level of the vena contracta.[33] Likewise, EOA by the Gorlin formula is derived from recovered pressures such that its value is higher than EOA derived by the continuity equation, which measures the actual area occupied by flow at the valvular level. Hence, the extent of pressure recovery and thus the discrepancies between Doppler and catheter measurements are more important in patients with smaller aortas and/or with mild, moderate, or moderate-to-severe AS. Nonetheless, these discrepancies can in large part be reconciled by taking into account the pressure recovery phenomenon. To

this effect, one can calculate the "energy loss coefficient" (ELCo), a new parameter proposed by Garcia et al. that adjusts the Doppler EOA for the size of the aorta in order to take into account the pressure recovery (Fig. 37.6):[5]

$$ELCo = (EOA \times A_A)/(A_A - EOA)$$

where A_A is the cross-sectional area of the aorta measured at about 1 cm downstream of the sinotubular junction. This energy loss coefficient is easily measurable by Doppler echocardiography and is more or less equivalent to the catheter EOA calculated with the use of the Gorlin formula. Several studies have demonstrated that the energy loss coefficient is superior to the Doppler EOA in predicting the actual energy loss and the occurrence of LV dysfunction and adverse outcomes in patients with AS.[50,56] Not accounting for pressure recovery in patients with small aortas may lead to overestimation of severity by Doppler echocardiography and unwarranted investigations or interventions.

Pressure recovery also occurs downstream of surgical or transcatheter prosthetic valves that are used to replace the disease native aortic valve. It is important to make a distinction between the pressure recovery phenomenon that may occur with any type of native or prosthetic aortic valve versus the localized high gradient phenomenon that occurs within the central orifice of the bileaflet mechanical valves. As for the native aortic valve, the magnitude of pressure recovery is higher in patients with a small aorta. Furthermore, recent studies suggest that pressure recovery may be relatively more important in prosthetic valves versus native disease aortic valves and in transcatheter versus surgical bioprosthetic aortic valves.[57–59]

Interaction between hypertension and AS

Arterial hemodynamics, and, in particular arterial compliance, may also interact with the diagnosis of AS. Hypertension may contribute to increase the LV afterload and therefore lead to a decrease in LV contractility, stroke volume, and transvalvular flow.[60–62] Given that the transvalvular pressure gradient is highly flow dependent, any decrease in flow may substantially reduce the gradient (i.e., low-flow, low-gradient pattern) and thereby lead to an underestimation of stenosis severity. Hence, when hypertension and AS coexist, there is a decrease in flow that leads to a "pseudo-normalization" of gradient and also blood pressure with ensuing underestimation of both AS severity and hypertension severity.[63] In contrast to the gradient, the EOA measured in a hypertensive patient may yield to an overestimation of stenosis severity. Indeed, although less flow dependent than the gradient, the EOA may nonetheless decrease with decreasing flow rate and may thus be "pseudo-severe."[60,61]

It has also been suggested that a reduction in arterial compliance, which is frequent in patients with bicuspid AS or in older patients with trileaflet, AS may cause a decrease in the gradient, independently of transvalvular flow (Fig. 37.6).[64,65] Indeed, faster and earlier reflection of arterial wave from the periphery may blunt the transvalvular gradient. This phenomenon may, at least in part, be responsible for some of the discordant grading (i.e., small EOA with low gradient) situations observed in patients with AS and normal flow rate. Hence, in patients with hypertension, it is recommended to reassess severity after normalization of blood pressure.

Systemic arterial hypertension is associated with faster progression of aortic valve calcification and stenosis.[66] This association may be explained, at least in part, by the increased mechanical stress on aortic valve leaflets and by the disturbed flow transaortic flow patterns caused by hypertension.

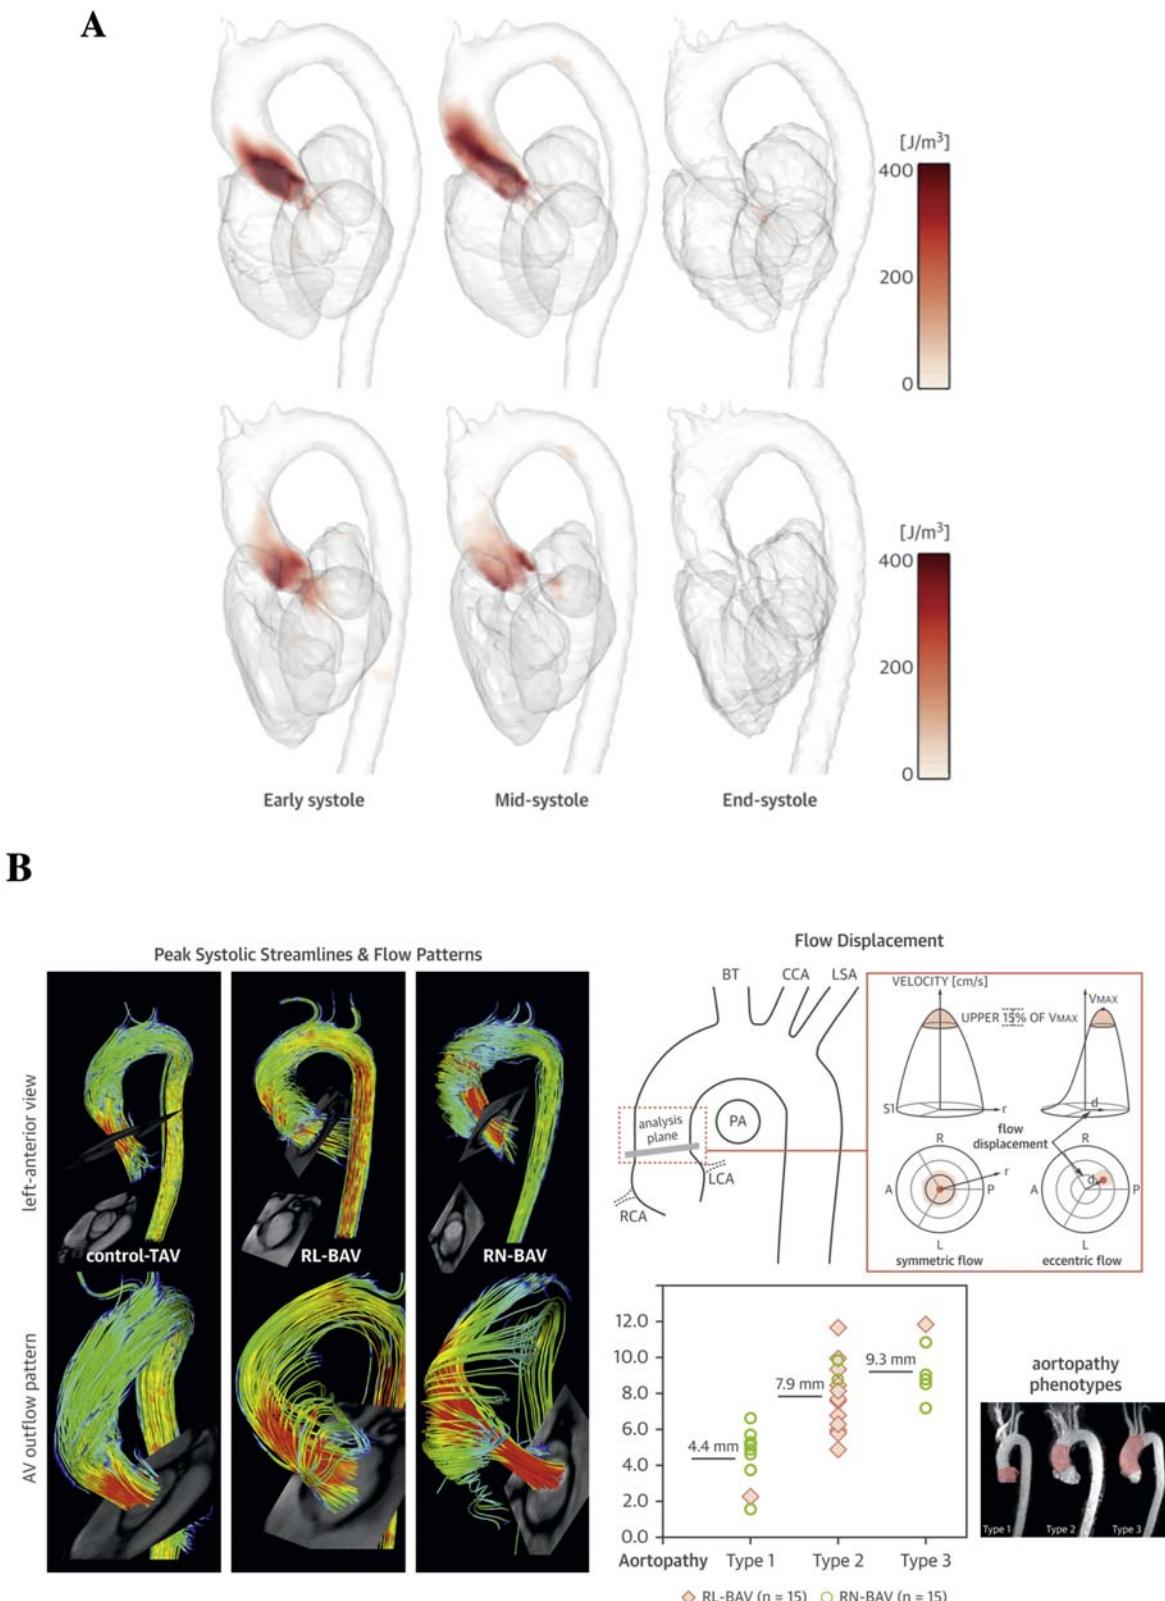
Aortic regurgitation

Aortic regurgitation can result from abnormalities of the aortic valve leaflets or from dilation of the aortic root. When the aortic leaflets are involved, there is frequently a destructive process occurring such as infective endocarditis, rheumatic heart disease, or degenerative valvular disease. Any disease process that results in dilation of the aortic root (i.e., Marfan's syndrome, BAV, etc.) may cause a tethering of the leaflets and thus a lack of coaptation in diastole. Similarity with the Carpentier's mitral classification, aortic regurgitation caused by leaflet tethering is often referred as type I.[67] Dilatation can affect the ascending aorta starting from the sinotubular junction (Type IA) or can present as an aneurysm of the entire aortic root with dilation of the aortic annulus, the sinuses of Valsalva and the sinotubular junction (Type IB). Surgical treatment is different in both types, consisting in a supracoronary tube graft sutured above the aortic root without need for coronary arteries reimplantation in the type IA, while in type IB, the entire aortic root is replaced, and the coronary ostia reimplanted, the native aortic valve being spared if its leaflets are normal.

Interaction between aorta, aortic valve, and LV in AS

The pathophysiology of heart failure in AS is essentially determined by the extent of imbalance between the increase in LV hemodynamic load due to the valvular obstruction and/or concomitant arterial hypertension, on the one hand, and the capacity of the LV to overcome this increase in load both at rest and during exercise, on the other hand (Figs. 37.4 and 37.6). In patients with calcific AS, several factors may lead to an unbalance between Ea and Ees and thus to ventriculo−arterial decoupling.

First, the aortic valve obstruction contributes to increase in the LV afterload. In response to pressure overload, the LV generally develops concentric remodeling. This is an adaptive process whereby the increase in wall thickness tends to stabilize the wall tension. This adaptive process is initially useful to maintain myocardial contractility and systolic function. However, with progression to more advanced stages of AS, LV hypertrophy is not able to compensate for the increase in afterload and myocardial contractility decreases due to afterload mismatch. Furthermore, because of the major LV pressure overload and the pronounced LV hypertrophy, the coronary perfusion declines, whereas the myocardial oxygen demand increases, thus leading to repetitive myocardial ischemia. These processes in turn induce dysfunction and then apoptosis of myocytes and development of myocardial fibrosis, which leads to reduced LV myocardial contractility (decrease in Ees) and compliance (increase in LV end-diastolic pressure). Hence, in the more advanced stages of the disease, patients develop LV diastolic and systolic dysfunction, which eventually progress to heart failure. Therefore, AS is currently considered a disease of both the valve and the myocardium.[68] The myocardial response of the LV to AS has a major impact on the presence of symptoms and clinical outcomes, but the timing and type of LV remodeling is not predictable for the individual patient and is influenced by other load-independent factors such as the metabolic milieu. Advanced cardiac imaging has greatly contributed to the understanding of the complex interaction between the increased afterload (both valvular due to AS and vascular due to increased peripheral resistance and aortic impedance) and the myocardial consequences (LV hypertrophy, adverse remodeling, myocardial fibrosis, and, ultimately, decreased contractility).[69] However, the amount on which decreased LVEF is secondary to increased afterload (*"afterload mismatch",* therefore relieved by AVR) or to intrinsic myocardial damage has proven to be difficult to assert. Several echocardiographic and CMR imaging biomarkers of early "subclinical" systolic dysfunction (e.g., LVEF 50%−59%, decreased global longitudinal strain, midwall focal fibrosis and increased extracellular volume) are being currently tested in randomized clinical trials as markers for an earlier intervention

in asymptomatic stages (EVoLVeD, NCT03094143; EARLY-TAVR, NCT03042104).[70] Furthermore, the interaction of a nonsevere increase in afterload (moderate AS) with an already failing LV has been shown to be associated with worse outcomes and, therefore, an early intervention might be of benefit. This hypothesis is currently being tested in the TAVR-UNLOAD randomized clinical trial (NCT02661451).[71]


Second, patients with calcific AS are generally older and thus frequently have reduced arterial compliance and associated systolic hypertension.[23,66,72] As a matter of fact, hypertension, and particularly systolic hypertension, is highly prevalent (30%—70%) in patients with AS.[23,72] These patients thus often have increased Ea as a result of concomitant reduced arterial compliance and increased vascular resistance.[16,73] Because the LV of these patients is facing a double (i.e., valvular + arterial) hemodynamic load, they are predisposed to the development of symptoms, LV dysfunction, and heart failure (Fig. 37.6).[23,24,72,74] To this effect, Antonini-Canterin et al. also reported that symptoms of AS develop at an earlier stage (i.e., nonsevere) of the valvular stenosis in hypertensive patients compared to normotensive ones.[74] LV dysfunction may also develop at a lower degree of AS severity in patients with concomitant hypertension.[23,24] Recent studies also suggest that hypertension may accelerate the progression of the severity of AS per se.[66,75] Finally, the presence of hypertension is associated with a twofold increase in the risk of all-cause mortality in patients with AS.[72,75] Once again, advanced cardiac imaging (and especially 4D-Flow CMR) allows to noninvasively assess arterial physiology, such as aortic pulse wave velocity,[76] wall shear stress,[77] and advanced hemodynamic measures such as vorticity and helicity, flow displacement, pressure gradients, viscous energy loss, and turbulent kinetic energy (Fig. 37.7).[45] Furthermore, the combination of valvular (AS) and vascular (increased peripheral vascular resistance, increased or premature wave reflection, and/or decreased vascular compliance) hemodynamic load cumulate to increase LV afterload and, thus, the degree of LV hypertrophy and myocardial fibrosis.[73] Hence, it is crucial to optimize diagnosis and treatment of systemic arterial hypertension in patients with aortic valve disease.

Third, Ees is often reduced in AS patients, thus further contributing to the increase in Ea/Ees ratio, ventriculo—arterial decoupling, and heart failure. The main factors responsible for the decline in Ees in AS are **(i)** LV afterload mismatch and associated decrease in myocardial contractility related to the disproportionate increase in LV afterload (resulting from AS and frequent concomitant hypertension) relative to LV performance; **(ii)** Impaired LV contractility due to concomitant coronary artery disease—which is also frequent in the elderly population with AS, myocardial fibrosis[78] or concomitant cardiac amyloidosis.[79]

The ventricular—arterial decoupling ultimately results in a decline in LV ejection and stroke volume, which yields to heart failure symptoms.[80,81] Furthermore, in these conditions of low flow state, the transvalvular gradient, which is highly flow dependent, may decrease and thus underestimate the actual severity of the stenosis.[80,82] Dobutamine stress echocardiography may be useful to confirm the stenosis severity in these patients with low LV ejection fraction, low-flow, low-gradient AS (Fig. 37.4). However, the recent advent of MDCT aortic valve calcium quantification has revolutionized AS evaluation in the last years. It requires an ECG-gated, noncontrast acquisition with low radiation (<1 mSv). Quantification relies on the Agatston method using semiautomated software and provides a flow-independent quantitative assessment of AS anatomical severity. Details on the scan protocol, quantitative analysis, and caveats have been recently published.[83] AVC quantification has excellent reproducibility and performance for AS severity assessment and has consistently proven to be of incremental prognostic value in several studies.[84,85] Furthermore, it has been incorporated into ESC/EACTS guidelines to be used in patients with symptomatic, discordant grading AS and both reduced (<50%) and preserved LVEF (≥50%).[86] Due to sex differences in AS pathophysiology (women present with more fibrosis and less calcification than men[87]), specific cutoffs defining severe AS differ for women (≥1200 Agatston Units [AU]) and men (≥2000 AU).

However, the majority of patients with severe AS develop symptoms prior to decline in LV ejection fraction. In these patients, the symptoms are mainly related to the development of LV diastolic dysfunction and increased LV filling pressures. When it becomes severe and evolves toward restrictive pattern, LV diastolic dysfunction can even cause a low-flow, low-gradient phenotype but with preserved LV ejection. This entity is named "paradoxical" low-flow, low-gradient AS and it corresponds to the "heart failure with preserved LV ejection fraction, i.e., HFpEF" form of AS, whereas the classical low-flow, low-gradient with low LVEF described above represents the "heart failure with reduced LV ejection fraction, i.e., HFrEF" form (Fig. 37.4).[80,82] As mentioned previously, in patients with

FIGURE 37.7 Cardiovascular magnetic resonance 4D flow for assessment of advanced hemodynamic measures. Panel A: Turbulent kinetic energy (in Joules/m^3) in a patient with AS (top) and a healthy volunteer (bottom). Panel B: 3D flow visualization of streamlines (left panel) and flow displacement (right panel)—a semiquantitative measurement of flow eccentricity—in patients with tricuspid and bicuspid aortic valves with right-left and right-noncoronary cusp fusion. Different flow patterns showed association with specific types of aortopathy. Panel C: Average of 3D wall shear stress in healthy controls (A), dilation of the aorta with tricuspid aortic valve (B) and aortic stenosis (C). *Panels A—C Reproduced with permission from Garcia J, Barker AJ, Markl M. The role of imaging of flow patterns by 4D flow MRI in aortic stenosis. **JACC Cardiovasc Imag**. 2019; 12:252—266.*

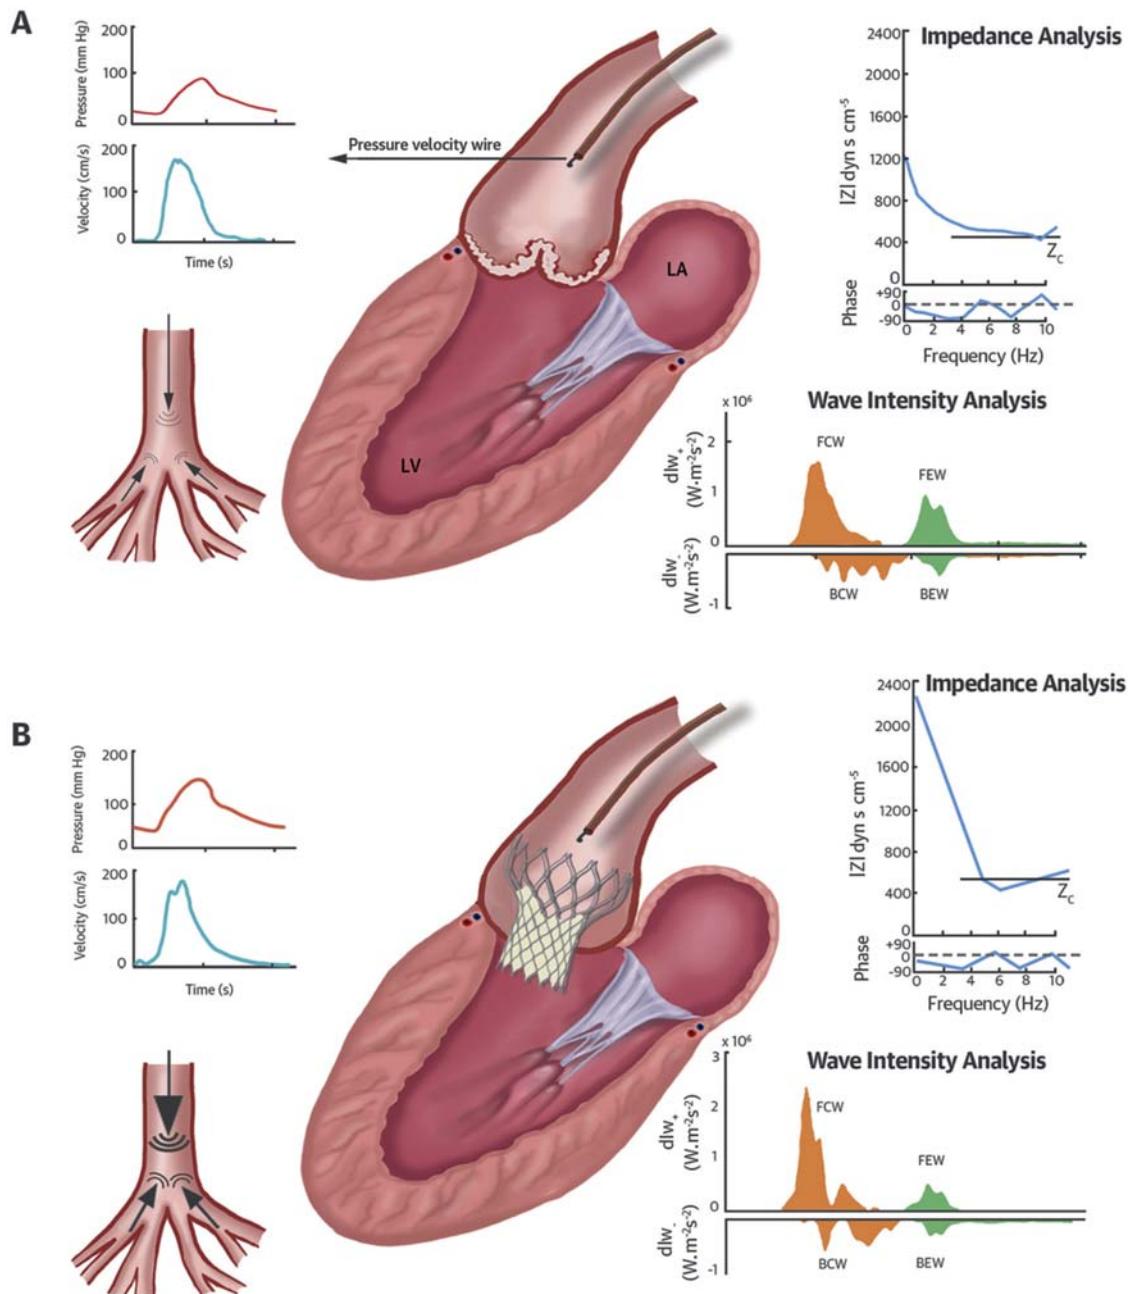
paradoxical low-flow, low-gradient AS, quantitation of aortic valve calcium burden by CT may be used to confirm stenosis severity.


Impact of arterial load following aortic valve replacement

Aortic valve replacement addresses the aortic valve disease per se and therefore corrects the valvular hemodynamic load imposed on the LV. However, this procedure does not correct the arterial abnormalities associated with the aortic valve disease, if any (Fig. 37.8). New onset or a worsening of arterial hypertension is frequently observed following aortic valve replacement.[88,89] This intriguing phenomenon may be related to the increase in stroke volume and cardiac output resulting from the LV afterload reduction achieved by the valve replacement procedure. The postprocedural increase in flow may lead to an increase in systemic arterial pressure and may therefore unmask a preexisting hypertensive disease in patients with severe AS, low flow state, and thus pseudo-normal arterial pressure prior to the procedure. Furthermore, Yotti et al. reported that aortic valve replacement may be associated with an acute worsening of the arterial load in patients with severe AS (Fig. 37.8).[88] Indeed, the valvular obstruction may dampen forward and backward compression waves in the arterial tree of these patients. An acute relief, by aortic valve replacement, of this valvular obstruction and of the associated dampening effect may actually result in an increase in the arterial load, and particularly of its pulsatile component. This may, in turn, limit the benefit of the valve procedure on the reduction of LV afterload and thus on the postprocedural regression of LV hypertrophy and improvement of patient's functional status. Several studies reported that abnormal arterial properties and increased arterial load are important determinant of i) the persistence of LV hypertrophy,

ventriculo—arterial uncoupling, and low-flow state; ii) suboptimal improvement in functional capacity and quality of life; iii) persistent or recurrent heart failure; and iv) mortality following aortic valve replacement.[73,89—91] In particular, systemic arterial compliance is often abnormal in patients with severe calcific AS and appears to be the most important contributor to postprocedural outcomes. Given that patients with severe AS are often in low flow state both before and after aortic valve replacement, increased pulsatile arterial load, rather than blood pressure, may be a target for adjunctive medical therapy to improve outcomes after TAVR.[89]

Conclusion

Optimal anatomical and functional interplay between the LV, the aortic valve, and the aorta is essential to maintain adequate blood flow and pressure, and thus adequate organ perfusion (Fig. 37.6). Any abnormality in the anatomy or the function of any of these three entities may cause a ventriculo—arterial decoupling, which may in turn lead to heart failure. The assessment of the ventriculo—valvulo—arterial coupling may thus help to identify patients with ventricular, valvular, or arterial diseases being at risk for the development of heart failure and also to reconcile discordant situations such as i) EOA being smaller than the AOA in patients with AS; ii) the concomitance of a small EOA with a low gradient in patients with low-flow or normal-flow AS; iii) the underestimation of AS severity in patients with concomitant arterial hypertension; iv) and the development of LV dysfunction in patients with nonsevere AS or AR but concomitant arterial hypertension. Advanced cardiac imaging, and especially 4D-CMR, has a fundamental role in assessing the complex interaction between the LV, aortic valve (stenotic and/or regurgitant), and the arterial system.

FIGURE 37.8   Changes in arterial load following transcatheter aortic valve replacement in patients with severe AS. Panels A and B: Aortic impedance and wave intensity analysis are shown in a patient before (A) and after (B) transcatheter aortic valve replacement (TAVR). Aortic systolic and pulse pressures increased after TAVR. Fourier decomposition of the simultaneous aortic pressure and velocity signals shows that SVR and the first three harmonic frequencies of the impedance spectrum (Z) increase after TAVR. Wave intensity analysis was used to separate total wave intensity into contributions from the forward (dIwþ) and backward (dIw-) traveling waves. Compression waves (salmon) increase pressure, and expansion waves (green) decrease aortic pressure. The forward compression wave (FCW) increases immediately after TAVR. *BCW*, backward compression wave; *BEW*, backward expansion wave; *dIw*, wave intensity; *FEW*, forward expansion wave; *LA*, left atrium; *LV*, left ventricle; *SVR*, systemic vascular resistance. Panel C: Boxplots and individual value plots (patients showing a decrease [salmon] or increase [blue] in SVI after TAVR) show values of mean pressure gradient, systolic blood pressure, peak left ventricular pressure, and stroke volume index (SVI) in 23 patients with severe AS before and after TAVR.

Chapter 38

Arterial stiffness and atherosclerosis: mechanistic and pathophysiologic interactions

Kazuomi Kario[1,2]

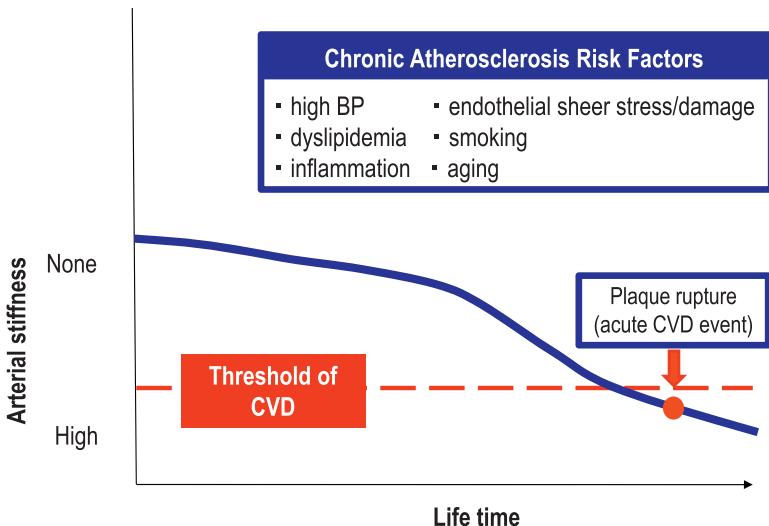
Introduction

There are two common types of arterial disease: atherosclerosis triggered by endothelial damage and stiffness of the large arteries (which is linked to small artery remodeling). Atherosclerosis is primarily associated with, and promoted by, the presence of metabolic risk factors (e.g., dyslipidemia, diabetes mellitus),[1,2] whereas arterial stiffness is closely associated with aging and hypertension.[3] Large artery stiffness is an important contributor to atherosclerotic cardiovascular disease (CVD) and to microvascular disease, which in turn plays a role in renal and cerebrovascular disease.[4]

Vascular failure: interaction between atherosclerosis and arterial stiffness


Progressive atherosclerosis is characterized by accumulation of inflammatory cells, lipids, fibrous elements, and calcification in the wall of larger arteries, resulting in progressive narrowing of the vessel lumen.[5,6] This narrowing reduces the ability of arteries to deliver oxygen-rich blood to important organs like the heart and brain. Endothelial dysfunction, which reflects the inability of the vascular endothelium to maintain homeostasis, plays a fundamental role in the development of atherosclerosis.[2,7–11]

A reduction in the ability of an artery to expand and contract in response to pressure changes is known as arterial stiffening.[5] This progressive phenomenon occurs as a result of the thickening and stiffening of the wall material (arteriosclerosis),[6,12,13] and is closely associated with age and hypertension.[3] From an early age, blood pressure (BP)-related stress on the arterial wall may initiate endothelial

cell damage that contributes to the atherosclerotic process (Fig. 38.1).[14] Thus, endothelial dysfunction might represent the first step in the pathophysiology of atherosclerosis, prior to the development of arterial stiffness.[15] However, endothelial dysfunction and arterial stiffness may develop simultaneously, or arterial stiffness may even occur before endothelial dysfunction.[15] At later stages (and older ages), the circumferential force of BP and resulting stretch of the arterial wall may trigger rupture of an atherosclerotic plaque or the arterial wall, resulting in the occurrence of an atherothrombotic CVD event (Fig. 38.1).[14]

Significant relationships between endothelial dysfunction and arterial stiffness have been reported in longitudinal studies.[16] A study of Japanese patients with treated hypertension found a significant association between endothelial dysfunction (based on flow-mediated vasodilatation of the brachial artery) and longitudinal progression of arterial stiffness (determined using brachial-ankle pulse wave velocity [baPWV]).[2] However, the potential mechanisms linking arterial stiffness and atherosclerosis have not been widely studied to date.[17] Increasing arterial stiffness is associated with increases in systolic BP (SBP) and pulse pressure. Higher SBP increases afterload leading to left ventricular (LV) hypertrophy, and lower diastolic BP (DBP) decreases coronary perfusion. Both of these effects contribute to myocardial ischemia and coronary atherosclerosis. Increased pulse pressure is associated with damage of the blood–brain barrier, contributing to cerebral atherosclerosis. In addition, arterial stiffness directly or indirectly contributes to vascular remodeling, progression of atheroma, endothelial dysfunction, accumulation of extracellular matrix, oxidative stress, and plaque rupture.[17] Furthermore, risk factors for atherosclerosis (e.g., hypertension, diabetes,

dyslipidemia, smoking, inflammation, etc.) are also risk factors for arterial stiffness, contributing to the high cardiovascular (CV) morbidity and mortality associated with these conditions.

Pulse wave velocity and atherosclerosis

Perhaps the most widely studied and most commonly used measure of arterial stiffness studied to date is pulse wave velocity (PWV).[18,19] This parameter reflects segmental arterial elasticity. Increasing arterial stiffness is associated with an increase in the propagation speed of the pulse wave generated by contraction of the left ventricle.[15] There are two approaches to evaluating PWV: carotid-femoral (cf) PWV (which is a measure of aortic stiffness) and baPWV (which provides an indication of stiffness in both the aorta and peripheral muscular arteries). PWV is determined to a large extent by BP and age, and is also influenced by genetics, CV risk factors, and the presence and extent of atherosclerosis.[20–29]

There is a large body of evidence for significant associations between PWV and the presence of atherosclerosis in coronary, cerebral, and carotid arteries.

In coronary arteries

In symptomatic patients, both cfPWV and baPWV have been significantly associated with the presence and severity of invasively assessed coronary artery disease (CAD).[23,30–37] Similar associations have been reported in patients with type 2 diabetes mellitus. In one of these studies, coronary plaques with unfavorable characteristics were more prevalent in asymptomatic patients with well-controlled type 2 diabetes compared with healthy controls. In addition, the presence of coronary plaques was significantly and independently associated with baseline cfPWV, independent of age, sex, diabetes, and BP.[38]

Studies of middle-aged adults without CAD reported a link between baPWV and atherosclerosis (based on the presence of coronary artery calcification).[21,39–42] These data highlight the potential for evaluation of arterial stiffness to identify the presence of subclinical atherosclerosis, facilitating early intervention to reduce the risk of atherosclerosis progressing to overt CAD, and prevent the clinical adverse events that occur in patients with symptomatic CAD.

In cerebral arteries

Data from population studies and patients with hypertension highlight a link between baPWV or cfPWV and the presence of cerebral small vessel disease, including cerebral microbleeds, white matter hyperintensity, or lacunar infarction.[25,43–48] These subclinical manifestations of cerebral atherosclerosis are common in older populations and are recognized as important risk factors for cognitive impairment and stroke.[49,50] PWV has also been associated with the longitudinal progression of cognitive decline in the elderly.[51,52]

In patients with ischemic stroke, it has been reported that baPWV is significantly correlated with calcification or stenosis of cerebral arteries.[53,54] In addition, baPWV increases the risk of cerebral infarction, above and beyond the risk associated with traditional risk factors, including hypertension, diabetes, dyslipidemia, and fasting blood glucose.[55] However, not all studies have reported these positive associations. One cross-sectional study of 66 patients with stroke found that baPWV was not independently associated with an increased risk of stroke, white matter hyperintensity, or cerebral microbleeds after adjustment for potential confounders (e.g., hypertension).[56] However, this was a small study, and the majority of currently available data support an association between PWV and cerebral atherosclerosis.

In the carotid artery

Intima-media thickness (IMT) in the carotid artery is generally considered an atherosclerotic marker, and has been associated with the occurrence of both stroke and CAD.[57,58] Carotid IMT has shown a positive linear correlation with cfPWV in general population studies,[59–62] and in patients with hypertension[63] or diabetes.[61] In addition, data from cross-sectional or longitudinal studies show an association between baPWV and increased carotid IMT or formation of atherosclerotic plaques in the carotid artery in community-based populations,[64,65] and in patients with hypertension,[66] cerebral artery thrombosis,[67] end-stage kidney disease,[68] or type 2 diabetes mellitus.[69] Again, the majority of data support a relationship between PWV and carotid atherosclerosis, but one study showed that only cfPWV (not baPWV) was significantly associated with carotid IMT in a general population.[59]

Cardio-ankle vascular index and atherosclerosis

The cardio-ankle vascular index (CAVI) is a newer measure that provides information on arterial stiffness from its origin at the aorta to the ankle.[70] There is a linear increase in CAVI with age[71–74] but, in contrast to PWV, CAVI is largely independent of BP.[70,75] Data from a study conducted in Japan showed a statistically significant positive correlation between IMT of the carotid artery and CAVI in patients with essential hypertension, suggesting that CAVI may be a useful marker for evaluating atherosclerosis in this patient group.[76] CAVI is also significantly associated with the degree of coronary artery calcification and stenosis in asymptomatic subjects,[77] and may therefore be useful as a screening tool to reveal the subclinical atherosclerotic burden in symptom-free individuals. It has been suggested that a CAVI of ≥ 8.0 might be associated with subclinical arterial stiffening and/or subclinical atherosclerosis, and CAVI ≥ 9.0 seems to be associated with an increased CV risk based on currently available data.[15] However, caution needs to be exercised when applying CAVI cutoff values in the general population due to a lack of longitudinal data from population-based studies.[15]

Support for an association between arterial stiffness determined using CAVI and atherosclerosis comes from the growing body of evidence highlighting the relationship between CAVI and future CV events.[78–84] In addition, CAVI appears to add value to the coronary artery calcium score for the assessment of future CVD risk.[78] Longitudinal assessment of CAVI showed that the incidence of CVD events over a mean 2.9 years of follow-up was significantly lower in patients/subjects/individuals who did versus did not show an improvement in CAVI over the first 6 months.[82]

Other arterial stiffness parameters

Several other parameters can provide data on arterial stiffness.[85] These include the beta stiffness index of the carotid artery evaluated by carotid ultrasound and aortic stiffness evaluated by magnetic resonance imaging (MRI). Increased arterial stiffness detected using these measures reflects an increase in both structural stiffness due to changes in the matrix (smooth muscle cell hypertrophy, increased collagen, decreased elastin, and fibrosis) and functional stiffness due to neurohumoral activation (activation of sympathetic nervous system, renin–angiotensin–aldosterone system, endothelin system, etc.). The stiffness parameter beta reflects arterial stiffness without the influence of BP,[86] and was used in the development of CAVI.

Another potential measurement that may be related to arterial stiffness is reflection magnitude (RM), which is defined as the ratio of the amplitude of the backward wave to that of the forward wave.[87–89] RM is determined by the structure and function of the total arterial tree, including the central aorta and peripheral arteries of different diameters. Rather than a stiffness index per se, pronounced wave reflections interact with high aortic stiffness (PWV) such that in the presence of a stiff aorta (high PWV), they increment LV afterload, whereas in the presence of an elastic aorta (low PWV), they increase coronary perfusion pressure. Wave RM has been shown to be a strong predictor of incident heart failure (HF) and CV events in prospective studies in older populations (which tend to have stiff aortas).[87,88]

Interaction between vascular disease and hemodynamic stress

The prognostic significance of arterial stiffness is likely to be due, at least in part, to the adverse hemodynamic effects associated with stiffened arteries, including increased systolic load and decreased myocardial perfusion pressure.[5] Increases in large artery stiffening with advancing age increase the pressure required to generate blood flow (known as characteristic impedance), resulting in impaired ventricular:vascular coupling.[90] This accounts for the marked increases in systolic pressure and pulse pressure as age increases, and the associated increase in ventricular load, which contributes to the development of HF, especially HF with preserved ejection fraction.[91–94]

Hemodynamic factors influence several aspects of vascular physiology and play an important role in vascular homeostasis, meaning that they contribute to the development of vascular pathologies, including atherosclerosis.[95] Local flow hemodynamics (e.g., endothelial sheer stress) and inflammatory mechanisms both contribute to localized alterations in the endothelium that progress to atherosclerosis.[96] The preferential localization of atherosclerotic plaques at branches and sharp bends in the arterial system is indicative of an important role for hemodynamics in the development of atherosclerosis.[97]

By definition, BP is associated with cyclic physical stress on the CV system, including continuous vertical

physical force on arterial walls.[98] The shape of the pulse wave changes based on cardiac function and vascular tone and differs between central and peripheral arterial sites.[98] Exaggerated BP surges place strain on the CV system, especially in the presence of stiffened arteries. The synchronization of a variety of BP surges with different time phases and triggers (resonance hypothesis of BP surge)[99] is likely to be particularly problematic in terms of increasing hemodynamic stress and impact on atherosclerotic vessels, and is a potential mechanism for triggering of CV events.[85] Exaggerated BP surges occur more frequently in the morning compared with other times of the day because baroreflex sensitivity is reduced in the morning due to increased central sympathetic activation at this time.[85]

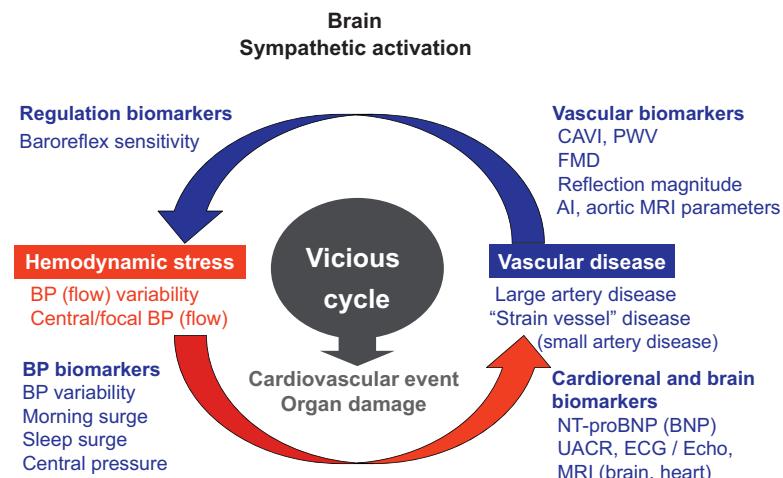
SHATS: a proposed novel clinical entity

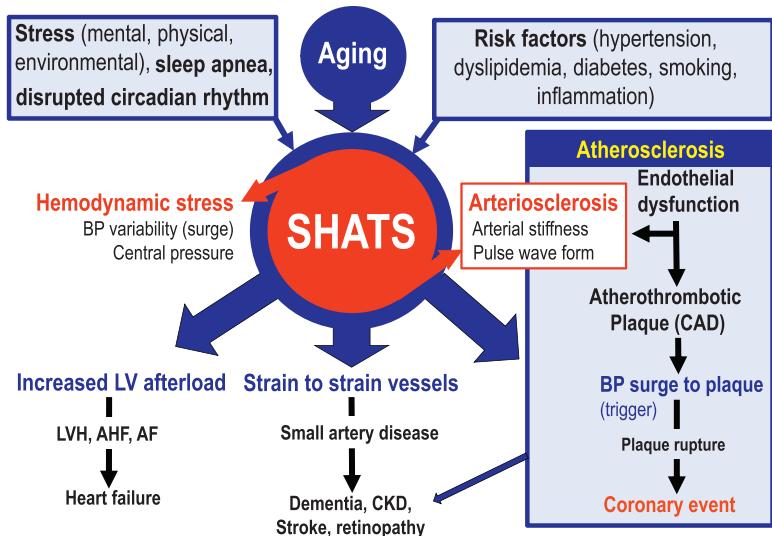
The term systemic hemodynamic atherothrombotic syndrome (SHATS) has been proposed to describe an age-related and synergistic vicious cycle of hemodynamic stress and vascular disease (Fig. 38.2).[85,100,101] A synergistic combination of different forms of BP variability (BPV) and hemodynamic stress related to vascular disease forms the basis of the SHATS concept. This approach also separates the role of physical hemodynamic stress from other CV risk factors (e.g., hyperglycemia, dyslipidemia, and inflammatory processes.).[101]

The clinical manifestations of SHATS including common CV conditions such as stroke, CAD, and HF; small artery disease and microvascular disease–related conditions such as dementia, chronic kidney disease (CKD), and retinopathy are also closely linked with SHATS (Fig. 38.3).

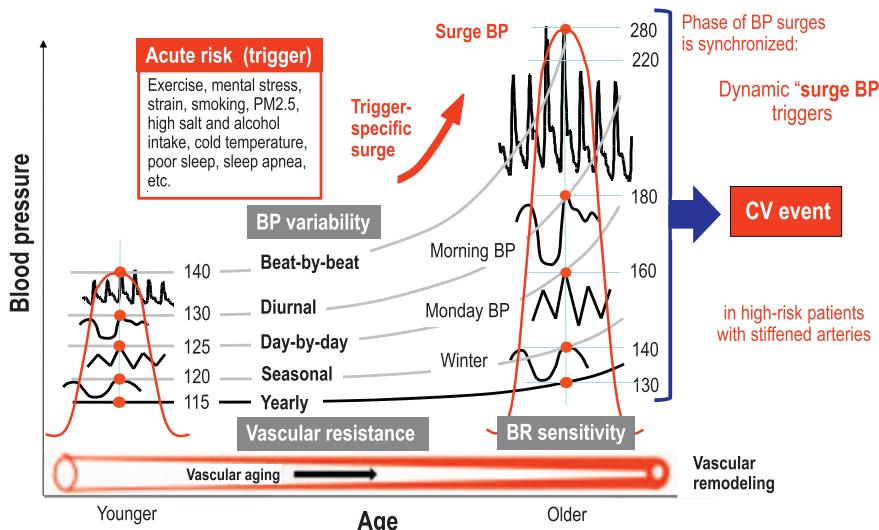
Mechanisms and evidence

BP variability

Increasing arterial stiffness due to aging and in the presence of hypertension is closely associated with BPV, including


the morning BP surge.[102] Variability in BP is seen across a variety of timeframes (beat-by-beat, diurnal, day-by-day, visit-to-visit, and yearly). BP also varies based on different environmental stimuli (e.g., temperature, humidity, light level, etc.) and by season (being higher in winter and lower in summer).[103] BPV increases with increasing age, and although most forms are related, the magnitude of variability differs between individuals.[104–107] Growing evidence suggests that each type of BPV is associated with organ damage and CVD.[103,106–108] The synergistic resonance hypothesis suggests that various forms of BPV could coincide to generate a large dynamic surge in BP, which in turn would trigger CV events, especially in high-risk patients with arterial stiffening (Fig. 38.4).[99,109]


Hemodynamic factors

The hemodynamic stress of SHATS refers to the combination of BP-related circumferential stress and blood flow–related shear stress. This means that BP is the most important hemodynamic component of SHATS.[100] BP represents the continuous physical force transmitted to cardiac and arterial walls by cyclic cardiac contractions. Even when SBP and DBP values are the same, there may be different continuous waveform shapes in each cycle that produce different stress on the CV system. Cardiac function and vascular tone influence the shape of pressure waveforms, and differ based on location of atherosclerotic plaques (e.g., central CV system or peripheral sites).


SHATS is characterized by increased LV afterload via high aortic stiffness and a reduced transit time of reflected pulse waves. Therefore, reflected waves arrive at the heart in systole, while the left ventricle is ejecting blood, increasing late systolic LV afterload. Increased LV afterload, particularly late systolic load from wave reflections, promotes chronic LV hypertrophy,[110,111] diastolic dysfunction,[112–114] and atrial dysfunction,[115] and is associated with an increased risk of HF.[87,116] Acutely elevated

LV afterload secondary to exaggerated BP surges increases LV pressure and may contribute to triggering acute HF in high-risk patients with stiff arteries and LV hypertrophy.

Systemic BP-dependent hemodynamic stress affects the microcirculation, and could therefore contribute to age-related microcirculatory disease, including white matter disease (predisposing to dementia, depression, and falls in the elderly),[117,118] cardiac diseases such as microvascular angina and HF with preserved ejection fraction,[119] and CKD.[120]

Vascular component

Large arterial atherosclerosis with arterial stiffness is the central vascular component of SHATS. Stiffened conduit arteries (e.g., the aorta) do not properly absorb the power of the pulse (BP surge), and this is therefore transmitted to peripheral atherothrombotic plaques, resulting in plaque rupture and triggering atherothrombotic events such as myocardial infarction and stroke.

Microvascular disease in strain vessels also plays a key role in SHATs. Even in the absence of a large artery atherosclerotic plaque, exaggerated BP surge that is not absorbed at the conduit arteries is transmitted to small arteries anatomically exposed to high pressure that must maintain strong vascular tone in order to dampen the penetration of large pressure gradients from large arteries to the capillaries (known as strain vessels).[121] The higher wall strain on these strain vessels is partly due to their size, stiffness, and maladaptive remodeling, and from branching at a right angle from relatively larger arteries. Stiffness in

larger arteries influences the burden on strain vessels, meaning that focal pressure on the proximal portion of a strain vessel is higher when large artery stiffness is increased. Silent cerebral infarct (SCI) and clinical cerebral hemorrhage and infarction occur most often in the area of small perforating arteries (e.g., the lenticulostriate and paramedian pontine arteries) and are particularly common in elderly patients with hypertension. SCI (especially multiple SCIs), detected using brain MRI, are more prevalent in patients with versus without an exaggerated morning BP surge.[122] Burden on strain vessels also occurs in the glomerular afferent arterioles of juxtamedullary nephrons—the nearer the large artery (arcuate artery), the greater the pressure overload in afferent arterioles of the glomeruli.[121] The filtration of albumin into the urinary space is higher in the "deep" glomeruli, those nearest the arcuate arteries of the outer medulla.[121]

Role in organ damage and cardiovascular events

Even in patients without clinically overt atherosclerotic CVD events and small artery disease, small artery remodeling impairs autoregulation of blood flow to the microcirculation and organs. There is evidence that SHATS makes an important contribution to increasing the risk of CVD events or organ damage. For example, in elderly patients, increased office BPV and arterial stiffness (based on PWV and/or stiffness of the carotid artery) had a synergistic negative effect on cognitive function.[123] In the Japan Morning Surge-1 study on the effect of alpha blockade on urinary albumin excretion in 404 elderly patients with hypertension, albuminuria was significantly reduced when home BP decreased.[124] In addition, those with decreased PWV had a greater reduction in albuminuria than those with increased PWV.[124] This suggests that decreases in both BP and arterial stiffness are necessary to ameliorate organ damage.

In a recent study, SHATS was defined as simultaneous occurrence of target organ damage in the heart (LVH), carotid artery (IMT >0.9 mm and/or presence of a plaque in the common carotid artery), and the kidney (based on estimated glomerular filtration rate). Subjects with versus without SHATS had a higher prevalence of "very stiff artery" (PWV >10 m/s; 84.9 vs. 64.3%, $P < .01$) and used more antihypertensive medications.[125] For a similar level of office BP, patients with SHATS had higher 24-hour SBP and DBP, smaller nighttime SBP fall, and a twofold higher prevalence of the riser pattern of nocturnal BP (48.2 vs. 20.2%, $P < .001$) compared to those without SHATS. "Very stiff artery" and abnormal BPV were significant, independent, and strong predictors of SHATS.[125]

One of the key components of SHATS, arterial stiffness, appears to play an important role in the development of structural heart disease, including LV diastolic dysfunction,[126−128] LV hypertrophy,[129] and left atrial enlargement.[130−132] Hypertension, another important factor in SHATS, is also a risk factor for structural heart disease, especially LV hypertrophy as a marker of cardiac damage.[133]

Proposed diagnostic score

The SHATS concept provides the opportunity to assess BPV and arterial disease as a strategy to identify changes and intervene early to ameliorate progression to hypertension in younger patients or to end-organ damage and CVD events in older patients. However, there is currently no consensus on how to define or diagnose the severity of SHATS. The first step toward achieving this was the development of a proposed SHATS score[134] based on the above data suggesting that BP, hemodynamic alterations, and vascular disease play a central role in the vicious cycle of events that accelerates organ damage and triggers CVD events. The overall score includes a BP score and a vascular score, which are multiplied to calculate the SHATS score.[134] This reflects the synergistic effects of BP/BPV and vascular disease on organ damage and CVD events.

The BP score includes the following measures: office, home, and ambulatory SBP and systolic BPV, and/or the presence of atrial fibrillation (seen as the extreme manifestation of complete hemodynamic variability of BP and blood flow).[134] The inclusion of BPV measures reflects the significant associations reported between these measures and CVD risk, independent of average office BP.[135−138]

The vascular score depends on the presence of clinically overt CVD, asymptomatic CVD based on test of arterial structure or function, and/or microvascular disease. Clinically overt CVD includes stroke, CAD, HF, aortic stenosis, cognitive dysfunction, and both symptomatic and asymptomatic peripheral artery disease/aortic dissection.[134] The number of these conditions present is used to determine the CVD score, while the number of abnormal vascular test findings is used to calculate the asymptomatic CVD score. The following five components are determined to inform the vascular score: pulse pressure, ankle-brachial index or the presence of carotid plaque; arterial stiffness based on CAVI, baPWV, or cfPWV), abnormal cardiac findings (e.g., LV hypertrophy determined using echocardiography or elevated N-terminal probrain natriuretic peptide level); and other abnormalities such as reduced flow-mediated dilatation of the brachial artery, renal artery stenosis, or white matter lesion, SCI or microbleeds assessed by brain MRI. The microvascular disease score includes the presence of diabetes-related CKD and/or small artery retinopathy.

Minimum requirements to calculate the SHATS score are the following tests used in clinical practice: 1) Measurement of office BP; 2) Measurement of out-of-office (home or ambulatory) BP; 3) Measurement of large artery stiffness (using CAVI, cfPWV, or baPWV); 4) A basic cardiac evaluation (ECG); and 5) Blood (glucose, creatinine) and urine (albuminuria/proteinuria) analysis.[134]

The SHATS score has been developed with the goal of improving individualized patient management to prevent CV events. However, it requires validation before widespread use in clinical practice can be recommended.

Potential treatment strategies

To obtain the greatest benefit, the goal would be to detect and reduce the risk of SHATS in its early phase. SHATS precedes hypertension in younger adults and therefore earlier detection of SHATS and lifestyle modification before the development of HTN is important for the prevention of future CVD. In older patients with advanced SHATS, surge BP could trigger CVD events. Therefore, more strict control of BP and returning BPV to a normal circadian rhythm (including suppression exaggerated BP surge) should contribute to the prevention of CVD events.

Strategies to reduce the risk of SHATS should concentrate on preventing or interrupting the synergistic vicious cycle involving BPV and vascular disease. There is a range of international guidelines to inform evidence-based approaches to reducing high BP.[139−145] In addition to reducing BP levels, maintenance/restoration of adequate dipping status of nocturnal BP, and reducing exaggerated BP surge(s) are important components of achieving "perfect 24-hour BP control."[14] Morning home BP is closely associated with CVD (including both stroke and CAD),[146] especially in those with high CVD risk,[147] and therefore is an important target in managing SHATS. Achieving 24-hour BP control with well-controlled morning BP requires the use of long-acting antihypertensive agents, use of split or bedtime drug dosing, and/or combination therapy.[148] Inclusion of a long-acting calcium channel blocker would be useful because this reduces BPV.[149,150] In addition, the combination of a long-acting calcium channel blocker and an angiotensin receptor blocker has been shown to effectively reduce PWV as well as ambulatory and home BPV.[151] For patients with both hypertension and diabetes, treatment with a sodium−glucose co-transporter-2 (SGLT2) inhibitor effectively reduces morning and 24-hour BP, regardless of baseline glucose control status.[152] In addition, renal denervation may reduce 24-hour BP, including nighttime and morning BP.[153] However, the efficacy of renal denervation remains unclear and requires further study.

In contrast to the well-documented approaches to managing hypertension, there are currently no specific pharmacologic approaches to improve subclinical vascular disease (particularly large artery stiffening). However, a strategy that involves management of multiple risk factors and interventions based on current evidence-based therapies (such as statins and glucose-lowering drugs that reduce the risk of atherosclerotic CVD [e.g., glucagon-like peptide 1 agonist] and/or HF [e.g., SGLT2 inhibitors] in diabetes) may attenuate the progression of SHATS. There is not yet any specific evidence for use of antiplatelets and/or anticoagulants in SHATS, but data from the use of these agents for the primary or secondary prevention of CVD events in high-risk individuals based on standard clinical risk factors suggest that they may have a role in SHATS. However, a substantial proportion of the current burden of CVD may not be attributable to these standard CVD risk factors. Evolution of knowledge around the phenotyping of SHATS will require the design and implementation of new trials to assess the potential benefits of targeting early-stage, asymptomatic vascular disease, even when clinical factors might not suggest the need for intervention. In addition, the search for specific strategies that reduce large artery stiffening with age should be aggressively pursued.

Conclusion

There is a rapidly growing body of evidence for interactions between arterial stiffness, atherosclerosis, and hemodynamics as important contributors to CVD and cerebrovascular events. The SHATS syndrome combines these three important pathologies and provides a mechanistic link between arterial stiffness and CVD events. Evaluation of SHATS offers the possibility of early intervention to reduce CV risk and the occurrence of outcome events such as stroke and CAD. However, it remains to be determined whether assessment and monitoring of vascular failure (including arterial stiffness and vascular disease such as atherosclerosis) and early intervention based on this information will facilitate improvements in CV prognosis. This needs to be investigated in appropriately designed randomized clinical trials, and the resulting data used to inform future treatment approaches and evidence-based guidelines.

Chapter 39

Arterial stiffness and pulsatile hemodynamics in coronary artery disease and other forms of atherosclerotic vascular diseases

Junichiro Hashimoto

Miyagi University of Education Medical Center, Sendai, Miyagi, Japan

Introduction

Many acute cardiovascular events occur in the presence of atherosclerotic lesions in arteries responsible for vital organ perfusion. For early prevention of cardiovascular diseases, numerous efforts have been made to clinically evaluate atherosclerosis noninvasively. The various evaluation methods include the local assessments of intimal (stenotic) plaques and the regional or systemic assessments of arterial stiffness, since this can be a consequence of atherosclerosis. Strictly speaking, however, atherosclerosis and arteriosclerosis (assessed as arterial stiffness) are distinct entities (Table 39.1); they are different from each other in terms of pathology (i.e., intimal thickening vs. medial degeneration)

and distribution (i.e., local vs. systemic). Since atherosclerosis (at least in the initial stage) may be patchy throughout the large arteries, not all atherosclerotic plaques necessarily influence actual stiffness measures until they become thickened, confluent, and calcified. For instance, studies disagree about aortic distensibility in patients with hypercholesterolemia (a major risk factor for atherosclerosis). Some studies of young patients have reported reduced distensibility,[1] whereas other studies of older patients showed opposite results,[2] indicating that the involvement of atherosclerosis in arterial stiffening differs considerably according to whether it is in the early or late stage. Despite their different pathologies, however, atherosclerosis and arteriosclerosis coincide in most cases

TABLE 39.1 Traditional view of arteriosclerosis and atherosclerosis.

	Arteriosclerosis	Atherosclerosis
Mainly affected arterial wall layer	Media of elastic arteries	Intima of elastic and muscular arteries
Predilection site	Diffuse	Focal (bifurcation, high curvature)
Arterial lumen	Dilatation	Stenosis/occlusion
Pathology	Elastic fracture/degeneration	Lipid accumulation/inflammation
Hemodynamic etiology	Tensile stress	Shear stress
Main risk factors	Age/hypertension	Age/hypercholesterolemia/diabetes/smoking
Reversibility	−	± (Stabilization +)
Wall stiffness	↑	↑ or →

and have common risk factors, such as older age. From a hemodynamic point of view, diffuse arteriosclerosis (specifically, the stiffening of large arteries) leads to substantial changes in systemic hemodynamics. These changes are represented by an increase in central systolic pressure and a decrease in diastolic pressure, which affect local hemodynamics in organs and tissues perfused by these arteries. When arteries are narrowed by atherosclerosis, local hemodynamics can be impaired and relevant tissues underperfused, leading to end-organ ischemia or infarction. These findings indicate a clinically inextricable link between atherosclerosis and arterial stiffness.

This chapter addresses the roles of aortic stiffness and pulsatile hemodynamics in various atherosclerotic diseases, including coronary artery disease (CAD), peripheral artery disease (PAD), and stroke. This chapter is focused on (a) the clinical and epidemiological evidence regarding associations between aortic stiffness/hemodynamics indices and atherosclerotic diseases and (b) potential underlying mechanisms responsible for these associations.

Coronary artery disease

Clinical evidence

CAD is the leading cause of mortality and morbidity worldwide.[3] CAD has various risk factors, including age, smoking, hypertension, diabetes, and hypercholesterolemia. In addition to these traditional risk factors, further focus has recently been directed toward arterial stiffness and pulsatile hemodynamics.

Several studies have shown associations between aortic stiffness and CAD. Cross-sectional studies have demonstrated that carotid-femoral pulse wave velocity (PWV), which is the gold standard for noninvasive measures of aortic stiffness,[4] and PWV index, which is calculated as ([measured PWV−theoretical PWV]/theoretical PWV), are associated with the extent and severity of stenotic lesions detected by coronary angiography.[5,6] In addition, prospective studies have shown that carotid-femoral PWV is a predictor of primary coronary and total cardiovascular events, independent of conventional risk factors.[7−10] Furthermore, in recent years, the prognostic significance of aortic stiffness for cardiovascular events has been evaluated based on other PWV measures, rather than the traditional carotid-femoral PWV. In the Multi-Ethnic Study of Atherosclerosis (MESA), aortic arch PWV was assessed using magnetic resonance imaging (MRI) in 3527 participants, and it was found to be predictive of cardiovascular (including coronary) events during the 10-year follow-up of middle-aged individuals.[11] In another study, a 48-h PWV was estimated in 170 hemodialysis patients by an ambulatory blood pressure monitor, and was shown to predict

cardiovascular events (including fatal/nonfatal myocardial infarction and coronary revascularization) during the median follow-up period of 26 months.[12] That study[12] also showed that ambulatory PWV was a stronger predictor of cardiovascular events than brachial resting or ambulatory blood pressure, suggesting that arterial stiffness does have an impact on the risk for cardiovascular events. However, as discussed in Chapter 7, estimations of PWV via single-site cuff measurements are problematic and may be confounded by various factors.

There is increasing evidence regarding the significance of central pulsatile hemodynamics in CAD. Nishijima et al.[13] were the first to report a cross-sectional observation that aortic pulse pressure, but not mean arterial pressure, was higher in patients with CAD, indicating the importance of the pulsatile, rather than steady, component of central pressure as a CAD risk. Weber et al.[14] showed that the aortic augmentation index (AIx) and augmented pressure correlated with the presence and severity of coronary stenotic lesions in patients suspected of CAD, suggesting the involvement of peripheral wave reflection in coronary atherosclerosis progression.

Prospective studies have repeatedly demonstrated the involvement of aortic pulsatile hemodynamics in the prognosis of CAD.[15] Most of the studies have shown indices of pulse wave reflection (e.g., aortic AIx, augmented pressure, and reflection magnitude) to be independent predictors of major adverse cardiovascular events (such as myocardial infarction, coronary restenosis, and death) in patients with CAD,[16−20] emphasizing the potential relevance of peripheral wave reflection to CAD progression. In addition, some studies attempting to compare the predictive ability between aortic and brachial pressures have revealed that aortic pressure is a better predictor of cardiovascular events than conventional brachial pressure. For instance, Chirinos et al.[21] showed that higher aortic but not brachial pulse pressure, as well as lower diastolic pressure, were significantly associated with an increased risk of major adverse cardiovascular events (unstable angina pectoris, myocardial infarction, coronary revascularization, stroke, and death) in a CAD cohort. Jankowski et al.[22] demonstrated that aortic pulse pressure, but neither brachial pulse pressure nor mean arterial pressure, was predictive of cardiovascular events (myocardial infarction, stroke, cardiac arrest, heart transplantation, myocardial revascularization, and death) in CAD patients. In the MESA cohort, Chirinos et al.[20] showed that lower pulse pressure amplification (i.e., radial/aortic pulse pressure ratio) was associated with a higher incidence of cardiovascular events (including myocardial infarction, angina, stroke, and cardiovascular death) in a general population. This clearly indicates that the predictive ability of aortic pulse pressure is independent of peripheral pulse pressure.

The evidence mentioned above indicates that aortic stiffening and widened pulse pressure are closely related to the development and progression of CAD. Together with a recent finding that the combination of higher carotid-femoral PWV and wider central pulse pressure were associated with a considerably higher incidence of cardiovascular disease than either alone,[23] aortic stiffening and increased pressure pulsatility may have synergistic adverse impacts on CAD.

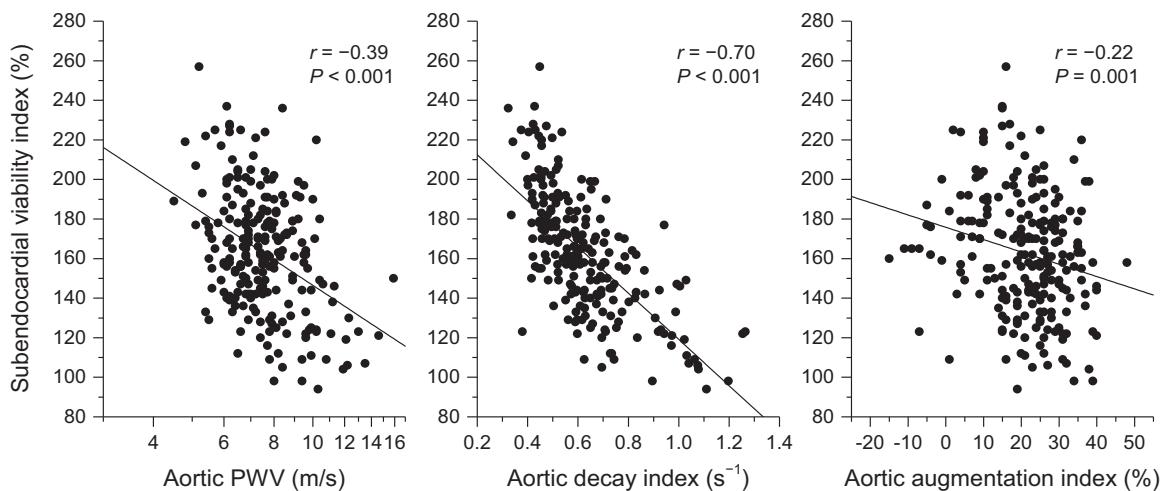
Mechanism

Atherosclerotic narrowing of the large coronary arteries is the main cause of CAD. Formation of atheromatous plaques with or without thrombus or calcification narrows the coronary artery lumen, reduces blood flow downstream of the stenotic lesions, and induces myocardial ischemia, which leads to coronary events. Besides atherosclerotic CAD, other etiologies for ischemic heart disease include coronary vasospasm and microvascular dysfunction, which are usually diagnosed when the epicardial coronary arteries appear structurally normal on conventional coronary angiography. The common pathophysiology to atherosclerotic and nonatherosclerotic CAD is the presence of abnormalities in coronary hemodynamics.

Coronary arteries have characteristic structures and hemodynamics. Anatomically, the coronary arteries branch off vertically from the central aorta. Hemodynamically, coronary flow occurs mostly during diastole. These structural and hemodynamic features suggest that diastolic lateral pressure in the central aorta is an important determinant of coronary flow.

Aortic stiffness plays a major role in determining coronary hemodynamics.[24] Stiffening of the elastic aorta leads to an increase in systolic blood pressure, a decrease in diastolic blood pressure, and, consequently, a widening of pulse pressure. The elevation of aortic systolic pressure increases left ventricular afterload, resulting in an increase in myocardial oxygen demand. Peripheral wave reflection enhanced by aortic stiffening can cause the extra left ventricular workload to maintain the cardiac outflow against the reflected waves, and such wasted left ventricular effort contributes to an increase in systolic tension-time index and compensatory development of left ventricular hypertrophy.[25,26] The reduction of aortic diastolic pressure leads to a decrease in coronary perfusion pressure and myocardial oxygen supply. Such an imbalance between myocardial oxygen supply and demand resulting from central hemodynamic alterations may account for the predisposition of hypertensive patients (particularly those with isolated systolic hypertension) to CAD.[27]

Despite such a theoretical basis for the relationship between increased aortic stiffness and decreased coronary blood flow, direct in vivo evidence has been scarce on any aorto-coronary relationship until relatively recently. Previous experimental studies have shown conflicting results; some have associated arterial stiffness with reduced coronary flow,[28] while others have associated it with increased coronary flow.[29] However, subsequent clinical studies in humans have consistently reported a significant contribution of aortic stiffening to decreased coronary flow. For instance, in patients undergoing percutaneous coronary intervention, aortic PWV was related to resting and hyperemic coronary blood flow irrespective of the presence of stenosis.[30] In another study of patients with CAD, the aortic PWV and central (carotid) pulse pressure were inversely correlated with the time to myocardial ischemia during a treadmill test.[31] Nelson et al.[32] recently used intracoronary Doppler flow measurement and noninvasive cardiovascular MRI to confirm significant associations between aortic stiffening with reduced resting and hyperemic coronary blood flow among patients with minor angiographic coronary disease. That study also showed that aortic pulse pressure was inversely associated with hyperemic coronary blood flow and coronary flow velocity reserve.[32]

The influence of central hemodynamics on coronary hemodynamics has been assessed noninvasively using the subendocardial viability ratio (SEVR), also known as the Buckberg index.[33,34] The SEVR is calculated on the basis that the aortic systolic pressure-time integral (SPTI, the area under the aortic pressure curve during systole) represents the myocardial oxygen demand,[35] and that the aortic diastolic pressure-time integral (DPTI) represents the myocardial blood supply; therefore, the ratio of the latter to the former represents the myocardial oxygen supply/demand balance. Buckberg et al. showed that there was no significant difference between the subepicardial and subendocardial blood flow when the SEVR (i.e., the ratio of DPTI/SPTI) exceeded 1.0. When the SEVR was below 0.8, the subendocardial muscle was underperfused relative to the subepicardial muscle.[34] Barnard et al. determined that subendocardial ischemia became apparent on ECG when the SEVR fell below 0.45 in normal hearts.[36] Subendocardial ischemia can occur at an even higher SEVR with large increases in left ventricular mass or dilatation, and therefore, the critical value of 0.8 may be considered reasonable.[37] The SEVR reflects coronary flow reserve in hypertensive patients with normal coronary arteries.[38]


The SEVR is determined by not only ejection duration (heart rate) and aortic mean diastolic/systolic pressure ratio but also age and sex. An epidemiological study of 3682 healthy volunteers showed that the SEVR decreased with aging in both men and women, but women consistently had lower SEVRs than men at all ages.[39] These data indicate that age-related arteriosclerosis predisposes elderly people to myocardial ischemia and also supports the fact that

women are more prone to ischemic episodes as they get older, even in the absence of significant stenosis on coronary angiography (i.e., syndrome X).[40]

Several studies have reported significant associations between the SEVR and aortic stiffness and wave reflection. Guelen et al.[41] demonstrated that, in a general population of 2490 older adults, aortic SPTI increased, whereas DPTI decreased with increasing aortic carotid-femoral PWV and, accordingly, the SEVR decreased with aortic stiffening. In a study of cardiology outpatients, Namasivayam et al.[42] showed that both incident and reflected waves were strong predictors of tension-time index (i.e., the product of SPTI and heart rate), but only the reflected wave was associated with a longer ejection duration. They also reported greater independent contributions of incident waves (as measured by the incident pressure wave height) and reflected waves (as measured by augmented pressure) to lowering SEVRs.[39] A recent study extended these findings by using the SEVR in 222 hypertensive patients without CAD and confirmed significant inverse associations of aortic PWV and AIx with the SEVR.[43] Notably, this study[43] revealed an additional finding that the exponential decay of aortic pressure during diastole, a marker of total arterial compliance,[44] was correlated with the SEVR ($r = -0.70$, $P < .001$) more closely than with the aortic PWV or AIx (Fig. 39.1). In mediation analysis, the association between higher PWV and lower SEVR was indirect and mediated through faster aortic diastolic pressure decay, indicating that the impairment of myocardial viability secondary to aortic stiffening resulted from accelerated diastolic exponential decay of central blood pressure. In addition, the rapid decline of blood pressure during diastole was a characteristic of hypertensive patients with stiff aorta.[43]

Taken together, these findings suggest that the faster the diastolic pressure decay, the lower the SEVR becomes, thus predisposing hypertensive patients to ischemic heart disease.

The evidence mentioned above indicates that abnormalities in central pulsatile hemodynamics are a key initiator of myocardial ischemia, even in the absence of coronary stenosis. On the other hand, major adverse coronary events are also attributable to local (i.e., coronary) atherosclerosis progression and plaque instability. To date, however, evidence for the potential association between aortic stiffness and coronary atherosclerosis is limited. A possible association between arterial stiffness and coronary artery calcification (which may not only cause luminal narrowing but could also contribute to "stable" plaques) has varied among different study samples, such as a general population[45] and renal transplant recipients.[46] A recent prospective study of patients with type-2 diabetes demonstrated an association between baseline aortic PWV and low-density noncalcified plaque volume on computed tomography coronary angiography 5 years later.[47] Local stiffness measured as coronary PWV may be "lower" in patients with acute coronary syndromes versus stable CAD, even when aortic PWVs do not differ.[48] In addition, while higher PWV is associated with carotid intraplaque hemorrhage (i.e., a sign of vulnerable plaques) in the general population,[49] its potential involvement with coronary plaques is currently unclear. Finally, although brachial pulse pressure (as an indicator of pulsatile tensile stress) is independently associated with carotid plaque ulceration,[50] it remains to be determined whether aortic pulsatile pressure triggers coronary plaque rupture. Further studies are necessary to clarify these important issues.

FIGURE 39.1 Relationships between aortic function measures and subendocardial viability index in patients with hypertension.[42] Aortic decay index (λ) is calculated as $P(t) = P_0 e^{-\lambda t}$, where $P(t)$ is the pressure at the time from the end of systole (t), P_0 the estimated pressure at end systole, by regarding diastolic pressure curve as a monoexponential decay.

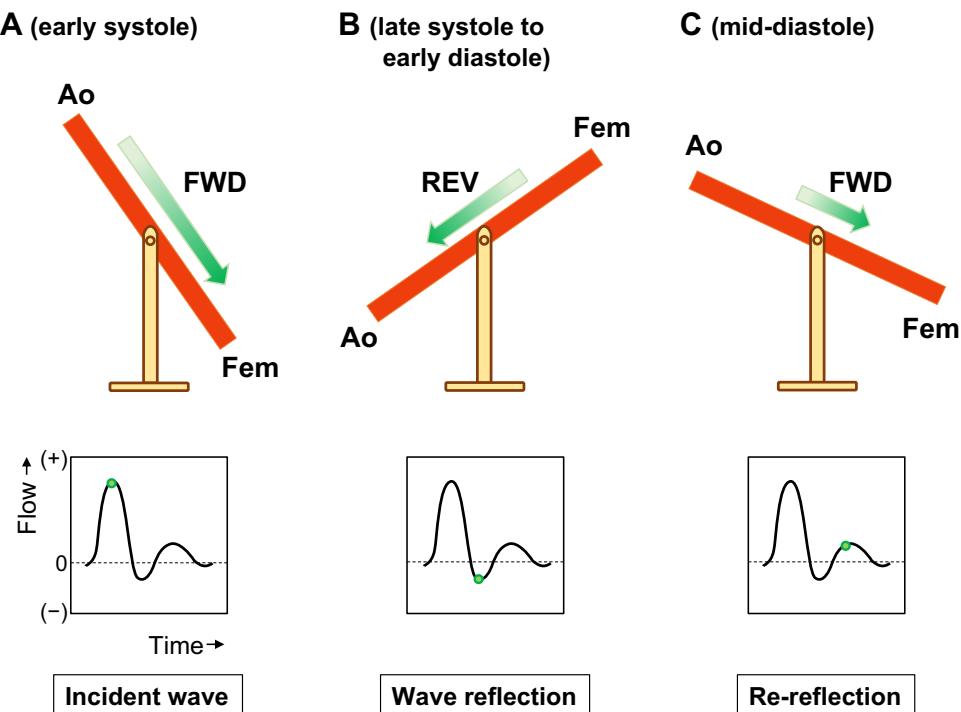
The reader is referred to Chapter 18 for a comprehensive review of the hemodynamic determinants of myocardial supply and demand.

Peripheral artery disease

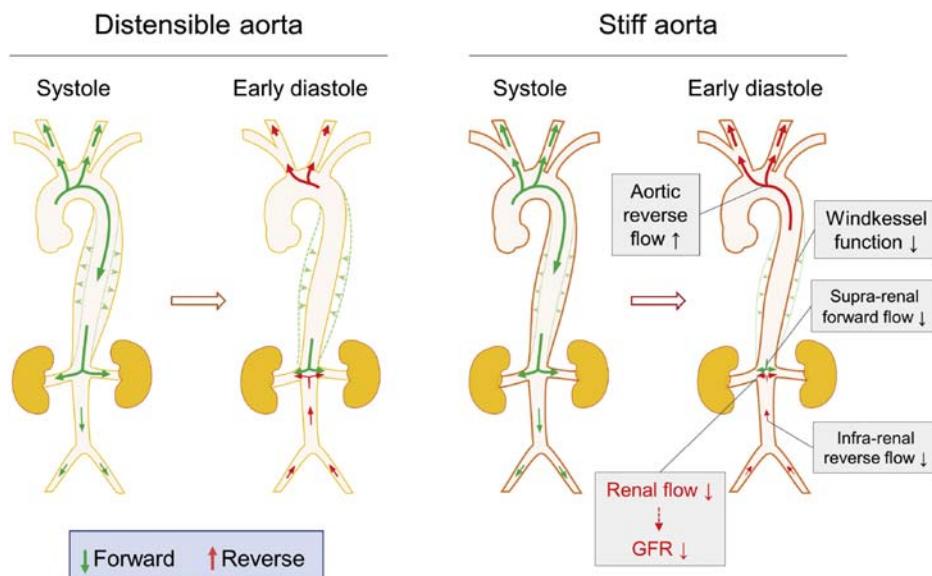
Clinical evidence

PAD is mainly caused by the progression of atherosclerosis in the arteries of the lower extremities. A world database recently estimated that 237 million people (5.6%) aged >25 years had PAD in 2015.[51] PAD is linked to a significantly increased risk of cardiovascular morbidity and mortality as well as disability, and it is the third most common clinical manifestation of atherosclerosis, after CAD and stroke.[52]

Several studies have investigated arterial stiffness indices in patients with PAD. Most of the studies have demonstrated that aortic AIx and pulse pressure are higher in patients with PAD than in controls.[53−55] Such alterations in central hemodynamics are related to lower limb function; higher AIx and lower round-trip travel time of pulse waves (i.e., earlier return of the reflected waves) are associated with decreased walking ability in PAD patients.[56] Furthermore, revascularization of peripheral artery stenosis with percutaneous transluminal angioplasty contributes to a significant reduction in AIx.[57] In contrast to AIx, the relationship between aortic PWV and PAD is more complex and likely depends on the severity of PAD. Some studies have shown that when PAD is diagnosed as an ankle-brachial pressure index (ABI) of <0.9, the PAD patients as a whole have significantly increased carotid-femoral PWV compared with subjects without PAD.[58,59] However, in cases of critical limb ischemia with more advanced arterial obstruction, the carotid-femoral PWV is decreased, although the AIx is increased.[55]

Mechanism


There is ample evidence for an inverse correlation between aortic AIx and ABI in patients with and without PAD.[60−62] This suggests that the presence of lower extremity atherosclerotic disease increases wave reflection or, alternatively, increased wave reflection (and arterial stiffness) may increase the risk of developing lower extremity PAD. The former may be explained on the basis that (1) atherosclerosis itself can increase arterial stiffness[58] and then hasten pulse wave propagation and reflection, and (2) arterial obstructions and atherosclerotic bifurcations create larger impedance mismatches at sites closer to the normal sites, which causes an increase in and premature return of wave reflection.

In patients with PAD, the incidence of CAD is reported to be extremely high, and the long-term prognosis depends on the presence and severity of CAD. As mentioned previously, aortic stiffening and earlier return of wave reflection lead to faster aortic diastolic pressure decay and thereby lower SEVR,[43] which may account for a predisposition of patients with PAD to CAD. This assumption is consistent with the fact that lower ABI in PAD patients is associated with lower SEVR, as well as higher AIx.[60] These alterations in central hemodynamics are also likely to have adverse impacts on other target organs, resulting in markedly increased risks of cerebral artery disease and renal artery stenosis in patients with PAD.[52]


Normally, the flow waveform of the lower extremities is triphasic with a systolic forward flow, early diastolic reverse flow, and mid-diastolic forward flow (Fig. 39.2).[63,64] In advanced PAD, however, the flow waveform is monophasic without diastolic flow reversal; this loss of flow reversal is attributed to compensatory reduction in peripheral vascular resistance. In the case of milder atherosclerosis, the flow waveform may become biphasic, since the recoil function of the elastic and muscular arteries is lost.[63] A study on pulsatile flow waveforms of the femoral artery in hypertensive patients without PAD revealed that the reverse/forward flow index is inversely correlated with aortic PWV and AIx, and positively correlated with aorta-to-femoral pulse pressure amplification.[63] This finding indicates that aortic stiffening and a reduced aorta-to-leg pressure gradient attenuate femoral diastolic flow reversal (Fig. 39.2).[64] A similar flow reversal has been observed throughout the infra-renal aorta and iliac arteries, and diastolic reverse flow is considered essential for blood supply to internal organs, including the kidneys.[65] Specifically for the kidneys, both the forward flow from the suprarenal aorta and the reverse flow from the infrarenal aorta generate the total inflow into the renal arteries in early diastole (Fig. 39.3),[65,66] and the infrarenal aortic (as estimated from the femoral) flow reversal determines the intrarenal diastolic flow.[67] Therefore, it seems likely that the disappearance of diastolic flow reversal due to lower extremity artery atherosclerosis will cause hypoperfusion in the kidney as well as the pelvic organs, which will lead to functional impairments.[63] In addition, a reduced mid-diastolic forward flow (typically seen as a biphasic pattern of the femoral flow) resulting from aortic stiffening[63] could contribute to a decrease in total blood flow into the lower extremities and hence predispose patients to PAD.[68]

Caution is required when using carotid-femoral PWV to evaluate aortic stiffness in patients with PAD. In the case of critical limb ischemia, even if a markedly attenuated PWV is observed, it may not be attributable to a true reduction in aortic stiffness, but rather to a decrease in distending pressure distal to arterial stenosis (e.g., due to aortoiliac disease). In this regard, the ratio of aortic pulse pressure to PWV may be helpful in diagnosing advanced PAD.[55]

FIGURE 39.2 Hypothetical mechanism for the association between alternate pressure gradients and bidirectional (triphasic) flow at the femoral artery (seesaw theory).[63] *Ao* indicates aorta; *Fem*, femoral artery; *FWD*, forward flow; *REV*, reverse flow. Upper panels: The slope of the seesaw (shown in red) represents pressure gradient, and the *arrow* (in green) represents flow velocity and direction. Changes in pressure gradient and flow velocity are shown in chronological order from early systole (A) late systole/early diastole (B) to mid-diastole (C) Middle panels: Femoral flow waveform is depicted in time domain, with the horizontal *dotted line* as zero flow. The *green circle* represents femoral flow at the corresponding time. Lower panels indicate main hemodynamic events.

FIGURE 39.3 Estimated aortic, carotid, renal, and femoral blood flow patterns during systole and early diastole in the case of distensible aorta (left) and stiff aorta (right).[66] Aortic forward and reverse flows are depicted as *arrows* in terms of magnitude and direction. *Light green arrows* represent Windkessel function of descending thoracic aorta.

Aortic calcification

Clinical evidence

As mentioned above, several previous studies have investigated the associations between aortic stiffness and local atherosclerosis in coronary and lower extremity arteries. However, atherosclerosis is a systemic but patchy disease; thus, the presence of plaque in one area might not equate to its presence in another. As such, studies examining the link between arteriosclerosis and atherosclerosis have also included the aorta itself.

In the Rotterdam Study of elderly subjects,[58] atherosclerosis of the abdominal aorta was determined by assessing the calcified deposits on a plain radiograph. The results showed that an increased number of aortic calcified plaques was associated with a higher carotid-femoral PWV.[58] A study of healthy volunteers also confirmed a significant association between aortic PWV (but not AIx) and aortic calcification, which was quantified as aortic calcium content observed from high-resolution computed tomography.[69] In patients with chronic kidney disease, a strong positive association between aortic calcification and stiffness is well recognized.[70,71] In a recent prospective study investigating annual changes in brachial-ankle PWV and aortic calcium score, increased aortic calcification was found to be an independent determinant of greater progression of arterial stiffness in healthy middle-aged men.[72]

Compared with calcified plaques, the association between noncalcified atheromatous plaques and aortic stiffness is less obvious. A heritability study of female twins used combined computed tomography and MRI to demonstrate that, whereas there was an independent significant association between aortic PWV and calcification mediated by genetic factors, aortic PWV was not linked to plaque score.[73] An autopsy study that examined the relationship between premortem carotid-femoral PWV and postmortem plaque scores of systemic large arteries showed only a weak correlation, which was independent of age and blood pressure.[74] A recent magnetic resonance study of subjects without clinical symptoms of cardiovascular disease failed to find an independent association between total arterial compliance (the ratio of pulse pressure to indexed stroke volume) and atherosclerotic stenosis of systemic large arteries.[75]

Mechanism

Aortic stiffening has generally been thought to result primarily from structural degeneration of elastic fibers in the medial layer, which is accompanied by an increase in collagen fibers, ground substance, and often calcium deposition. Given the evidence mentioned above,[58,69−72] aortic calcification is causally linked to aortic stiffness and can be proposed as an additional mechanism for aortic

stiffening. Aortic calcification is pathologically classifiable into two types: (1) intimal calcification attributable to advanced atherosclerotic plaques and (2) medial calcification attributable to arteriosclerosis. The reported lack of association between early-stage (noncalcified) atheromatous plaques and stiffness[73] suggests that aortic stiffness is determined by calcification rather than by plaque burden alone. Accordingly, aortic stiffening is likely to be due to medial more than intimal calcification.[76]

However, it is also possible that aortic calcification is a consequence, rather than a cause, of aortic stiffening. Hypertension (which often accompanies aortic stiffening) is associated with increased, and faster progression of, calcification.[77] This association is theoretically explicable on the basis that increased repetitive tensile stress resulting from aortic stiffening accelerates elastic degeneration of the aortic wall, thereby contributing to aortic calcification. If this is the case, the prognostic significance of aortic calcification for predicting cardiovascular disease[77] is likely a result of adverse hemodynamic effects with respect to pulsatile load on the heart and arteries, where plaque rupture may cause thrombosis and tissue infarction. The potential mechanisms by which aortic pulsatile hemodynamics cause aortic plaque instability and thrombosis in patients with a stiff aorta will be discussed in the next section of *Stroke and Cerebrovascular Disease*.

Stroke and cerebrovascular disease

Clinical evidence

Stroke is the second leading cause of death worldwide and is responsible for excessive loss of disability-adjusted life years. Although age-standardized mortality rates decreased sharply from 1990 to 2016, the decrease in age-standardized incidence has been less steep, indicating that the burden of stroke remains high.[78]

Associations between aortic stiffness and stroke have been investigated in many previous studies. Cross-sectional, case−control studies have shown greater aortic stiffness in patients with acute ischemic stroke.[79,80] Longitudinal prospective studies have shown aortic PWV to be predictive of stroke mortality.[8,81,82] Laurent et al.[81] reported that each 1-SD (4 m/s) increase in carotid-femoral PWV was associated with a relative risk increase of 1.72 for fatal stroke. A metaanalysis of 16 prospective studies confirmed the significant predictive ability, independent of conventional risk factors, of aortic PWV for stroke events.[10] Aortic PWV is also a predictor of functional outcome in patients after ischemic stroke.[83]

Arterial stiffness is related not only to major stroke events but also to cerebral small vessel disease. Increased PWV was found in asymptomatic individuals[84−87] as well as those with symptomatic[88] lacunar stroke. Patients with

lacunar stroke are likely to have higher aortic PWV than patients with large-artery atherosclerotic, cardioembolic, or cryptogenic stroke.[89] Higher aortic PWV is also associated with the presence of white matter hyperintensities (WMHs), whether qualified using the Fazekas scale or quantified using hyperintensity volume.[85−87,90−93] In two prospective studies, baseline aortic PWV was shown to be independently predictive of WMH volume after 7−10 years.[94,95] Aortic PWV is also cross-sectionally associated with cerebral microbleeds[90] and enlarged perivascular (Virchow−Robin) spaces.[96]

These microvascular brain lesions (WMHs, lacunar infarcts, microbleeds, and enlarged perivascular spaces) are closely linked to cognitive impairment. In addition, a number of studies have reported a cross-sectional relationship between increased aortic stiffness and cognitive decline using mini-mental state examination scores.[97,98] Longitudinal studies have also shown that aortic stiffness is associated with faster rates of cognitive decline[99,100] and can be predictive of mild cognitive impairment and dementia.[101]

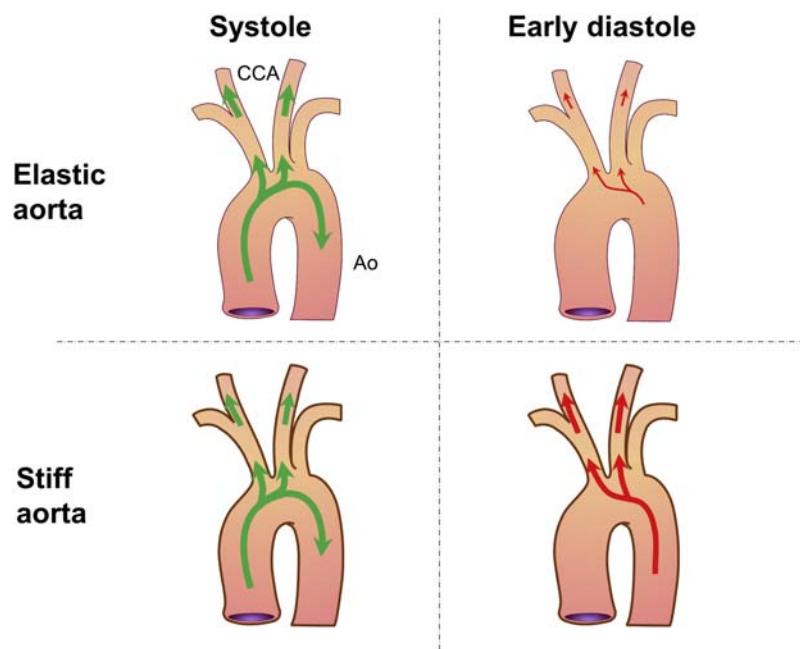
Analogous to aortic stiffness, measures of central hemodynamics have also been considered to be predictive of, and significantly associated with, stroke. A cross-sectional study demonstrated higher aortic AIx in patients with acute ischemic stroke than in control subjects.[88] Several prospective studies have shown that central pulse pressure and AIx predict cardiovascular events, including major (mostly large vessel) stroke, and their predictive abilities can be more precise than, or independent of, brachial blood pressure.[18,22,102,103]

Recent focus on central hemodynamics has been directed toward the prediction of asymptomatic small vessel diseases in the brain. Kearney-Schwartz et al.[104] were the first to report aortic AIx as an independent correlate of the severity of WMHs when they were assessed using the Fazekas scale, and this finding was confirmed by subsequent studies.[105,106] Shrestha et al. showed central systolic pressure to be associated with WMH severity independent of carotid plaque score.[107] Radial late systolic pressure (an estimate of aortic systolic pressure)[108] and central pulse pressure[86] are associated with silent lacunar infarcts. Aortic AIx can serve as a potential predictor of short-term outcomes (e.g., length of stay in hospital) after acute ischemic stroke, due largely to lacunar infarction.[109]

Central hemodynamic measures can predict brain function. Aortic pulse pressure and AIx were correlated with memory speed in healthy volunteers.[110] A cross-sectional observation of the Framingham Heart study showed that wider central pulse pressure was associated with lower logical memory-delayed scores.[85] In a prospective survey of the Framingham cohort, higher baseline central pulse pressure (as well as carotid-femoral PWV)

was associated with greater progression of neurocognitive decline, independent of the WMH volume.[111]

Mechanism

Cerebrovascular disease can be classified into macrovascular and microvascular types. Macrovascular (large vessel) stroke is generally attributable to atherothrombotic lesions in the carotid, cerebral, or vertebral arteries, or to thromboembolism of cardiac origin. Macrovascular stroke occurs frequently in the cortical regions that are perfused from the outside by branches arising from the pial arterial plexus. In contrast, microvascular stroke (including lacunar stroke, branch atheromatous disease, and intracerebral hemorrhage) occurs more often in the deep regions that are perfused from the inside out by short penetrating branches, which arise directly from the large cerebral arteries and circle of Willis.


One of the main mechanisms for macrovascular stroke is thromboembolism secondary to atheromatous plaque rupture in the carotid, cerebral, or vertebral arteries. Increased pulsatile stress may be responsible for plaque vulnerability and disruption,[112] given that pulse pressure is independently associated with carotid plaque ulceration.[50] Aortic stiffness is also likely related to this mechanism by increasing the central (carotid) pulse pressure. The second mechanism is cardiogenic embolism attributable to atrial fibrillation. A prospective study demonstrated that a wider central pulse pressure and higher AIx are associated with an increased risk of new-onset atrial fibrillation,[113] suggesting a potential involvement of central hemodynamics and peripheral wave reflection in triggering the development of embolic stroke.

Previously, as many as 25% of all ischemic strokes have been considered to be from unknown causes ("cryptogenic"). However, the current understanding is that most cases of cryptogenic stroke are attributable to embolic stroke of an undetermined source.[114] Potential embolic sources include minor-risk heart disease (e.g., aortic valve stenosis), covert paroxysmal atrial fibrillation, cancer-related emboli, arteriogenic emboli, and paradoxical embolism (e.g., due to the right-to-left shunt via patent foramen ovale). Arteriogenic emboli have generally been attributed to nonstenotic (<50% diameter stenosis) atherosclerotic plaques in the carotid arteries, vertebral arteries, ascending aorta, or an aortic arch proximal to the origin of the supra-aortic arteries. Recent evidence, however, indicates that even the descending thoracic aorta (which is distal to the origin of the supra-aortic arteries) is a potential source for embolism.[115] Such a retrograde plaque embolism can occur[116] because the proximal descending aorta has flow reversal in early diastole,[117] which can transport detached plaques from the descending aorta or

aortic arch to the supra-aortic arteries.[116] Of further importance, it was found that aortic stiffening (which might be exacerbated by atherosclerotic plaque lesions) increases aortic flow reversal, which can prompt any mobile complex plaques to detach from the aortic wall and increase the risk that they will flow into the supra-aortic arteries (Fig. 39.4).[117] It is also possible that degenerated aortas exhibit complex vortices that may include caudal to cranial flow in the arch or proximal descending aorta even during systole,[118] which could also trigger thrombus formation and retrograde embolism. In addition, greater aortic flow reversal contributes to a reduction in glomerular filtration rate,[66] which is recognized as a strong risk factor for stroke. There is also solid evidence that aortic atherosclerosis is one of the leading causes of embolic stroke,[119] and aortic complex plaques are much more prevalent in the descending aorta than in the ascending aorta or aortic arch.[120] Recent investigations have demonstrated that cryptogenic stroke patients more often have large vulnerable plaques in the aortic arch and descending aorta than control subjects,[121] and aortic retrograde flow markedly increases in stroke patients with concomitant complex plaques in the proximal descending aorta.[121] Taken together, further investigation is needed to establish the clinical importance of retrograde plaque embolism as a cause of cryptogenic stroke.

Similar to macrovascular stroke, microvascular cerebral diseases are attributed to aortic stiffening and altered central hemodynamics, but the underlying mechanisms may be different. The deep perforating arteries, which are responsible for subcortical lacunar infarcts and WMHs, directly branch off of the large cerebral arteries. These short, small arteries are exposed to the high pulsatile pressure of the large arteries and are therefore particularly vulnerable to cyclic tensile stress. Moreover, like the kidney,[67] the brain requires high-flow, low-resistance (and low-impedance[122]) arterial properties because of its high metabolic demands. This inevitably exposes its fragile microvessels to torrential, highly pulsatile flow from the large arteries upstream.[24] Such high pressure and flow pulsations may predispose patients to microvascular injury in the subcortical areas, which can subsequently lead to tissue damage, and finally to hypoperfusion. White matter is more susceptible to hypoperfusion because it is far less vascularized and receives less perfusion than the gray matter.

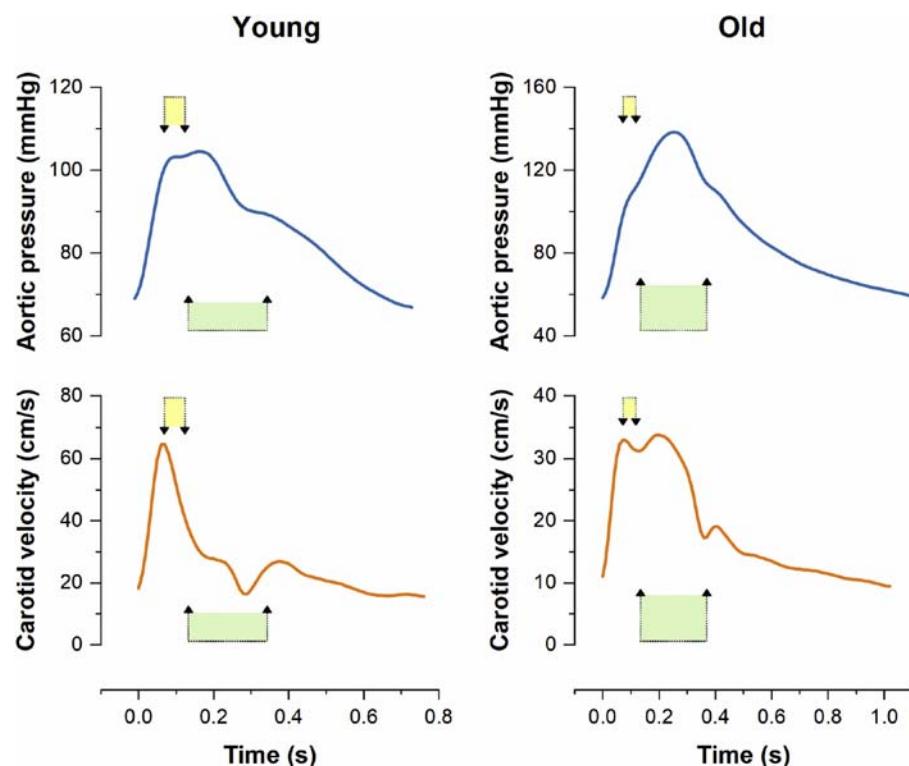
Large-artery (aorta and carotid artery) stiffening increases pressure and flow pulsations, both of which are transmitted deeply into the cerebral microvasculature, can cause microvascular baro- and trauma from excessive shear forces, respectively, leading to lacunar infarction or microbleeding in the basal ganglia. Microvascular trauma may also cause extravascular fluid exudation and


FIGURE 39.4 Association between aortic stiffness and flow dynamics in systole (left) and early diastole (right).[117] *Green* and *red arrows* represent forward and reverse flows, respectively. Thickness and length of *arrow lines* indicate flow intensity. *Ao* indicates aorta; *CCA*, common carotid artery.

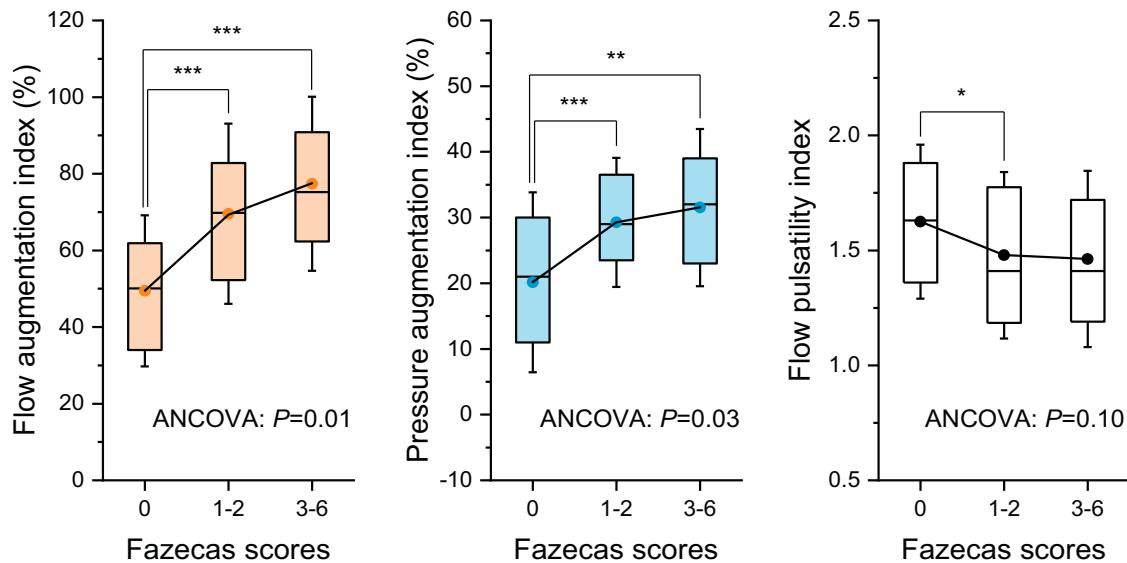
perivascular tissue edema, resulting in WMHs.[93,123] In fact, the pulsatility index (a measure of flow pulsation) of the middle cerebral artery is independently associated with WMH, along with aortic stiffness.[124] Recent studies have emphasized the pathogenic influence of peripheral pressure wave reflection on increasing the flow as well as pressure pulsations in the cerebral vasculature. Pressure wave reflection from the lower body penetrates the brain as a forward wave, this increasing pressure and flow in the carotid and brain circulation. Such influence of wave reflection becomes more marked with advancing age (Fig. 39.5). Furthermore, impedance matching at the aortic–carotid interface (due to aortic stiffening) paradoxically promotes the penetration of the reflected wave returning from the lower body into the carotid arteries.[125] Late systolic augmentation of the carotid flow, which is determined by aortic stiffness and aortic pressure augmentation,[126] was found to be associated with the presence and severity of WMHs (Fig. 39.6).[106] In addition, flow AIx was more predictive of WMHs than the pressure AIx.[106] The flow peak in early systole markedly attenuates while traveling from the extracranial to intracranial arteries but, in contrast, the flow peak or shoulder in late systole (which is augmented by pressure wave reflection) remains unchanged throughout the arterial path.[126,127] This suggests that the late, rather than early, systolic peak of the carotid artery is an indicator of intracerebral flow pulsation. The importance of the late systolic peak flow is also supported by the finding that intracranial (including middle cerebral and basilar) artery flow waveform (recorded with transcranial Doppler ultrasound) resembles the central aortic pressure waveform,[122] in which the late systolic peak is generally more prominent than the early systolic peak.


The presence of cerebral small vessel disease may account for the relationship between aortic stiffening and cognitive impairment. In fact, one study showed a direct association between higher aortic PWV and lower memory function to attenuate when WMHs and cerebrovascular resistance were regarded as mediators in pathway analysis.[128] However, it is also possible that the relationship between aortic stiffness and cognitive dysfunction appears even before overt small vessel disease develops, if cerebral blood flow is decreased. A recent study has reported greater aortic stiffening relative to lower regional cerebral blood flow in cognitively normal older adults, especially individuals with increased genetic predisposition for Alzheimer's disease.[129]

The above-mentioned discussion has focused mainly on aortic stiffness, as measured by carotid-femoral PWV. A recent metaanalysis claimed that carotid stiffness, as

FIGURE 39.5 Aortic pressure and carotid velocity pulse waveforms in young (left) and old (right) subjects.[106] The early *double down arrow* (in yellow) represents the suggested influence of wave reflection from the upper body, and the later *double up arrow* (in green) wave reflection from the lower part of the body. The length and interval of the *double arrows* indicate the estimated intensity and duration of wave reflection, respectively.

FIGURE 39.6 Association between carotid hemodynamic measures and white matter hyperintensities (WMH).[103] WMH was classified using Fazekas scale into three groups: none (0), mild (1−2), and moderate-to-severe (3−6) WMH. ANCOVA indicates analysis of covariance adjusted by potential covariates. ***$P < .001$, **$P = .01$, *$P = .03$.

assessed by ultrasound, is associated with incident stroke independent of aortic stiffness, and carotid stiffness can improve stroke risk prediction beyond aortic PWV.[130] In addition, measurement of carotid-cerebral PWV may be useful to detect segment atherosclerosis between the common carotid artery and ipsilateral middle cerebral artery,[131] which is the most frequent cause of anterior circulation ischemic stroke. Further studies are needed to clarify the clinical usefulness and pathophysiological implications of these local stiffness measurements for stroke prediction and prevention.

Although not directly related to atherosclerosis, some of the mechanisms discussed above are also relevant for cognitive dysfunction associated with aortic stiffening, which is discussed in more detail in Chapter 41.

Perspectives

In conclusion, aortic stiffness and central hemodynamics are deeply involved in the pathophysiological mechanisms of atherosclerotic diseases. Current data imply that destiffening therapy and antihypertensive therapy may have the potential to ameliorate central hemodynamic abnormalities and improve the long-term prognosis of patients with systemic atherosclerotic diseases. The reported contribution of aortic calcification to arterial stiffness indicates that anticalcification therapy may also be a potential therapeutic modality for preventing aortic stiffening. Future investigations are needed to clarify whether these therapies can contribute to the stabilization or regression of atheromatous plaques and to the restoration of blood flow into target organs.

Arterial stiffness and pulsatile hemodynamics in renal disease

Raymond R. Townsend

Perelman School of Medicine, University of Pennsylvania Health System, Philadelphia, PA, United States

Importance of kidney disease

Roughly one adult in seven has impaired kidney function relative to their age.[1] Kidney function is estimated by combining a serum creatinine level with age, gender, and race to calculate the estimated glomerular filtration rate (eGFR).[2] Currently (*c.2020*) an eGFR less than 60 mL/min/1.73 m^2 is considered the lower limit of normal, and values <60 reflect impaired kidney function.[3] Kidney disease is important for two reasons. First, when the kidney function declines to a level that causes symptoms ("uremia"), in the absence of undergoing dialysis or kidney transplantation, a person will die. Although dialysis is commonly undertaken, it is expensive, averaging about $90,000 (USD) per year in 2018 (https://pharm.ucsf.edu/kidney/need/statistics accessed July 2020). Transplantation is the preferred therapy when a patient losses kidney function to the point of end-stage kidney disease (ESKD), but there is an imbalance here since about 100,000 patients reach ESKD each year, but only 20−21,000 people are transplanted each year and waiting times for a kidney transplant can exceed 5 years.[4] Second, kidney function impairment enhances the likelihood of cardiovascular events,[5] particularly hospitalized heart failure,[6] adding further burden to the individual suffering with kidney disease, and the public health economic burden of caring for this population. Consequently, an understanding of the factors involved in kidney disease progression is critical to the development of intervention studies that can mitigate the otherwise relentless progression of kidney function loss that happens to most patients with chronic kidney disease (CKD).

Unique features of the kidney circulation

The consequences of increased arterial stiffness for an organ like the kidney are likely to be selectively amplified because of characteristics that require the kidney to filter a large volume of blood continuously. In most tissues, the microcirculation is protected from the increased pulsatility attending large artery stiffening by "upstream" arterial/arteriolar constriction. The kidney, however, has a much lower inherent vascular resistance and the pulsatile nature of the large artery pressure profile penetrates deep into the kidney microcirculation.[7,8] To understand the transmission of energy contained in the large artery pulse wave, and how it may be transmitted into the kidney circulation, Woodard and colleagues in the AGES-Reykjavik Study used magnetic resonance (MR) imaging and mediation analysis.[9] This study used a *pulsatility index*, defined as the maximum minus the minimum (i.e., the amplitude) of the flow waveform divided by the mean flow in the kidney artery as ascertained from the MR imaging. They observed that large artery stiffening was associated with greater transfer of pulsatile energy into the kidneys and an associated drop out of renal vessels (rarefaction). They also noted an elevation in renal vascular resistance in this cross-sectional study

which correlated with reduced kidney function. These findings link plausibly to the idea that as the aorta stiffens, the impedance mismatching between the aortic and renal vessels results in less local wave reflection, fostering damage to the kidney microcirculatory apparatus, especially the glomeruli. The result is further impairment in the filtration function of the glomeruli, adding to kidney function loss.

Another unique feature of the kidney circulation is the distribution of glomeruli in the cortex, where a subpopulation (of roughly 10%) is situated deep in the cortex at the corticomedullary junction. This location may be particularly vulnerable to vascular strain as shown in elegant work by Ito and colleagues in Japan.[10] Since the arcuate arteries traverse the corticomedullary area, the pressure wave should be higher in the more proximal segments of the branches leading to the nearby deepest glomeruli, potentially transmitting more energy, differentially, to these deeper juxtamedullary glomeruli via their afferent arterioles. The afferent arterioles in these juxtamedullary glomeruli are also quite short, and need to generate high vascular tone to protect their downstream glomeruli. The consequences of hypertension and diabetes, which take a toll on the afferent arterioles serving these glomeruli through reducing their "gatekeeper" function, result in glomerular damage, including

albuminuria. They have labeled this a "strain vessel hypothesis," and given that a similar vascular situation exists in the brain/eye and the coronary circulation, the emergence of albuminuria may be a signal linking the known associations of CKD to the brain,[11] retina,[12] and coronary[13] circulations potentially mediated through strain vessel damage in patients with CKD.

Role of known factors for chronic kidney disease progression

Unlike cardiovascular disease (CVD), fewer risk factors are known to be significantly associated with CKD occurrence and progression. Blood pressure elevation was among the first factors associated with the development of ESKD.[14] Diabetes contributes both to the occurrence of CKD and the rate at which kidney function is lost.[15] Increasing levels of urine protein excretion are also associated with a faster decline in kidney function.[16] In addition, the recent identification of the APOL1 disease alleles helps to explain the greater susceptibility to more rapid kidney function in patients of African descent.[17,18]

In recent years, more attention has been given to pulsatile hemodynamics and arterial stiffness in CKD which will be the basis for the balance of this chapter.[19]

In depth box for clinicians: unique features of the interactions between hemodynamics and the kidney

Although protection of the heart and brain from hypertension-mediated damage has been a consistent finding in hypertension trials, there is far less data guiding clinical practice on preserving kidney function. Surprisingly perhaps, there are little data to support the concept that treating elevated BP prevents kidney disease. Moreover, once kidney failure is established, recent trials like SPRINT have shown that more aggressive BP reduction does not translate into less need for dialysis or kidney transplantation. Why is this so? One reason to consider is that unlike the heart or the brain, the kidneys are located below the heart level, and when a person is sitting or standing, they experience higher levels of BP than the heart or the brain because the column of blood in the aorta contributes to the pressure that the kidneys "see." The peculiar nature of the kidney circulation that offers a very low resistance to blood flow in the interest of cleaning the circulation through filtering high volumes of blood occurs in a situation disadvantaged by exposure to these high pressures. The delicate filtration mechanism in the glomeruli of the kidney are scrupulously protected by the afferent arteriole. However, aging, diabetes, salt sensitivity, and perhaps obesity reduce the vigilance of the afferent arteriole protective effects, and these are groups that are susceptible to kidney failure. As described in the text, a clue to the afferent arteriolar failure is the presence of elevated protein, particularly albumin, in the urine. In our experience in the CRIC Study, proteinuria is the most impressive independent risk factor for the rate at which kidney failure progresses. Drugs which reduce the urinary protein losses also seem to favorably affect large artery stiffness. Furthering our understanding of the interactions of large artery stiffness, pressure wave reflection, and afferent arteriolar responsiveness represents a logical research initiative with a promise of substantial public health benefit.

Clinical epidemiology of large artery stiffness in chronic kidney disease

Cross-sectional findings

General populations with kidney measurements

A representative general population of 1291 people incorporated measures of large artery stiffness and in their cross-sectional study, Mourad and colleagues evaluated the relationship between kidney function using serum creatinine,[20] and PWV measured with the Complior © device.[21] They noted a direct correlation between increasing large artery stiffness and measures of decreasing kidney function, but only in the tertile with the lowest kidney function.

Chronic kidney disease—not on dialysis

In a Taiwanese study of established CKD patients, Wang and colleagues conducted measurements of carotid-femoral pulse wave velocity (cfPWV) using the Sphygmocor device,[22] and measurements of kidney function using the Cockcroft-Gault equation.[23,24] They observed an increase in cfPWV from an average value of 8.4 m/s in NKF Stage 1−2 kidney function, to values of 10.1 m/s in stages 3−4 and 11.6 m/s in stage 5.

The largest study to date of arterial stiffness measurements in nondialysis CKD patients is the NIH-funded Chronic Renal Insufficiency Cohort.[25] cfPWV measurements were incorporated into an annual visit of participants enrolled in this study beginning in 2005. The first publication from the CRIC study in 2564 CKD participants showed an average cfPWV of 9.5 m/s in a population ranging in age from 21 to 75 years.[26] More than one third of the CRIC participants had a cfPWV higher than 10 m/s, the level considered clinically important for future CVD events in the European guidance document.[27] Diabetes, present in roughly half the participants, contributed about 2 m/s greater cfPWV when matched for age with nondiabetic participants. This study also showed that for every 10 mL/min/1.73 m^2 decrement in eGFR, there was an increase of 0.4 m/s in cfPWV.

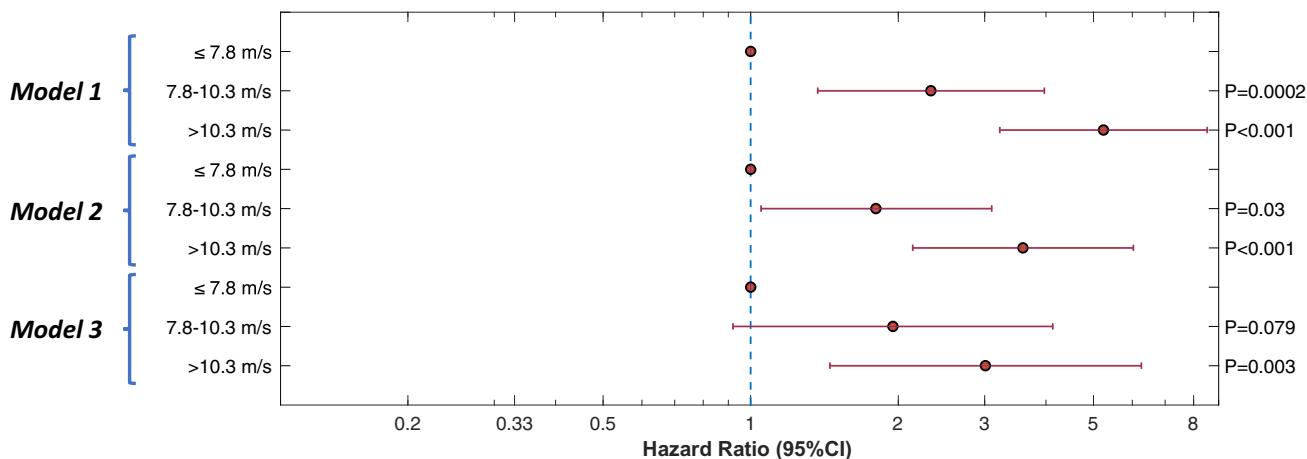
Chronic kidney disease—on dialysis (endstage kidney disease/end-stage renal disease)

In the Hemodialysis Patients treated with Atenolol or Lisinopril (HD-PAL) study,[28] Agarwal and colleagues measured aortic PWV using an echo-Doppler technique.[29] In hemodialysis patients with an average age of 52 years, they observed a mean aortic PWV of 7.0−7.2 m/s and found that atenolol was more effective than lisinopril on reducing arterial stiffness, but this was mediated by a reduction of BP and not an independent effect.

Several European Centers have studied aortic stiffness in hemodialysis patients,[30,31] including children on hemodialysis.[32] The often cited study of Pannier and colleagues from Paris evaluated 305 subjects aged 53 years at first study using carotid-femoral tonometry.[33] The mean aortic PWV was 11 ± 3 m/s. Their study also showed that while it was possible to also measure carotid-radial and femoral-dorsalis pedis PWV, these measures were not predictive of CV survival, while the aortic PWV was clearly (and impressively) so. This study settled the issue of which vascular bed to study prospectively in patients with kidney disease.

The work of Levin and colleagues[34] from Vancouver, Canada in peritoneal dialysis (PD) patients reveals a substantial spectrum of cfPWV, which was measured using the Sphygmocor device.[35] In their study of 50 PD patients, the overall cfPWV was about 10 m/s, but ranged from average values of about 8 m/s in those with a mean age of 48 years to more than 12 m/s for those with a mean age of 68 years.

An impressive number of cohorts have obtained cross-sectional and longitudinal evaluations of LAS in kidney disease including NephroTEST[36]; Hoorn[37]; Chronic Renal Insufficiency Standards Implementation Study (CRISIS)[38]; Age, Gene/Environment Susceptibility-Reykjavik Stud (AGES-Reykjavik)[39]; Taiwan[40]; Tokyo[41]; and Tohoku.[42]

Longitudinal studies (see Table 40.1)


Increased arterial stiffness enhances the risks of death and the likelihood of CVD events, and contributes to a sharper decline in renal function in established CKD. The dramatic study of Pannier cited previously noted a marked reduction in survival in hemodialysis patients with the highest tertile of cfPWV.[33] In the Vlachopoulos meta-analysis, 4 of the 17 longitudinal studies of arterial stiffness in human cohorts enrolled patients exclusively with ESKD.[43] In that meta-analysis, hazard ratios for patients on dialysis with higher PWV values ranged from 2 to 4x the referent population for CV events and reduced survival. Arterial stiffness is clearly linked to reduced survival and likely a significant component of the marked disparity in longevity between a dialysis patient compared with an age matched non-CKD control.[44]

In the CRIC Study, we were able to measure cfPWV using the Sphygmocor © device in 12 enrolling centers in the United States.[25] We successfully obtained measurements on 2795 CRIC participants who underwent yearly assessment of kidney function for 4−5.5 years after their PWV measurement.[47] CRIC recruitment was specifically designed to encourage the participation of diabetic and black patients.[49] In our cfPWV Study, we observed that among our initial 2795 participants, 394 participants died during the 5.4 years of follow up for this outcome. We also observed that 504 participants reached ESKD (defined as

TABLE 40.1 Examples of longitudinal studies of arterial stiffness in established kidney disease cohorts.

Author year	n	Age ± SD	Method/ Device	%F	F/U duration (years)	Deaths	CV events	ESKD events	Comments
Blacher (1999)[45]	241	52 ± 16	Doppler	39%	6.0	73	48	N/A	ESKD only
Briet (2011)[36]	180	60 ± NR	Wall track and complior		3.5	10	NR	41	Increased carotid circumferential wall strain predicted GFR loss, cfPWV did not predict GFR change
Pannier (2005)[33]	305	53 ± 16	Complior	38%	5.8	96 (all CVD)	NR	N/A	End-stage renal disease only; aortic PWV predictive, but not PWV in arm or leg
Shoji (2001)[46]	265	55 ± 11	PWV-200	59%	5.3	81	NR	N/A	ESKD only; diabetics fared worse than non-DM
Townsend (2018)[47]	2795	60 ± 11	Sphygmocor	45%	4–5	394	NR	504	CKD not on dialysis; Tertiles of PWV predicted death and ESKD
Zoungas (2007)[48]	207	55 ± 13	Millar SPT-301	33%	3.6	17	65	N/A	ESKD only

cfPWV, carotid-femoral pulse wave velocity; *CKD*, chronic kidney disease; *DM*, diabetes mellitus; *ESKD*, end-stage kidney disease; *F*, female; *GFR*, glomerular filtration rate; *N/A*, not applicable; *NR*, not reported; *PWV*, pulse wave velocity.

FIGURE 40.1 Figure shows a horizontal bar graph depicting hazard ratios (with 95% CI) of carotid-femoral pulse wave velocity (PWV) tertiles in participants with chronic kidney disease for the outcome of first hospitalized heart failure in the CRIC Study. A PWV of less than or equal to 7.8 m/s is the referent group in all three models. Model 1 is the unadjusted HR for the heart failure outcome. Model 2 is HR of the heart failure outcome adjusted for age, race, sex, and enrollment site in the CRIC Study. Model 3 adjusted for diabetes mellitus, proteinuria, the presence of chronic obstructive pulmonary disease, mean arterial pressure, heart rate, high-density lipoprotein (HDL)-cholesterol, low-density lipoprotein (LDL)-cholesterol, body mass index, triglycerides, history of myocardial infarction (MI)/revascularization, current smoking, hemoglobin, human recombinant erythropoietin use, angiotensin-converting enzyme inhibitor use, beta blocker use, calcium channel blocker use, history of hypertension, fasting glucose, and serum albumin. *Adapted from Chirinos, J.A., et al., Arterial stiffness, central pressures and incident hospitalized heart failure in the chronic renal insufficiency cohort (CRIC) study.* **Circ Heart Fail.** *2014; 7(5):709−716.*

starting dialysis or receiving a kidney transplant) during the 4.1 years of follow up for this outcome. We noted that both the mean arterial pressure (MAP) and the cfPWV each had independent contributions to these outcomes. In an earlier study in CRIC, we studied 2602 participants who were free of heart failure at the time of cfPWV Study and noted that cfPWV was a significant and independent predictor of incident hospitalized heart failure in the CRIC Study participants (Fig. 40.1).[6] We observed a hazard ratio of 1.95 [0.92, 4.13; 95% CI] for the middle tertile of cfPWV (>7.8 m/s and <10.3 m/s), and 3.01 [1.45, $8 = 6.26$] for the highest tertile of cfPWV (>10.3 m/s) adjusted for diabetes mellitus, proteinuria, the presence of chronic obstructive pulmonary disease, MAP, heart rate, HDL-cholesterol, LDL-cholesterol, body mass index, triglycerides, history of MI/revascularization, current smoking, hemoglobin, human recombinant erythropoietin use, angiotensin-converting enzyme (ACE) inhibitor use, beta blocker use, calcium channel blocker use, history of hypertension, fasting glucose, and serum albumin.

Summarizing, large artery stiffness, as reflected in measurements of PWV is independently predictive of kidney function loss, ESKD, and interval CVD events. The high prevalence of diabetes in CKD populations, and the accelerated vascular aging that attends CKD, especially in patients with diabetes, are likely contributors to this phenomenon.[50] Mechanisms stiffening the large arteries in CKD are covered after the next section on pulsatility.

Clinical pulsatility indices and kidney function

Several indices exist that evaluate maximal, minimal, and mean flow parameters in the kidney circulation using either ultrasound or MR imaging. Ultrasound studies are more established, and most of the pulsatility literature on kidney function is ultrasound based.

Pulsatility index

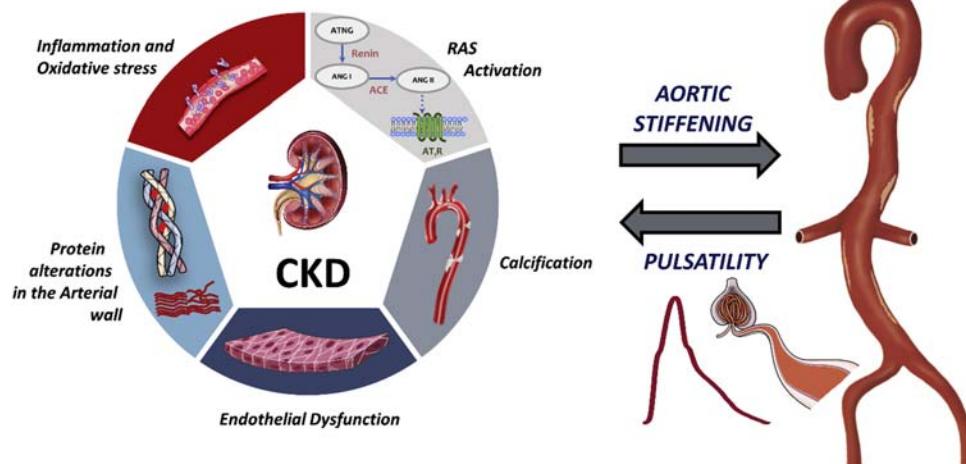
Pulsatility is an inherent property of the circulatory system. It reflects the vulnerability differential across vascular regions, in which energy in the more proximal (upstream) vasculature enters into the (downstream) microcirculation, ideally at a desirable mean pressure, with the goal of providing adequate perfusion. An early paper describing the ultrasound-derived pulsatility index appeared in 1974.[51] The basic calculation of the pulsatility index ciphers (the peak systolic flow velocity minus the minimal diastolic flow velocity) divided by the mean flow velocity. An example of the usage of the pulsatility index was cited previously in this chapter using MR imaging.[9] The mechanisms by which pulsatility promotes vascular damage in an organ like the kidney result from a reduction in the mismatch of impedance between the aorta and the kidney circulation, which reduces wave reflection, enhances flow pulsatility, and promotes damage to and loss of the kidney

microcirculation, especially the glomeruli.[19] This, in turn, results in a decrement in kidney function.

Resistive index

A resistive index (RI) is also available which is calculated by subtracting the end-diastolic velocity from the peak systolic velocity, and then dividing that by the peak systolic velocity.[52] The interlobar and the arcuate arterial beds in the kidney are the insonation target in this measurement, and a commonly used normal range is 0.50−0.70 (it is a ratio, thus unitless).

It was initially hoped that the RI would predict benefit from interventions like percutaneous renal artery angioplasty, and be useful in patient selection for that invasive procedure.[53] In this high profile study, Radermacher and colleagues observed that an RI of >0.8 indicated a reduced likelihood of benefit following successful intervention on the main renal artery in terms of ultimate BP reduction, and stabilization or improvement of kidney function. Other studies have not found this to be the case,[54,55] for reasons which include the challenge of assessing the three-dimensional aspects of threatened blood flow inferred by a two dimensional arteriogram image.[56]

The use of the renal RI is more common, at least in this author's experience, compared with the pulsatility index. It is, however, often misinterpreted as being a proxy for kidney arterial "resistance," which it is not, despite the name.[57] What it does reflect is the influence of systemic hemodynamics, particularly that of the central aorta, on the kidney circulation.[42]


The use of the renal RI has a niche in kidney transplant care, where a number of findings have emerged over the years. Renal RI is a proxy for central hemodynamics in the kidney transplant recipient, and is more reflective of the milieu of the kidney transplant *recipient* rather than the *donor*,[58,59] and when the renal RI increases in conjunction with kidney allograft dysfunction, it is predictive of antibody-mediated rejection.[60]

Mechanisms of increased arterial stiffness in chronic kidney disease

The multitude of excretory and hormonal functions that are part of normal kidney function, when impaired or absent, underscore the complex nature of the influence of the kidney on large artery health. Moreover, most of the aberrations that occur as kidney function declines have bidirectional effect wherein the loss of kidney function worsens their influence and the resultant LAS increase in turn, continues to more kidney function loss (see Fig. 40.2).

Vascular calcification

Large vessel calcification has an adverse effect on arterial stiffness.[61] The increase in stiffness, in turn, promotes a greater pulse pressure which contributes to the pathophysiology of the vessel wall calcification processes, thus perpetuating a vicious cycle.[62] Both CKD and diabetes are marked by increased vascular calcification.[63] The mechanisms leading to vascular calcification in CKD involve a

FIGURE 40.2 Figure shows bidirectional relationship of processes within (or related to) kidney disease promoting large artery stiffness and, in turn the result of increased large arterial stiffening on kidney function in patients with chronic kidney disease. See text for details.

deranged bone-mineral axis with the result that vascular smooth muscle cells take on the phenotype of osteochondrogenic cells, a process worsened by elevated glucose and lipid levels, elevated phosphorous and aldosterone concentrations that characterize the CKD patient.[64] When vascular calcification is present, it markedly enhances the CV risk of patients with this profile, particularly in the presence of end stage renal disease.[65] At this time, there are no treatments to reverse calcification in humans, though the use of pyrophosphate in an animal model of uremia associated vascular calcification was promising,[66] and accession of the clinicaltrials.gov Website using the search term "vascular calcification" returned 75 results (accessed July 2020), thus, this may change in the near future.

Renin system activation

Increased renin system activity generates additional angiotensin-II, which in turn contributes to vasoconstriction, inflammation (superoxides), vascular remodeling, and increased production and release of aldosterone.[67–69] Many years of use of blockers of the renin system have demonstrated the potential benefit of ACE inhibitors, angiotensin receptor blockers (ARBs), and mineralocorticoid receptor antagonists in managing patients with CKD.[70] The use of ACE-inhibitors and ARBs may not necessarily reduce aldosterone concentration[71] and rationale exists for combining MRAs with these agents if the patient's potassium level can tolerate the combination.[72]

Changes in vessel wall proteins

There are two key proteins in the vascular smooth muscle, elastin and collagen. Elastin proteins have good recoil, but poor load bearing function.[73] Collagens have excellent load bearing, but poor recoil.[74] The combination of both protein types results in a desirable balance of recoil and load bearing in health. In CKD there is an accelerated fragmentation and loss of elastin, and an increase in the relative amount of collagen.[67] Additionally, there is increased cross linking of collagen which reduces its turnover in the vessel wall.[75] An increase in the activity of tissue matrix metalloproteinase (MMP) activity in CKD promotes greater elastin and collagen turnover, resulting in disarray of the extracellular matrix.[76] In particular, MMPs have been shown to be upregulated in the internal mammary artery of patients with CKD,[77] and in the kidney arteries of patients on dialysis compared with the levels in kidney donors,[78] and MMPs are felt to contribute in particular to the loss of elastin. As elastin is lost and collagen gained, the large artery wall becomes stiffer.[79] Specific chemical inhibition of MMPs as well as exercise are potential tools in altering MMP activity (Table 40.2).

Advanced glycation endproducts

Similar to the section immediately prior, the cross-linkage occurring within collagen proteins in the vessel wall contributes to larger artery stiffness, and another pathway by which this happens is through the nonenzymatic glycation of carbonyl products with cross linking, particularly at lysine residues in protein[80]. Such cross linking restricts the ability of inherent process to turn over collagen protein, leading to a build-up of collagen with increasing stiffness as the result. AGEs accumulate more rapidly in the kidneys of those with diabetic nephropathy—and more so with declining renal function.[81] AGEs are both generated by the kidney, in addition to settling within the kidney in diabetic and nondiabetic kidney diseases.[82] Hope remains for a nontoxic compound to be deployed in humans either blocking the generation of AGE or blocking the receptors for AGE (RAGE).[83,84]

TABLE 40.2 Potential interventions to reduce large artery stiffness in chronic kidney disease.

Process	Goal	Possible Rx
Increased pulsatility	Reduce pulsatility	Renin system blockade (angiotensin-converting enzyme—inhibitor, angiotensin-II receptor blockers)
Vascular calcification	Reduce calcium deposition	Vitamin K supplements, magnesium supplements, and pyrophosphate supplements
Metalloproteinase	Preserve elastin content	Doxycycline
Endothelial dysfunction	Improve vasodilation	Aerobic exercise and nitrates
Oxidative stress	Reduce reactive oxygen species generation; improve mitochondrial function	N-acetyl-cysteine supplements (in dialysis patients)
Glycation endproducts	Reduce formation of AGE or block the receptor for AGE	Green tea extract, sirtuin-1, and pyridoxamine

AGE, advanced glycation endproduct; *CKD*, chronic kidney disease; *LAS*, large artery stiffness; *Rx*, treatment.

Endothelial dysfunction

The ability of the endothelium of vessel, particularly in response to shear stress, to secrete nitric oxide (NO) and potentiate vascular smooth muscle relaxation is an important means to regulate blood flow in health.[85] The reduction in, or loss of, this capacity is termed endothelial dysfunction and is a recognized component of the vascular dysfunction attendant to CKD.[86] Endothelial dysfunction promotes large artery stiffness, particularly in CKD.[87] A principal mechanism of this endothelial dysfunction, but by no means the only mechanism, is the accumulation of asymmetric dimethyl-arginine (ADMA) in the circulation due to reduced renal excretion as kidneys fail.[88] ADMA accumulation interferes with intracellular mechanisms that free NO from arginine residues. We and others have shown that aerobic exercise improves endothelial function in CKD and also improves aortic pressure waveforms.[89]

Inflammation/oxidative stress

Chronic inflammation, characterized by increased circulating levels of inflammatory biomarkers, is part of the CKD profile,[90] particularly when co-morbidities like rheumatoid arthritis, and lupus are present.[91] Positron emission tomographic scanning using fluorodeoxyglucose has been used to investigate the presence of inflammation in the aortic wall, which in turn is associated with increased aortic stiffness.[92] Inflammation-mediated damage to vascular wall proteins like elastin reduces this component in aortic compliance, and healing phases of inflammation may deposit calcium in the vessel wall contributing yet further to large artery stiffening.[93] In the CRIC Study, we showed there were significant cross-sectional associations between elevated levels of inflammatory biomarkers and large artery stiffness.[94]

Oxidative stress also affects large artery wall function, particularly in CKD.[95] We have shown, for example, that specific inhibition of NADPH oxidases restores impaired cutaneous vasodilation in CKD.[96] However, a recent Cochrane review on this topic indicates that although administration of antioxidants in human CKD does no harm, it achieves little significant benefit on CVD endpoints, with the exception of dialysis patients, in which there was some encouraging outcome data.[97]

Therapies

One of the more significant problems in the study of large artery stiffness in humans has been the challenge of disentangling an intervention designed to improve stiffness from the simple hemodynamic benefit of lowering BP itself. This was addressed in the AHA Science Statement on arterial stiffness in humans.[98] In Table 40.2 are some examples of proposed therapies to possibly improve large artery stiffness in CKD. I suggest the reader consult www.clinicaltrials.gov, and enter either a keyword like "advanced glycation" or a compound like "green tea" in the site search box, since there is literally daily turnover of listings on this website. However, to date (August 2020), and to the best of the author's knowledge, there is no FDA-approved product or intervention specifically indicated to improve large artery stiffness in patients with CKD. A timely meta-analysis of destiffening therapies in dialysis patients evaluating pharmacologic approaches mainly for treating disordered bone-mineral metabolism (vitamin D, phosphate binders), or hypertension (CCB, RAS inhibitors), found mixed results and expressed concern over the low quality of many studies.[99] Similarly, a meta-analysis of nondrug therapies from the same group noted that lowering dialysate calcium concentration, careful volume management, and promoting intradialytic exercise also seem to improve large artery stiffness, however, again it is difficult to separate stiffness findings from that of systolic BP reduction.[100]

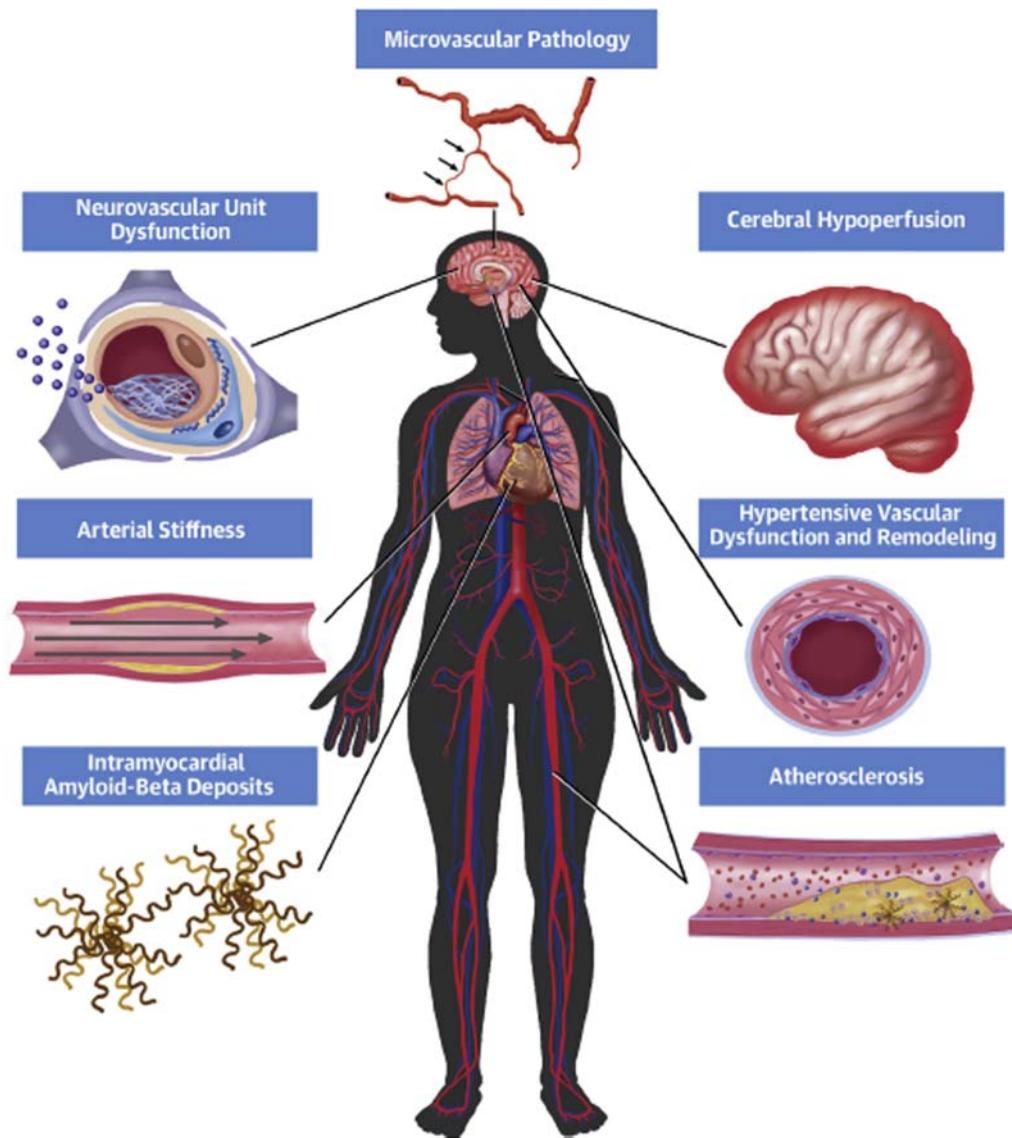
Arterial stiffness, pulsatile hemodynamics, and the vascular contributions to dementia

M.L. Meyer[1] and T.M. Hughes[2]

[1]Department of Emergency Medicine, School of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; [2]Department of Internal Medicine, Wake Forest School of Medicine, Winston-Salem, NC, United States

Introduction


Central arterial stiffness results in hemodynamic changes throughout the arterial tree and has marked effects on distal end-organs, such as the kidneys and brain. In fact, the brain pulsates with every beat of the heart.[1] Consistent perfusion of the brain is orchestrated at various levels by the sympathetic and neuromuscular tone controlling heart rate and arterial compliance, systemic blood pressure and resistance, and cerebral autoregulation. It only takes a bout of acute tachycardia induced by aerobic exercise or pre-syncope induced by orthostatic hypotension to appreciate the essential role of hemodynamics in proper functioning of the central nervous system. Chronic effects of hemodynamic insufficiency and excessive pulsatile force attributed to central arterial stiffness may be less apparent but far more insidious especially in late life.

Arterial stiffness is recognized as a vascular risk factor for age-related cognitive disorders including Alzheimer's disease (AD) and related dementias (ADRD). As previous chapters note, arterial stiffness is an age-related vascular disorder that is accelerated by cardiometabolic disorders like hypertension and diabetes. Notably, both hypertension and diabetes are identified as key modifiable risk factors for ADRD.[2]

Cognitive impairment is a clinical syndrome characterized by quantifiable deficits in cognitive performance in one or more cognitive domain with or without subjective cognitive concerns and functional impairments. At the level of dementia, functional impairments affect activities of daily living. The clinical presentation of cognitive decline along with neuroimaging biomarkers, biofluid assays, and ultimately neuropathological study of the brain are used to inform the etiology of dementia. AD and ADRD are distinct from vascular dementia in clinical presentation and underlying neuropathology. While vascular dementia is characterized by infarction, stroke, and acute, precipitous declines in cognitive function, AD is characterized by the development of hallmark AD pathology (β-amyloid [Aβ] and phosphorylated tau [p-tau]) and neurodegeneration, preceding by years and decades the insidious decline in cognitive performance over time. Yet, the vast majority of individuals with probable AD also have evidence of vascular pathology. Less than half (41%) of AD is attributable to the hallmark AD pathology[3] and the majority (75%) of probable AD have vascular pathology, especially cerebral infarction.[4] Recently, the term "Vascular Contributions to Cognitive Impairment and Dementia (VCID)" was developed to describe the broad field of research considering the role of a range of vascular risk and vascular lesions on cognition in the context of ADRD and is now used broadly by the American Heart Association,[5] the Alzheimer's Association,[6] and the NIH.[7]

The heterogeneity of ADRD pathology/etiology and the importance of VCID has implications for prevention and precision medicine. This is especially important in diverse populations as there may be ethnic/race differences in the prevalence of vascular comorbidities that may explain some of the reported excess risk for ADRD among Hispanic and African American older adults.[8] Although various vascular etiologies/pathways are important contributors to VCID and ADRD risk (Fig. 41.1),[9] this chapter will review and critique the evidence that arterial stiffness is a risk factor for reduced cognitive function and dementia through its

FIGURE 41.1   Vascular changes associated with Alzheimer's disease and related dementias. Age-related vascular changes across the cerebral vasculature and outside the brain are exacerbated in Alzheimer's disease. Intracranial and extracranial atherosclerosis, reduced cerebral microvascular density, cerebral amyloid angiopathy, and neurovascular unit dysfunction, together with large artery stiffening and hypertensive vascular remodeling, changes in heart function, and a procoagulant state, contribute to important reductions in cerebrovascular blood flow. Aβ may play a contributory role in these vascular changes. *Reprinted from Cortes-Canteli M, Iadecola C. associations with various cerebral pathologies underlying age-related cognitive decline and ADRD. In this chapter, we primarily focus the review of epidemiologic studies evaluating central and aortic arterial stiffness to ADRD. Although arterial stiffness can be measured by various modalities, the majority of studies to date measure central stiffness using aortic and carotid-femoral (cf) pulse wave velocity (PWV). We note throughout where confirmatory and novel evidence from other modalities (cardiac magnetic resonance imaging (MRI), phase contract cerebral blood flow MRI, and carotid ultrasound) when available. The second part of this chapter links this evidence with other lines of supporting research and evaluates the sum total in a causal framework linking arterial stiffness to ADRD.

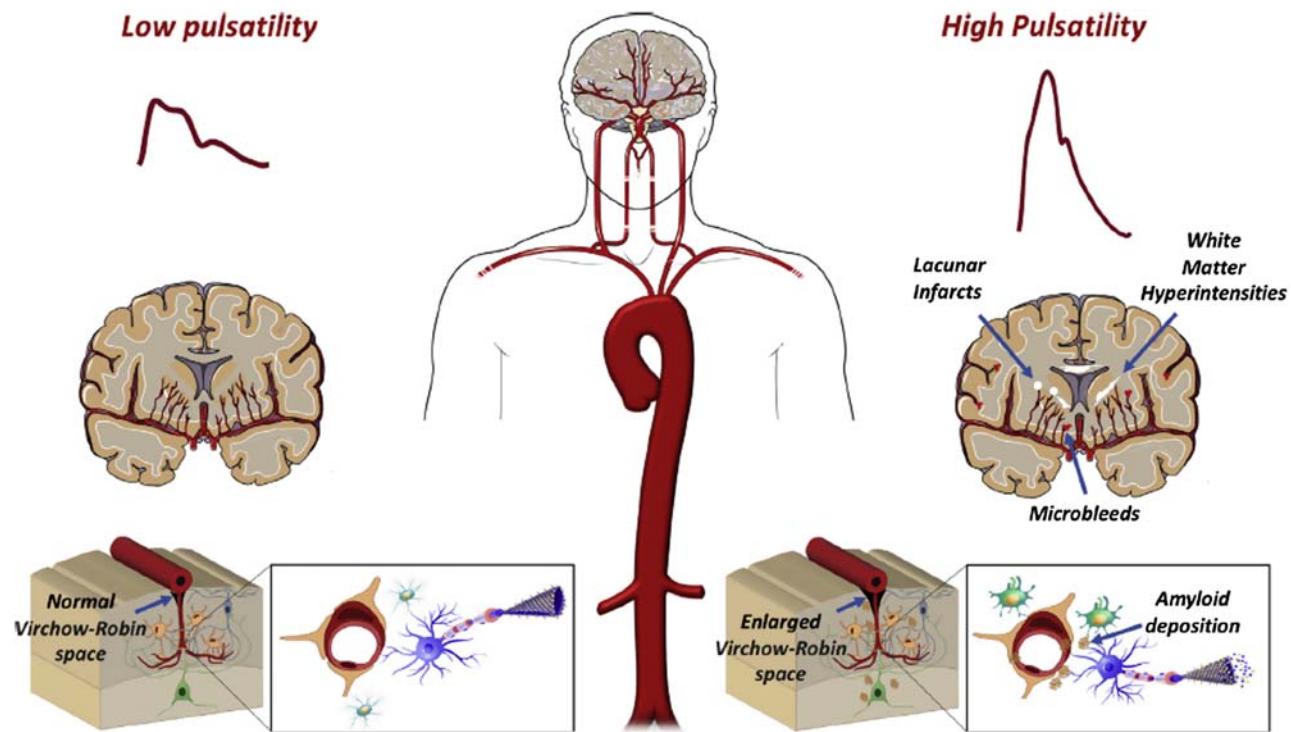
Review of studies linking arterial stiffness to Alzheimer's disease and related dementias

Arterial stiffness and cognitive impairment

Higher arterial stiffness is consistently associated with mild cognitive impairment (MCI) and dementia in most studies.[10−15] In one study of individuals with MCI, higher

cfPWV was associated with the conversion to dementia.[16] While most prior studies distinguished between a primary etiology of cerebrovascular disease and AD dementia, the two pathologies often overlap and most dementias in the elderly are a mix of both.[17] A meta-analysis report showed that PWV was higher among those with cerebrovascular disease compared to those with AD dementia or controls,[13] although these analyses pooled studies that used heterogeneous methods of cerebrovascular disease and AD dementia diagnostic classification, cross-sectional designs, and different PWV methods, as well as studies reporting on brachial-ankle PWV (baPWV). In the Atherosclerosis Risk in Communities Neurocognitive Study (ARIC-NCS) among 3550 White participants, higher cfPWV was associated with the prevalence of dementia and higher central pulse pressure (cPP) was associated with the prevalence of dementia and MCI.[18]

At this time, there are only three prospective, population-based studies on arterial stiffness, measured at one point in time, and risk of ADRD. The first showed an association of higher cfPWV with the 10-year incidence of MCI in all study participants (n = 1101) and with the incidence of all-cause dementia among those without diabetes.[19] The other prospective evaluation did not detect an association between cfPWV and the risk of cerebrovascular disease or dementia in 3714 participants after a mean follow-up of 4.4 years, although the number of cases of cerebrovascular disease was small (11 incident cases) and MCI was not ascertained.[12] Lastly, in the Cardiovascular Health Study (n = 356), higher cfPWV was associated with 15-year incidence of dementia.[20] As discussed in subsequent sections, the evidence of an association between arterial stiffness, cognitive function, brain imaging, and biomarker hallmarks of AD supports the evidence of an association of arterial stiffness with MCI and ADRD.

Arterial stiffness and cognitive function


Arterial stiffness is associated with reduced cognitive function in both community-based studies[21−26] and in systematic reviews and meta-analyses.[10,27−29] Few longitudinal studies on global cognitive function are available.[12,30,31] Among older adults in nursing homes, increasing tertiles of cfPWV at baseline were associated with greater one-year cognitive decline in Mini-Mental Status Examination (MMSE) scores (n = 873),[30] and baseline values of cfPWV and pulse pressure amplification were higher among those with a two-year decline of >3 points in MMSE (n = 682).[31] In contrast, the Rotterdam Study (n = 2767) found no association of cfPWV with decline in MMSE during a mean follow-up of 4.4 years.[12] These studies relied on the MMSE, whereas specific domains of cognition might be more sensitive to increased cfPWV and cPP.[12,21,23,25]

Declines in domains of executive function and psychomotor speed/attention are often related to cerebrovascular injury whereas declines in memory typically reflect neurodegenerative damage to the brain.[5] Extant reports indicate that arterial stiffness is more consistently associated with tests of executive function,[25,32] suggesting arterial stiffness and pulsatility most likely act through vascular processes rather than neurodegenerative processes. In the ARIC-NCS Study (n = 3703), cfPWV associated with lower executive function/processing speed and general cognition, but not with memory or language.[33] In contrast, cfPWV and cPP were associated with lower memory scores, but not with processing speed or executive function in a community-based cohort (n = 668).[23] Longitudinally, cfPWV was associated with seven-year global cognitive decline and phonemic fluency, but was not significantly associated with other domain-specific measures of memory, reasoning, and semantic fluency in the Whitehall II study (n = 4300).[34] In the Framingham Offspring Cohort (n = 1223), cfPWV was associated with a 6.4-year increase in Trail Making Test Part B minus Part A test (worse executive function), but not was not associated with change in Similarities test, a measure of executive function/abstract reasoning.[35] When evaluating other cognitive domains, higher cfPWV was associated with a three-year decline in psychomotor speed, and perceptual speed, but was not associated with verbal memory (n = 552).[25]

In the latest meta-analysis, higher PWV was associated with lower global cognitive function, executive function, and memory in cross-sectional studies, whereas in longitudinal studies, PWV was associated with reduced global cognitive function and executive function, but not with change in memory.[36] The discrepancies in the literature may be attributable to differences in the tests of domain-specific cognitive function, measures of arterial stiffness, cross-sectional designs, and study populations. Harmonization of cognitive function measures would facilitate a more direct comparison of the association of arterial stiffness and cognitive function across studies. Further, the inclusion of imaging biomarkers of ADRD continue to advance our understanding of the cerebral pathology underlying associations between arterial stiffness and cognitive function.

Arterial stiffness and brain structural abnormalities on magnetic resonance imaging

Arterial stiffness is consistently associated with macrostructural and microstructural brain abnormalities and cerebral small vessel disease before the development of ADRD (Fig. 41.2). Arterial stiffness is associated with reduced gray matter volumes and indicators of cerebral small vessel disease, quantified by white matter

FIGURE 41.2 Arterial stiffness and age-related changes in the brain commonly seen in Alzheimer disease and related dementias. These changes include declines in cerebral perfusion to the gray matter, evidence of multiple forms of cerebral small vessel disease (lacunar infarcts [*white circles*], white matter hyperintensities [*white streaks*], cerebral microbleed [*red triangles*], enlarged perivascular [Virchow-Robin] spaces), loss of brain volume, and β-amyloid deposition in the brain (*brown plaques*). Such changes are suspected to affect the integrity of the white matter and neurovascular unit. *Reprinted from Chirinos JA, Segers P, Hughes T, Townsend R, Large-artery stiffness in health and disease: JACC state-of-the-art review.* **J Am Coll Cardiol**. *2019; 74(9):1237−1263, with permission from Elsevier.*

hyperintensities (WMHs), and morphologic abnormalities on MRI (reviewed in Table 41.1 and Concept Box), such as microbleeds and lacunar infarcts in individuals with hypertension,[37−40] community-based samples,[23,24,37,41] and in meta-analyses.[10,29]

WMH is the most often reported form of cerebral small vessel disease reported in the literature and most commonly and consistently associated with arterial stiffness. In the community-based Age, Gene/Environment Susceptibility−Reykjavik cohort study (n = 668), cfPWV and cPP were cross-sectionally associated with the presence of subcortical infarcts and cfPWV was associated with a higher WMH volume.[23] In the ARIC-NCS Study (n = 1255), cfPWV was associated with WMH volume, smaller brain volume, and smaller AD signature region volumes.[33] Arterial stiffness is related to WMH in middle-aged adults.[42,43] In the Framingham Third Generation Cohort Study, cfPWV was associated with larger lateral ventricular volumes in 759 participants 30−45 years old and with white matter injury in 1129 participants 45−65 years old.[42] Two longitudinal studies have shown an association between higher cfPWV and a higher burden of WMH.[44,45] The first of these showed a positive association of cfPWV and WMH volume, with a stronger magnitude of effect among Black older adults compared to White older adults (n = 303; 41% Black).[44] The prospective Dallas Heart Study (n = 1270) reported that aortic arch PWV was associated with WMH volume measured seven years later, and estimated that a 1% increase in aortic arch PWV (m/s) corresponds to a 0.3% increase in WMH volume.[45] In contrast in the Framingham Offspring Cohort (n = 1118), cfPWV was not associated with 6.4-year change in total cerebral brain volume or WMH volume.[35] Additionally, higher carotid artery stiffness was associated with higher WMH volume 20 years later in the ARIC-NCS Study (n = 1402).[46]

Arterial stiffness is consistently related to WMH,[47,48] especially in the periventricular[49−51] and to a lesser extent deep white matter.[49,51] Arterial stiffness appears to show particular specificity for WM tracts susceptible to age-related damage,[44] likely contributing to WMH in areas of the brain that are directly supplied by the deep cerebral circulation. Furthermore, the arterial border zone of the cerebral white matter (watershed) is particularly sensitive to cerebral hemodynamic abnormalities and increased pulsatility.[52]

Changes in white matter integrity are thought to occur prior to visible WMH.[53] The microstructural integrity of

white matter can be measured using diffusion tensor imaging (DTI) by MRI. Higher mean diffusivity (MD) and lower fractional anisotropy (FA), indicating axonal damage, and demyelination signifies lower white matter microstructural integrity, which could lead to WMH. Arterial stiffness is associated with loss of integrity in various age-related regions in both middle-aged[54] and older adults.[43,55,56] In 54 cognitively unimpaired elderly individuals, cfPWV was associated with DTI measures of white matter microstructure, including FA and radial diffusivity (axonal organization/degeneration), but not with myelin volume fraction (myelination).[55] In the ARIC-NCS Study (n = 1484), cfPWV was associated with lower FA and higher MD even after adjustment for WMH volume.[57] In the Framingham Offspring and Third Generation cohorts (n = 1903), cfPWV was found to be associated with higher free water, particularly in the WM fed by the middle cerebral artery, and lower FA.[54] The relationship between central arterial stiffness and white matter integrity may be focal, localized to individual tracts, but detectable in

multiple ethnic groups.[44,57] These studies suggest that arterial stiffness effects WM integrity before the development of WMH.

Despite the numerous studies of arterial stiffness and white matter, few have included gray matter volume or density, which is the outermost layer of the brain and consists primarily of neuronal cell bodies. Studies among community-based populations are conflicting, as cfPWV was associated with lower gray matter density in one study (n = 1903),[54] not associated in another (n = 303),[44] and one showed that carotid pulsatility index, not cfPWV, was associated with lower gray matter volume (n = 668).[23] Similarly, among patients with arterial disease, carotid stiffness was associated with lower cortical gray matter volume (n = 526), but not with the four-year progression of cortical gray matter volume (n = 308).[58] Future studies should assess both white and gray matter to fully characterize the association of arterial stiffness and brain volumes.

The associations of arterial stiffness with other indicators of cerebral small vessel disease, such as lacunes and microbleeds,[47] are inconsistent. As lacunes represent small ischemic lesions, the associations with arterial stiffness seem less than direct and more likely to be mediated by prothrombotic comorbidities common to both. The exception would be for subcortical lacunes, which may present from generalized hypoxia. The inconsistent relationship with arterial stiffness and cerebral microbleeds may be attributable to differential associations with location of the microbleeds, with deep and infratentorial being associated rather than lobar regions.[47] Microbleeds are thought to hemosiderin-laden macrophages in perivascular tissue, consistent with vascular leakage of blood cells. Further, microbleeds are linked to vascular amyloid deposition especially when present outside of the white matter.[59] When extensively seen in the parietal lobe, they indicate presence of cerebral amyloid angiopathy (CAA). As discussed below, arterial stiffness is associated with cerebral Aβ deposition and the presence of microbleeds in older adults.[48]

General enlargement of perivascular spaces is associated with other morphological features of cerebral small vessel disease, including WMH and lacunes, but not atrophy.[60] Arterial stiffness is associated with the presence of enlarged perivascular spaces among 782 individuals with hypertension[40] and community-based samples of older adults, particularly in the basal ganglia.[47] One of the described functions of perivascular spaces is to drain interstitial fluid back to circulation. However, when the aorta is stiff, a high pulsatility wave is transmitted to end-organ vascular beds forcing small arteries to adapt to higher flows, which might facilitate the interstitial fluid leakage.[40]

This concept box details the magnetic resonance imaging (MRI)-based *macrostructural, microstructural*, and *hemodynamic* measures used to study the vascular contributions to dementia, as described below.

Macrostructural measures[59]

Recent small subcortical infarcts are occlusions of a single, deep perforating brain artery and is likely a consequence of cerebral small vessel disease.

White matter hyperintensities (WMHs), also known as Leukoaraiosis, are brain lesions with increased brightness when identified on MRI using fluid-attenuated inversion recovery (FLAIR) sequences.

Lacunes are small (3 mm and about 15 mm in diameter) fluid-filled cavities in the white matter or basal ganglia consistent with a previous acute small subcortical infarct or hemorrhage in the territory of one perforating arteriole. Lacunes are frequently observed coincidentally on imaging in older people, often not clearly associated with discrete neurological symptoms.

Perivascular spaces are also known as Virchow−Robin spaces, are fluid-filled spaces that follow the typical course of a vessel as it goes through gray or white matter.

Cerebral microbleeds are small hypointense lesions that are visible on paramagnetic-sensitive MRI sequences. These lesions are most commonly located in the cortico-subcortical junction, and deep gray or white matter in the cerebral lobes, brainstem, and cerebellum. Cerebral microbleeds are associated with other forms of cerebral small vessel disease, cerebral amyloid angiopathy, and Alzheimer's disease.

Microstructural measures

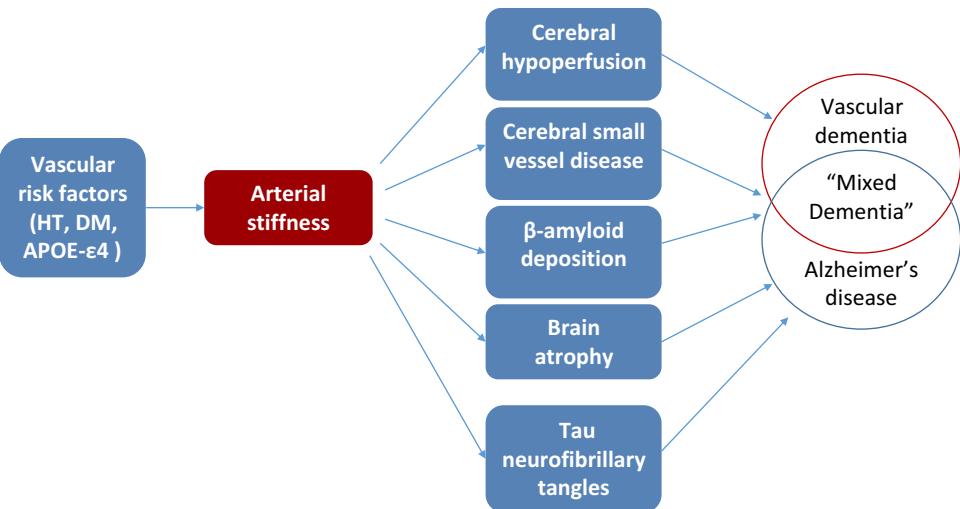
White matter diffusion is restricted (anisotropic flow) along nerve fibers and myelin of the white matter. Unrestricted (isotropic) flow can indicate areas of reduced microstructural integrity and freely diffusing water indicative of neuroinflammation. Diffusion imaging enables the assessment of microstructural integrity of the white matter and gray matter through several diffusion metrics.

Hemodynamic measures

Cerebral blood flow is remarkably constant under a normal physiological state. Cerebral blood flow is regulated by cardiac output, aortic distensibility, pulsatile pressure gradient along arteries, and cerebral autoregulation. It is also subject to the development of arteriopathies, such as arterial stenosis, atherosclerosis, and arterial stiffness.

Cerebrovascular reactivity is the response to a functional challenge (e.g., exercise, hypercapnia, and orthostatics) and is a measure cerebral autoregulation.

Association of arterial stiffness and Alzheimer's disease biomarkers

Emerging studies show associations of vascular risk factors with biomarkers of Aβ and p-tau, which are hallmarks of AD pathology that precede atrophy and onset of cognitive impairment.[61] Biomarkers of Aβ and tau aggregation measured by positron emission tomography (PET) represent the burden of AD pathology. In contrast, biofluid levels of ADRD biomarkers provide insight into the concentration of hallmark AD pathology (Aβ, p-tau), neurodegeneration (total tau (t-tau)), synaptic dysfunction (e.g., neurogranin), neuro-axonal injury (e.g., neurofilament light), neuroinflammation (e.g., YKL-40), and more. Arterial stiffness is associated with the extent and progression of cerebral Aβ plaques burden quantified by PET imaging in older adults without dementia, but may differ by vascular bed assessed.[48,62] While central aortic PWV is inconsistently associated with the extent of Aβ burden at a single time point, one study suggests that cfPWV appears to be most strongly associated with the accumulation of Aβ over time.[62] In contrast, markers of peripheral arterial stiffness (baPWV and carotid stiffness) appear to be more strongly associated with the extent Aβ in the brain.[48,62] Associations between arterial stiffness and Aβ burden have been replicated in a diverse cohort, and appear to be consistent across White and Black older adults (n = 320).[48] Currently, there are limited data available directly linking arterial stiffness and tau pathology and neurogenerative processes, the other hallmark of AD pathology. Tau PET imaging is beginning to associate vascular risk factors with tau aggregation in the brain.[63] Among older adults in their eighth decade of life, greater aortic stiffness measured by cardiac MRI is associated with higher cerebrospinal fluid levels of neurodegenerative (phosphorylated and total tau, neurogranin, and neuroinflammatory markers (YKL-40).[64] More studies are needed to further characterize the association of arterial stiffness and Aβ and tau aggregation and the role of arterial stiffness in the development of cognitive impairment and dementia (Fig. 41.3).


Assessing evidence of the association between arterial stiffness and dementia

As discussed herein, there is mounting evidence that age-related arterial stiffening is associated with the various forms of dementia pathology from cerebral small vessel disease to Aβ deposition to risk for cognitive decline and dementia. The accumulating literature warrants reflection on the potential causal role of arterial stiffness in ADRD through promotion of dementia related neuropathology and cognitive decline. Applying The Bradford Hill Criteria[65] framework to assess the evidence of association for the potential role of arterial stiffness in dementia, we see moderate and consistent evidence linking arterial stiffness to dementia through its related pathology.

Strength of evidence—As detailed above, the strength of associations between arterial stiffness, cerebral small vessel disease, cognitive impairment, and ADRD are of modest strength and follow the proposed causal pathway for the vascular contributions to ADRD depicted in Fig. 41.3.

Consistency of evidence—Measures of arterial stiffness show strong consistency for their relationships with specific dementia-related phenotypes, cognitive impairment, and structural abnormalities in the brain. There are, of course, limitations to this evidence. First, heterogeneity in results are apparent across methods used to measure arterial stiffness. Some inconsistent results may be attributed to variable measurement error across methods used to measure arterial stiffness (e.g., cfPWV, baPWV, cardiac MRI, and carotid ultrasound). In contrast, the vascular bed at which arterial stiffness is assessed could provide physiologic information about the proximity of each measure to cerebral hemodynamics, as well as the extension of arterial stiffness gradient.

A second major limitation of the current studies resides in the homogeneity of populations studied. Most of the studies to date have focused on individuals of European decent. This is an important public health issue given that

FIGURE 41.3   Conceptual model of the association between arterial stiffness and brain aging. *APOE-ε4*, Apolipoprotein E epsilon 4 allele; *DM*, diabetes mellitus; *HT*, hypertension.

underrepresented groups in the United States have not only a greater burden of subclinical cardiovascular disease, including arterial stiffness,[66] but also a greater risk for ADRD.[67–70] Racial and ethnic differences exist in vascular[71,72] and metabolic disorders,[73] apolipoprotein E epsilon 4 allele (*APOE-ε4*) frequencies,[74,75] Aβ deposition,[76] and the prevalence and incidence of ADRD.[77–80] A recent multiethnic autopsy study revealed that the brains of African-Americans with AD had more severe evidence of cerebral arteriosclerosis and atherosclerosis, more "mixed dementia" pathology, and less "pure AD" pathology than the brains of matched White counterparts.[81] Cardiovascular disease risk factor profiles differ for African-Americans[82] and Hispanics[83] compared to Whites.[84] Yet, the effects of these differential risk factor profiles have not been well studied in AD. Some studies report up to twice the prevalence of AD in African-Americans compared to Whites,[85,86] and lower pathologic thresholds for cognitive impairment in African-Americans[87] and Hispanics.[88] Taken together, these studies suggest that underrepresented groups are at greater risk for subclinical vascular disease, cardiovascular disease events, and ADRD. Further studies of arterial stiffness and brain aging are needed in diverse populations.

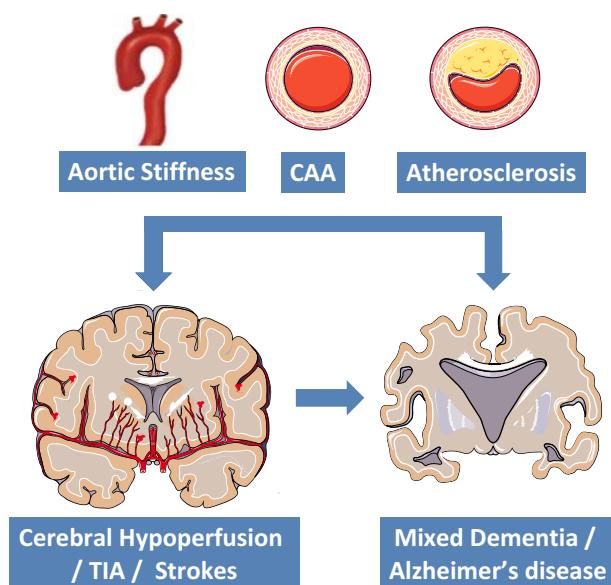
Biologic gradient—Most studies finding significant relationships between arterial stiffness and dementia pathology and risk for dementia employ linear models as a base for dose response relationships. While various thresholds for abnormal arterial stiffness have been proposed for different age groups (e.g., >12 m/s[89] or >10 m/s[90] for cfPWV), studies that report linear models of arterial stiffness and continuous outcomes (e.g., cognitive performance, brain volumes) find monotonic relationships. It should be noted that these published thresholds were developed for

cardiovascular events, dependent upon the age of the reference population, may represent statistical artifact rather than biology, and have not been validated for brain outcomes.

Specificity of evidence—The breadth of observed relationships of arterial stiffness with dementia-related pathology underscores the challenge to relate arterial stiffness to a complex, multifactorial disease such as ADRD in a causal framework. The predominant hypothesis is that arterial stiffness directly relates the pulsatile force of left ventricular function and systemic hypertension to deliver excess pulsatile force in the peripheral organs with dire vascular consequences to blood flow in the extensive microvasculature structure of the kidneys and brain. Arterial stiffness transmits unabated pulsatile flow along the carotid and vertebral arteries and deeper into the cerebral microvasculature with purported effects: microhemorrhages,[38] endothelial denudation, and thrombosis.[91,92] Neuroimaging biomarkers of cerebrovascular damage related to arterial stiffness are in primarily three forms: (1) excess pulsatile force delivered to the brain resulting in various form of gross cerebral small vessel disease[60]; (2) axonal damage in white matter; and (3) hypoperfusion of microvasculature particularly harmful in watershed regions. Arterial stiffness is associated with abnormalities in ADRD biomarkers of cerebral blood flow, cerebral small vessel disease, and AD pathology purported to precede cognitive dysfunction. Therefore, it may be difficult to isolate and attribute a single cerebral pathology associated with arterial stiffness. Further, more regional specificity in neuroimaging or neuropathologic outcomes are needed on studies of arterial stiffness in the vascular contributions to dementia to inform highly susceptible brain regions for endpoints in clinical trials.

Temporality—The evidence to date supports a chain of evidence linking arterial stiffness to cerebral hemodynamic

changes and structural abnormalities indicative of cerebral small vessel disease and AD pathology that are proposed to precede cognitive impairment by years and even decades. This suggest that cerebral effects of age-related arterial stiffness begin early in the lifecourse before they culminate in late-life cognitive impairment. Yet, the majority of the data available linking arterial stiffness to related dementia pathology are cross-sectional in design. Measures of carotid arterial stiffness accurately predict WMH burden 20 years later.[46] Several longitudinal studies show that arterial stiffness is associated with accelerated cognitive decline in various cognitive domains[34,93,94] and the risk for incident cognitive impairment.[19] While future studies are needed to provide support for temporal changes in arterial stiffness relative to changes in dementia pathology and cognition, the long subclinical phase of both age-related disorders of arterial stiffness and dementia pathogenesis add to the complexity of establishing temporal evidence.

Biologic plausibility—Dementia is a complex and multifactorial neurocognitive disorder with as many etiologies as there are subtypes. Accordingly, the vascular contributions to dementia are also multifaceted and correspond to various forms of cerebrovascular pathology evident in the brain, from ischemic and hemorrhagic stroke to evidence of cerebral small vessel disease.[7] Similarly, arterial stiffness is not only associated with the clinical syndrome of dementia but also multiple structural changes in the brain prior to onset of cognitive symptoms. It is important to note that the current research suggests that arterial stiffness is less likely to be related to vascular dementia, which is more often characterized by infarction, stroke, and acute, precipitous declines in cognitive function. While arterial stiffness does increase the risk for stroke,[95] is more closely related to cerebral small vessel disease and the insidious onset of cognitive symptoms characteristic of ADRD.


Increased arterial stiffness is posited to contribute to cerebral microvascular damage,[96] cognitive impairment, and dementia by reducing mean cerebral blood flow and increasing pulsatile stress in the brain (Fig. 41.3). Large elastic arteries, such as the aorta, absorb and dampen pulsatile flow, creating a steady flow to smaller resistance vessels incapable of absorbing pulsatile energy. As a consequence of arterial stiffening, higher pulsatility reaches the smaller resistance vessels in the brain, a high-flow, low-impedance organ particularly sensitive to excessive pressure and flow pulsatility.[91] With accelerated vascular aging, higher pulsatility reaches further into the cerebral vasculature,[97] promoting microvascular remodeling and impairing oxygen delivery to tissue (i.e., perfusion of the brain).[98] Chronic cerebral hypoperfusion and repeated occurrences of microvascular ischemia may lead to tissue damage[38,52,99] that is associated with cognitive decline and ADRD.[100–103] The primary sites for cerebrovascular damage from excess pulsatility delivered by arterial stiffness is

seen in various forms of cerebral small vessel disease[104] observed in the white matter and basal ganglia.[33,47]

The excess pulsatility to the cerebral vasculature also impairs cerebral autoregulatory mechanisms, a combination of myogenic, autonomic, and metabolic mechanisms of the cerebral circulation to maintain vascular resistance and perfusion.[105] Although cerebral autoregulation is not fully understood, it is characterized by cerebral blood flow and cerebrovascular reactivity. Indeed, cerebrovascular reactivity is lower in individuals with hypertension, with greater arterial stiffness,[106] and with MCI.[106,107]

Additional pathways contributing to cognitive decline and dementia associated with cerebral hypoperfusion have been proposed.[108,109] Cerebral blood flow is constant in a normal physiological state; however, individuals with ADRD and vascular dementia have lower mean cerebral blood flow and higher pulsatile flow velocity in middle cerebral arteries, compared with those with normal cognition.[110] The effect of arterial stiffness on cerebral blood flow increases the risk for subclinical brain infarction and incident stroke.[111] Central arterial stiffness, measured by PWV[112] and cPP[113] are associated with these hemodynamic alterations in the middle cerebral artery, as further links between arterial stiffness and cerebral microvascular damage, cognitive impairment, and ADRD.

Coherence of evidence—Novel preclinical murine models create central arterial stiffness through the following: hypertensive murine models; carotid artery calcification by direct injection of calcium chloride to the adventitia of the carotid artery; as well as elastin and fibrillin-1 haploinsufficiency. When crossed with transgenic AD mouse models, these novel models reveal mechanistic insights into the role of arterial stiffness and excess pulsatility in increased neuroinflammation, endothelial dysfunction, microvascular disease, neurodegeneration, Aβ production, and reduced Aβ clearance. (For informative review, see Winder, Reeve, and Walker).[114] In microvascular models of human cerebral vascular endothelial cells, pulsatile stretch modulates Aβ generation and secretion and activates endothelial inflammatory pathways,[115] supporting the role of excess vascular pulsatility in Aβ pathogenesis. In mouse models, cerebral arterial pulsatility contributes to blood−brain barrier breakdown and paravascular fluid exchange,[116] potentially increasing infiltration of solutes into the brain and inhibiting Aβ clearance from the brain along paravascular pathways.[117] Further evidence shows that the pulse wave may drive pulsatile flow of interstitial fluid,[118] suggesting that arterial stiffening may impair the clearing of interstitial waste, including Aβ, from the aged brain. Impairing clearance of soluble Aβ may contribute to aggregation of Aβ in the vessel wall, clinically termed CAA. Since CAA often occurs with the AD hallmark parenchymal Aβ plaques in individuals with AD,[119] CAA is an emerging

FIGURE 41.4 Functional effects of amyloid-beta (Aβ). Vascular Aβ deposition, called cerebral amyloid angiopathy (CAA), induces functional changes (vascular stiffening) and promotes vascular inflammation and atherosclerosis, all of which leads to cerebral hypoperfusion and associated dementias (mixed dementia and AD). *Modified from Stakos DA, Stamatelopoulos K, Bampatsias D, et al. The Alzheimer's disease amyloid-beta hypothesis in cardiovascular aging and disease: JACC focus seminar. J Am Coll Cardiol. 2020; 75:952−967.*

marker of risk for cerebral small vessel disease, vascular cognitive impairment, and AD. Cerebral arteries from older adults exhibit arteriosclerotic markers, reduced mechanical compliance, loss of elastin, and CAA.[120] The association of arterial stiffness with increased arterial pulsatility Aβ production and reduced clearance of interstitial waste may constitute a feed-forward cycle whereby Aβ deposition increases cerebral arterial stiffness leading to neurodegeneration (Fig. 41.4). These mechanisms provide support for an association between arterial stiffness and dementia pathogenesis.

Analogy—While arterial stiffness is associated with various aspects of ADRD when accounting for potential confounders (e.g., age, blood pressure, hypertension, and diabetes), it is plausible that arterial stiffness simply represents some residual aspect of accelerated vascular aging in the body or brain, but does not impart direct effects on the brain. Additionally, hemodynamic factors and arterial stiffness could have shared pathways contributing to ADRD, making it difficult to identify direct effects. As hypertensive models demonstrate, central arterial stiffness is both a potential cause and consequence of hypertension. Further, metabolic disorders such as glucose dysregulation, insulin resistance, metabolic syndrome, and diabetes increase the risk for hypertension and arterial stiffness.[121] Both of which are risk factors for ADRD and increase vascular pathology and therefore the vascular contributions to dementia.

Applying causal effects to blood pressure, hypertension, and diabetes is challenging because they represent complex multifactorial traits. Blood pressure level is determined by just two variables: peripheral vascular resistance and cardiac output. It exhibits a Gaussian distribution in the general population indicating that it is the net effect of a multitude of independent factors each with a small cumulative effect.[122] The same can be said for the multitude of factors regulating peripheral resistance. Principal and most proximal of these is arterial stiffness. It can be argued that arterial stiffness better relates hemodynamics to distal organ systems.

Similarly, arterial stiffness and atherosclerosis are interrelated forms of vascular pathology that makes disentangling the two difficult. Arterial stiffness and changes in vascular structure can occur from and be accelerated by atherosclerosis, which is a major risk factor for stroke.[123] Atherosclerotic plaques deposited in the media of the carotid wall changes both the regional blood flow and the local stiffness, and the calcification of atherosclerotic plaques imaged by computed tomography (CT). Several studies show that CT-assessed coronary calcification is associated with cerebral atrophy on MRI, poorer cognitive performance,[124,125] and worse microstructural integrity.[126] These relationships appear to be evident with both the extracranial and intracranial arteries.[127] Intracranial atherosclerosis is a confirmed, strong risk factor for dementia[128]; however, the presence of intracranial atherosclerotic plaque or stenosis is not associated with brain Aβ deposition.[129] Future studies will have to confirm this apparent lack of association between atherosclerotic disease and dementia pathology.

The presence of regional carotid atherosclerosis alone may be a risk factor for AD and dementia through its contributions to cerebrovascular disease. In fact, AD cases have a greater degree of cerebral artery (circle of Willis) occlusion than controls, and there was a positive correlation between the degree of arterial stenosis and neurofibrillary tangle score.[130] Regional atherosclerosis can be imaged by carotid ultrasound, CT, and MRI. Carotid ultrasound is routinely used to identify carotid plaques, identify vascular occlusions, and measure carotid intima media thickness (IMT). Greater IMT of the carotid and brachiocephalic trunk are associated with deep subcortical WMH[131] and brain infarcts.[104,123] Studies that relate both atherosclerosis (via IMT and plaques) and arterial stiffness (via PWV) to cerebral small vessel disease show arterial stiffness to be more strongly related to cerebral small vessel disease than atherosclerosis measures.[104]

Finally, it should be recognized that the gene encoding *APOE* and the function of ApoE is a risk factor for developing cardiovascular disease, arterial stiffness, and ADRD. Proper function of ApoE interrupts a mechanically driven feed-forward loop that increases the expression of

collagen-I, fibronectin, and lysyl oxidase in response to substratum stiffening.[132] Inefficiency of ApoE function is expressed with inheritance of the APOE-ε4, which is also the primary genetic risk factor for AD. Limited studies suggested a shared risk of APOE-ε4 may modify the relationship between arterial stiffness, cognitive decline, and AD. APOE-ε4 status modified the association of arterial stiffness (carriers worse)[133] and pulse pressure (noncarriers worse)[134] with cognitive function, but not with arterial stiffness and dementia.[20]

More deeply phenotyped and multifactorial studies of arterial stiffness and ADRD are needed to disentangle the relationships between arterial stiffness, atherosclerosis, APOE, and ADRD biomarkers.

Experimental evidence—Ultimately, experimental evidence is necessary to prove or refute causality. There are currently no randomized clinical trials aimed specifically at reducing arterial stiffness to prevent cognitive decline, dementia, or dementia-related pathology. The closest supporting evidence comes from the SPRINT MIND trial comparing intensive systolic blood pressure lowering (<120 mmHg) to standard treatment target for systolic (<140 mmHg) to risk of developing dementia and MCI. Intensive treatment of systolic blood pressure lowered PWV,[135] the risk for incident cognitive impairment,[136] and reduced the rate of WMH progression.[137] This suggests that improving hemodynamic risk factors could reduce the risk of cognitive impairment and cerebral small vessel disease. Future studies specifically targeting arterial stiffness should be sufficiently powered to cognitive and brain outcomes. Agents developed to target arterial stiffness or microvascular function may blunt or mitigate the effects arterial stiffness on cerebral health. Arterial stiffening is largely age-related, but also modifiable. Arterial de-stiffening[138] is an active area of research in blood pressure control[139,140] and lifestyle interventions such as habitual physical activity.[141–145] In addition to physical activity, weight loss, smoking cessation, salt reduction,[144] and dietary interventions[141] have been reported to reduce arterial stiffness. Neuroendocrine-directed therapies in development may reduce arterial stiffness. These include pharmacologic therapies targeting the renin—angiotensin system, natriuretic peptides, insulin modulators, as well as novel therapies that target advanced glycation end products and arterial fibrosis. Randomized clinical trials of arterial stiffness reduction and risk of ADRD are needed to provide experimental evidence for arterial stiffness as a modifiable target for cognitive impairment and ADRD.

Conclusions

This chapter reviewed and summarized the current state of evidence linking arterial stiffness to clinical evidence of ADRD biomarkers (cerebral hemodynamics, cerebral small vessel disease, neuroinflammation, neurodegeneration, Aβ deposition, and tau hyperphosphorylation), cognitive decline, and the risk for dementia, especially in older adults in the eighth and ninth decades of life who are at greatest risk for ADRD. These observations are supported by mechanisms detailed in biologic models linking arterial stiffness to neuroinflammation, neurodegeneration, and accelerated cerebral pathology, as well as evidence from clinical trials that aggressively reducing blood pressure slows small vessel disease and cognitive decline. Further, arterial stiffness is not only associated with forms of cerebral pathology related to ADRD but also the co-occurrence of cerebral small vessel disease and Aβ deposition most commonly seen in vast majority of age-related dementias that make up ADRD. Finally, the evidence to date posits that arteriosclerosis, but not atherosclerosis, as prime therapeutic target for the prevention of VCID and ADRD, by preserving structural integrity of the brain. The breadth and depth of observational data linking arterial stiffness to dementia warrants more detailed examination of relationships between the progression of arterial stiffness and specific aspects of dementia-related pathology, as well as clinical trials to directly test the purported relationships that place arterial stiffness at a nexus of vascular disorders and dementia-related pathologies commonly seen in older adults.

Arterial stiffness and pulsatile hemodynamics in pregnancy and pregnancy-related vascular complications

Stella S. Daskalopoulou

Fonds de recherche du Québec – Santé – Boursier Clinicien – Senior, Director, Vascular Health Unit, Department of Medicine, Division of Internal Medicine, McGill University Health Centre, McGill University, Montreal, QC, Canada

In healthy pregnancies, physiological changes occur to meet the increased metabolic demands of both the mother and the fetus. These maternal adaptations ensure adequate uteroplacental circulation for fetal growth and development. Early in the first trimester, the maternal cardiovascular system undergoes a complex series of vascular and hematological alterations; systemic vasodilation and increased vascular compliance occur, leading to decreased systemic vascular resistance to accommodate the increase in cardiac output (CO) and plasma volume. These changes result in a characteristic high-volume, low-resistance circulation.[1] Failure to accommodate the increased demands of gestation due to vascular maladaptation leads to vascular complications, such as preeclampsia (PrE), which can have devastating consequences for both mother and fetus.

Below, we will elaborate on the physiological changes that occur during healthy, uncomplicated pregnancy, followed by a discussion of pregnancy-related vascular complications, with a particular focus on PrE. Specifically, we will provide an overview of typical physiological changes in CO, blood volume, blood pressure (BP), vascular remodeling and resistance, and arterial stiffness within both contexts, followed by a discussion of the beneficial effects of exercise in enhancing cardiovascular adaptations in pregnancy.

Healthy pregnancy

Blood volume and hematological changes

Pregnancy is a state of circulatory volume expansion and vasodilation involving considerable orchestration of several physiologic processes. Plasma volume increases progressively throughout gestation, starting at around 6–8 weeks, with the steepest increase observed during the second trimester. Plasma volume continues to increase in the third trimester to a pooled maximum increase of over 1 L. Overall, plasma volume typically increases by about 45%–50% above nonpregnancy levels (varying from 20% to 100%), with expansion being proportional to fetal growth.[2–4] This increase is critical to maintaining sufficient circulating blood volume and pressure for uteroplacental perfusion and accommodating the oxygen requirements of maternal organs and the growing fetus.[2]

During pregnancy, there is systemic and renal artery vasodilation; the latter leading to a 50% increase in renal plasma flow and glomerular filtration rates by the end of the first trimester.[5] Vasodilation leads to a cardiovascular system that is underfilled. This underfilling is compensated by an activation of the sympathetic nervous system and an increase in CO, renin–angiotensin–aldosterone system (RAAS) activity, and plasma volume.[6] Indeed, early in pregnancy the sympathetic activity is elevated, with enhanced maternal baroreceptor reflex sensitivity and decreased responsiveness to α-adrenergic stimulation.[7] Additionally, in order to maintain BP and retain salt and water during pregnancy, there is increased activation of the RAAS system. Aldosterone activates the mineralocorticoid receptor, which plays an important role in the growth and development of the placenta and fetus.[8]

Stimulation of the RAAS in the second and third trimester leads to a net increase in exchangeable sodium of approximately 1000 mg. Conversely, relaxin, a hormone produced by the corpus luteum, decidua, and placenta, triggers thirst and antidiuretic hormone secretion, leading to water retention that is greater than the sodium retention induced by RAAS.[8,9] Furthermore, progesterone acts on the

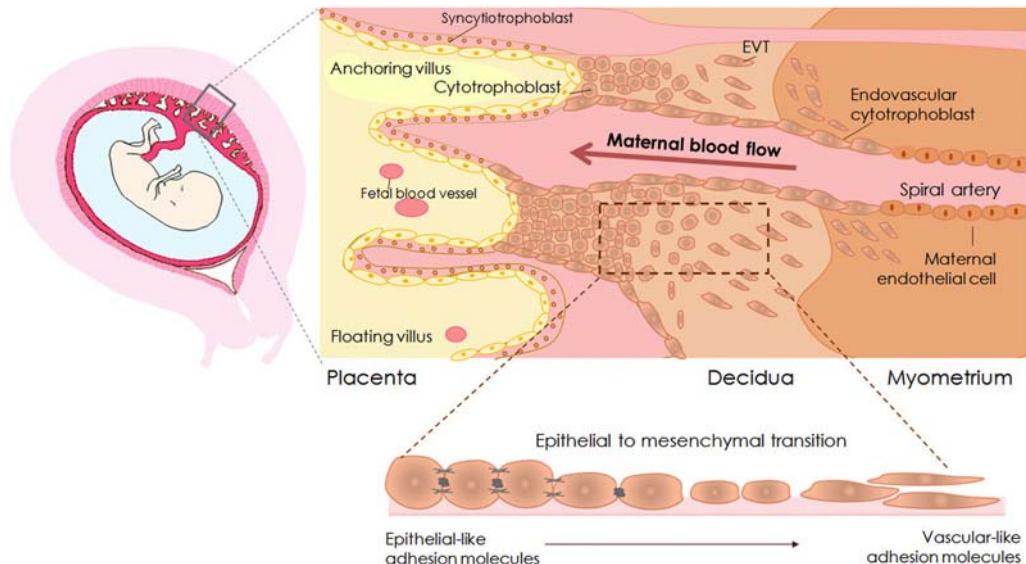
mineralocorticoid receptor as an aldosterone antagonist to prevent sodium retention and hypokalemia. Overall, the physiologic changes of pregnancy lead to hyponatremic hypoosmolar hypervolemia. In the third trimester, maternal plasma atrial natriuretic peptide levels increase by 40%, with a rise of 148% over the mean nonpregnant level noted during the first week postpartum, suggesting that atrial natriuretic peptide may be involved in postpartum diuresis.[10]

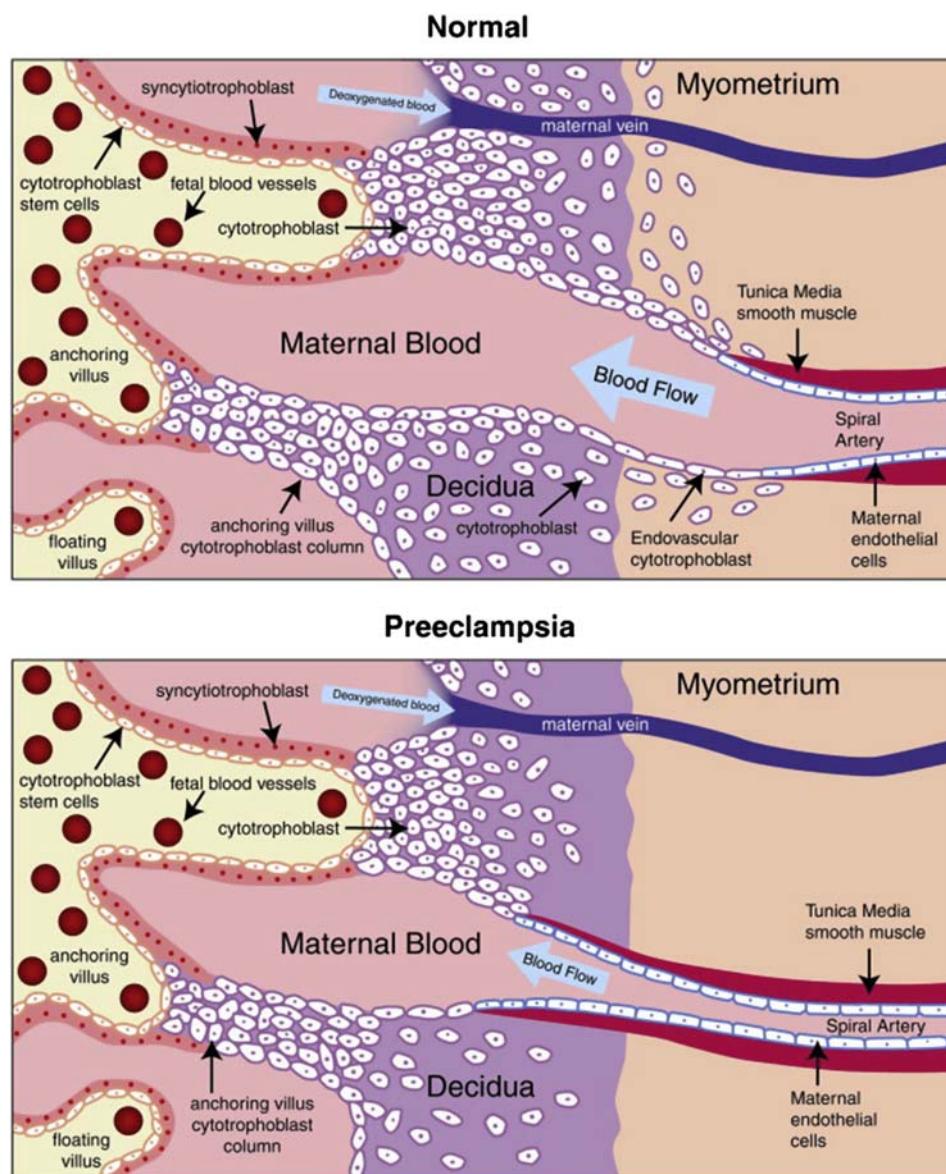
It is noteworthy that a significant increase in red blood cell production occurs during pregnancy, leading to a red blood cell mass increase of up to 40%.[11] Human placental lactogen (human chorionic somatomammotropin) enhances the production of erythropoietin, responsible for effective erythropoiesis. Although both plasma volume and red blood cell mass increase, there is a proportionally greater increase in plasma volume, leading to hemodilution and pseudoanemia with generally no change in mean corpuscular volume or mean corpuscular hemoglobin concentration.[6]

Cardiac output

CO is the product of heart rate (HR) and stroke volume (SV), calculated by the formula: $CO = HR \times SV$. CO is dependent on HR, heart contractility, preload, and afterload.[12] In normal pregnancy, CO increases with maternal weight, and decreases with maternal age.[11] The greatest increase in CO is observed at the beginning of the first trimester, and continues to increase up to the end of the second trimester.[13−17] CO remains stable after the second trimester, with a possible small decline toward the end of pregnancy.[13−17] In an uncomplicated singleton pregnancy, CO can increase by 30%−50% by the 24th gestational week, with a further increase of 15% observed in twin pregnancies.

In early pregnancy, increases in CO occur primarily in association with elevated SV. Later in pregnancy, the increase in CO is thought to be predominantly due to increased HR.[11] HR increases gradually throughout pregnancy, peaking in the third trimester, where an increase of 10−20 beats per minute (bpm), or 20%−25% over the baseline HR, is noted.[16] A recent metaanalysis demonstrated that the mean HR of healthy pregnant women significantly increased by 7.6 bpm (95% Confidence Interval [CI] 1.8−13.4) between 10 and 40 weeks'gestation.[18] SV also shows a gradual increase up to the end of the second trimester, where it then remains constant or decreases in the third trimester. Shortly after delivery, CO declines rapidly followed by a more gradual decrease over the next few weeks, reaching prepregnancy levels around 6 weeks postpartum.

Interestingly, myocardial contractility and ejection fraction do not appear to change during pregnancy.[19] Both echocardiography and cardiac magnetic resonance can be used to assess CO, SV, and cardiac function in pregnancy.[11] Typically, there is mild four-chamber dilatation with transient mild regurgitation of all valves, except for the aortic valve. Studies conducted in the third trimester and postpartum performed by both modalities demonstrated an increase in left ventricular end-diastolic volume, left ventricular mass, and CO during pregnancy, which subsequently resolved within 12 weeks postpartum; however, these values were underestimated by echocardiography when compared to cardiac magnetic resonance.[19] Indeed, cardiac magnetic resonance imaging evaluates left ventricular volumes more accurately than echocardiography and is also safe in pregnancy, as demonstrated by data from Ducas et al. and others.[19−21]


Vascular remodeling and vascular resistance


Arteries are highly adaptive structures that accommodate large increases in blood volume during pregnancy, redistributing blood flow to the growing fetus through vascular remodeling and vasodilation (Figs. 42.1 and 42.2).[22,23] Specifically, the vascular endothelium of the uterine arteries can increase its capacity to produce vasodilators to multiple agonists though increased expression of key mediators.[24]

Temporary vascular remodeling is primarily mediated by upregulation of vascular endothelial growth factors (VEGFs), including placental growth factor (PlGF). Upregulated by placental hormones, including the human chorionic gonadotropin hormone, the VEGF family of hormones promotes angiogenesis and maintenance of endothelial cell function during gestation.[25,26] These hormones increase to double their normal levels during early gestation and tend to decrease after placentation (13−16 weeks). Mediated by VEGF and PlGF, the uteroplacental unit undergoes angiogenesis and vasculogenesis. As a result, the uterine artery increases in length by 300%−500%, predominantly in the first trimester. Furthermore, high levels VEGF and PlGF lead to an increase in skin capillary density (by 13%) in the second trimester. Given that capillary beds contribute to 10%−15% of the total peripheral resistance, this results in a decrease in vascular resistance.

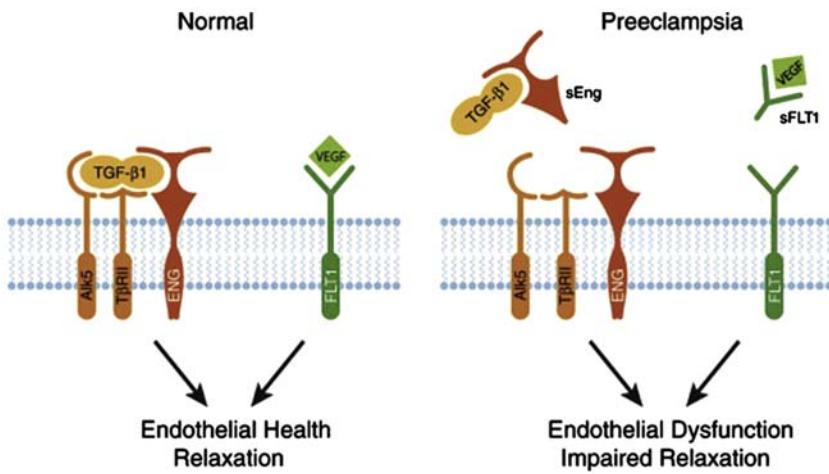
Conversely, soluble fms-like tyrosine kinase 1 (sFlt-1) is the nonmembrane-associated splice variant of VEGF receptor-1 (VEGFR-1) and is antiangiogenic (Fig. 42.3).[23] Specifically, sFlt-1 binds VEGF and PlGF, thus blocking their angiogenic effects on VEGFR-1. sFlt-1 is secreted by the placenta, and is thus increased in normal pregnancy. It progressively rises, with a greater increase observed in the third trimester, triggering a decline in VEGF and PlGF bioavailability in preparation for delivery. The ratio of sFlt-1/PlGF is an important clinical indicator of angiogenic status in pregnancy.[27]


FIGURE 42.1 Cytotrophoblast invasion of uterine spiral arteries in a normal pregnancy. Extravillous trophoblast cells (EVTs) transform into invasive cells through a partial epithelial—mesenchymal transition in which epithelial-like adhesion molecules are replaced by vascular-like adhesion molecules. EVT migrations occur through the decidua until reaching the inner third of the myometrium to invade the maternal spiral artery. Optimal EVT invasion is required to adapt the maternal vasculature to pregnancy and maintain blood flow to the placenta. *Reproduced from Garrido-Gómez T, Castillo-Marco N, Cordero T, Simón C. Decidualization resistance in the origin of preeclampsia.* Am J Obstet Gynecol. *2020.*

FIGURE 42.2 A schematic of placental vascular remodeling in health (upper panel) and in disease—preeclampsia (lower panel). Exchange of oxygen, nutrients, and waste products between the fetus and the mother depends on adequate placental perfusion by maternal spiral arteries. Blood from the intervillous space is returned to the mother's circulation via spiral maternal veins noted above. In normal placental development, cytotrophoblasts of fetal origin invade the maternal spiral arteries, transforming them from small-caliber resistance vessels to high-caliber capacitance vessels capable of providing adequate placental perfusion to sustain the growing fetus. During the process of vascular invasion, the cytotrophoblasts undergo a transformation from an epithelial to an endothelial phenotype, a process referred to as "pseudovasculogenesis" (upper panel). In preeclampsia, cytotrophoblasts fail to adopt an invasive endothelial phenotype. Instead, invasion of the spiral arteries is shallow, and they remain small-caliber, resistance vessels (lower panel). This is thought to lead to placental ischemia and secretion of antiangiogenic factors. *Reproduced from Karumanchi SA, Rana S, Taylor RN. Angiogenesis and Preeclampsia. 4th ed. Amsterdam: Elsevier; 2015:113—132.*

FIGURE 42.3 Soluble fms-like tyrosine kinase (sFlt-1) and soluble endoglin (sEng) causes endothelial dysfunction by antagonizing vascular endothelium growth factor (VEGF) and transforming growth factor-β (TGF-β) signaling. There is mounting evidence that VEGF and TGF-β are required to maintain endothelial health in several tissues including the kidney and perhaps the placenta. During normal pregnancy, vascular homeostasis is maintained by physiological levels of VEGF and TGF-β signaling in the vasculature. In preeclampsia, excess placental secretion of sFlt-1 and sEng (two endogenous circulating antiangiogenic proteins) inhibits VEGF and TGF-β1 signaling, respectively, in the vasculature. This results in endothelial cell dysfunction, including decreased prostacyclin, nitric oxide production, and release of procoagulant proteins. *Reproduced from Karumanchi SA, Rana S, Taylor RN. Angiogenesis and Preeclampsia. 4th ed. Amsterdam: Elsevier; 2015:113−132.*

Vasodilation of the maternal vasculature is mediated by hormonal and hemodynamic alterations. Estrogen, progesterone, and relaxin are implicated in dilation and relaxation of the muscular layer of the maternal arterial walls.[28] Relaxin levels, in particular, increase and peak at the end of the first trimester, then decrease to a lower level for the rest of gestation. Relaxin can cause endothelium-dependent vasodilation, affecting small arterial vessel resistance. Interestingly, women with higher levels of relaxin and progesterone early in gestation had lower systolic BP (SBP) in the second and third trimesters of pregnancy, while higher diastolic BP (DBP) in the third trimester was noted in women with lower relaxin levels.[29]

Systemic vasodilation with increased vascular compliance can be detected early in gestation (at 5−8 weeks). Systemic vascular resistance decreases substantially in the first trimester, reaching a nadir in the middle of the second trimester. Increased nitric oxide (NO), prostacyclin, endothelium-derived hyperpolarizing factor, estrogen, progesterone, and relaxin are thought to mediate these effects.[24,29] Consequently, systemic vascular resistance is reduced by 35%−40% from baseline, and return to prepregnancy levels approximately 2 weeks postpartum. The decrease in systemic vascular resistance compensates for the gestational increase in blood volume and CO, thus preventing an increase or even leading to a decrease in BP. However, while a drop in vascular resistance occurs throughout the body, a disproportionately large drop in vascular resistance is observed in the uterine circulation. The outcome is a greater proportion of CO being directed toward the uteroplacental unit to meet the needs of the growing fetus.[24]

During early pregnancy, endothelial function is improved, as assessed by increased flow-mediated vasodilation (FMD—the ability of a large conduit artery to dilate in response to a shear stress stimulus), decreased nonspecific vasodilation by glyceryl trinitrate, and endothelium-dependent skin microvascular reactivity to acetylcholine.[30] Interestingly, birth weight has also been shown to correlate positively with maternal endothelial function (as assessed by skin microcirculatory responses to acetylcholine and sodium nitroprusside).[31] Endothelial cells play a critical role in the redistribution of blood flow during pregnancy to accommodate the growing fetus. Endothelial cells are particularly responsive to hemodynamic shear stress, thus regulating blood flow.[32] Increased shear stress, due to elevated CO and blood volume, leads to a progressive increase in endothelial-dependent NO release throughout gestation, causing decreased peripheral resistance and vasodilation.[32] Specifically, the myometrial uterine spiral arteries show a threefold increase in NO synthase activity leading to an increase in the diameter of uterine arteries, which doubles by midpregnancy and then plateaus. This results in redistribution of up to 12% of the CO to the uteroplacental unit.[33] Interestingly, inhibition of NO synthase in pregnant women leads to greater vasoconstriction when compared to nonpregnant women.[33] In healthy pregnancies, the uterine arteries are remodeled from small muscular, high-resistance, coiled vessels to large capacitance vessels of low-resistance, promoting greater blood flow toward the placenta compared to other areas of the uterus.[34] During this process, there appears to be no significant change in the collagen and elastin arrangement. Vasodilation of the uterine arteries occurs through outward hypertrophic remodeling. As a result of these processes, by the end of pregnancy, blood flow in the uterine arteries more than doubles, with the uterus getting approximately 20% of the woman's prepregnancy blood supply.

Blood pressure

In healthy pregnancy, increases in vascular compliance and distensibility start in the first trimester. As a result, decreases in BP occur, including peripheral SBP, DBP, mean arterial pressure (MAP), and central BPs, with a relatively larger decrease in DBP and MAP than SBP. Central BPs are significantly lower than peripheral BPs; this difference between central and peripheral BPs has been shown to be most pronounced in the first-half of gestation, decreases in the third trimester and reaches its lowest point in the postpartum period.[35]

Typically, arterial pressures steadily reduce to a nadir during the second trimester, reaching 5–10 mmHg below preconception levels.[16] The majority of this reduction is observed by 6–8 weeks gestation.[16] Visit-to-visit BP variability increases from the second to the third trimester. BPs increase during the third trimester and return to near preconception levels after delivery.[16] A recent metaanalysis demonstrated that the mean SBP was lowest at around 10 weeks of gestation (110.4 mmHg, 95% CI 108.5–112.3) and significantly increased by 5.6 mmHg (95% CI 4.0–7.2) at 40 weeks. Mean DBP was lowest at 21 weeks of gestation (65.9 mmHg, 95% CI 64.2–67.7) and significantly increased by 6.9 mmHg (6.2–7.5) at 40 weeks.[18] Several longitudinal studies have also shown that when compared with women with a normal prepregnancy body mass index (BMI), women with BMI over 25 kg/m^2 have significantly higher BPs in the first trimester, which remain elevated throughout pregnancy and postpartum.[36,37]

Hormones also play an important role in modulation of BP during normal pregnancy. It is well established that estrogen affects the RAAS and modulates angiotensin II sensitivity. Indeed, estrogen decreases renin, angiotensin-converting enzyme (ACE), *angiotensin* II type 1 (*AT1*) *receptor* density, and the NADPH oxidase subunits Nox1 and Nox2, whereas it increases angiotensinogen, ACE2, AT2 receptor density, and endothelial NO synthase.[38–40] Altogether, these alterations favor the vasodilatory branch of the RAAS, leading to lower BP levels.

Arterial stiffness

Pulse wave velocity (PWV), a measure of pulse wave speed through the vascular system, is measured as the ratio of the total distance traveled to the transit time of the pulse waveform. As discussed in detail in Chapters 1, 3, and 7, PWV depends on the functional and structural features of arteries, which are related to their intrinsic elastic properties. Stiffer arteries propagate pulse waves faster. In pregnancy, alterations in arterial stiffness occur due to changes in vascular structure, NO bioavailability and responsiveness, and/or sympathetic vasoconstriction.[33,41] Carotid-femoral PWV (cfPWV) reflects the elasticity of the central, elastic arteries and is considered the gold standard measure of large artery stiffness from a clinical and epidemiological standpoint. While normal and reference values for cfPWV have been proposed for nonpregnant individuals,[42] cross-sectional comparisons of pregnant and nonpregnant women suggest that these reference values may not apply to pregnant women.[17,30,43,44]

Few studies[16,17,30,43–51] have assessed arterial stiffness parameters longitudinally across gestation (Table 42.1). Of those, only seven studies[16,17,30,43,44,46,50] followed the same group of women for repeated measurements, while the rest recruited women with normal pregnancies at varied gestational ages. Consistent with decreased peripheral vascular resistance, most available studies have demonstrated a U-shaped relationship between cfPWV and gestational age, with a nadir in midpregnancy[30,43] or in the third trimester.[50] It is estimated that the decrease is approximately 6%–13% when compared with nonpregnant counterparts.[33] Osman et al. reported a cubic relationship of cfPWV with gestational age ($P = .002$), with cfPWV reaching a nadir around 17–20 weeks gestation (7.27 m/s from 7.50 m/s at 13 weeks), increasing to a peak at 35 weeks gestation (8.33 m/s), and subsequently declining again toward term (8.02 m/s).[17] Franz et al. reported a similar cubic relationship, with the lowest cfPWV values noted at 20 weeks' gestation and the peak values at 35 weeks ($P = .015$). However, other authors have noted that the decrease in cfPWV was nonsignificant in the first[45] or second trimesters.[16,47,48] The postpartum cfPWV value was evaluated in six studies with conflicting results; when compared with the end of pregnancy measurement, three studies reported the cfPWV to be slightly elevated at 7 weeks,[43] 12 weeks postpartum (5.4 m/s vs. 6.7 m/s),[50] and 9 months postpartum.[30] Conversely, a nonsignificant decrease in cfPWV has also been reported at 3–6 months postpartum when compared with end of pregnancy measurements.[44] Furthermore, others have demonstrated that postpartum cfPWV values remained at a similar level to the second or third trimester when measured at 7 weeks[47] or at 14–17 weeks postpartum.[16] Thus, based on current limited evidence, there is no consensus as to the direction of cfPWV changes postpartum, and whether the values are similar or greater to those of nonpregnant women.

Similar mixed findings have been reported for carotid-radial PWV (crPWV), a measure of muscular (medium-sized) artery stiffness. It was reported to decrease in the second trimester by 6%–11%,[33] while it was shown to increase by the end of pregnancy, either to above nonpregnant levels[30] or similar to first trimester values.[47] Still others report no difference in crPWV with gestation and no significant difference between pregnant and nonpregnant women.[48]

TABLE 42.1 Longitudinal studies assessing arterial stiffness and hemodynamic parameters throughout healthy pregnancy and postpartum.

First author, year	Population	Design	Method	Metrics	Gestational timepoints	Results
Osman, 2017	Low-risk, healthy pregnant women with singleton pregnancy, n = 30	Longitudinal (same women followed prospectively)	Oscillometric (Arteriograph®); NICOM device	cfPWV, brAIx, aoAIx, MAP, CO	11−13, 20−22, 26−28, 32−34, and 37−40 weeks	cfPWV reached lowest value at 17 weeks, then increased to a peak at 35 weeks ($P = .002$); brAIx and aoAIx reduced during early pregnancy, reaching a nadir at 28 weeks and increasing toward 40 weeks ($P = .001$, .002, respectively); MAP increased from T_2 to term ($P = .023$); CO rose to a peak at 28 weeks before declining to term ($P < .001$)
Iacobaeus, 2017	Healthy nulliparous women with singleton pregnancy, n = 52	Longitudinal (same women followed prospectively)	Oscillometric (Omron 705IT); applanation tonometry; flow-mediated dilatation (FMD)	cfPWV, crPWV, AIx75, MAP, CBP, FMD	11−14, 22−24, 32−34, and 9 months postpartum	MAP and CBP decreased in T_1 and T_2 followed by an increase in T_3 ($P < .001$); adjusted cfPWV decreased during pregnancy and rose at term ($P < .001$); crPWV followed a similar pattern but rose above nonpregnant levels in T_3 ($P < .01$); AIx75 significantly reduced during pregnancy and rose at term ($P < .001$); FMD significantly increased during pregnancy ($P < .05$)
Pandey, 2014	Women with, normotensive, healthy, singleton pregnancies, n = 137; age-matched nonpregnant controls, n = 35	Longitudinal (different women at different gestational ages)	Oscillometric (PeriScope)	cfPWV, baPWV, CBP, AIx	12−14, 20−24, and 32−36 weeks	Central SBP, AP, and CPP greater in T_1 than in nonpregnant controls ($P < .05$), yet decreased to comparable levels in T_2 and increased again in T_3; baPWV lower in T_1 than in controls ($P = .0001$) then increased in T_2 and T_3 to level similar to controls; no significant change in cfPWV; AIx was higher in T_1 than in controls, decreased to a nadir in T_2, then rose again to a peak in T_3 ($P < .0001$)
Khalil, 2009	Healthy women with singleton pregnancy, n = 541	Longitudinal (different women at different gestational ages; 45 followed across all trimesters)	Applanation tonometry	AIx75, CBP, MAP	8−13, 14−26^{+0}, 26^{+1}−39 weeks (cross-sectional); 12, 23 and 32 weeks (longitudinal)	No significant differences in AP or AIx75 across pregnancy (cross-sectional); AP and AIx75 decreased significantly from T_1 to T_2, then rose again in T_3 ($P < .001$) (longitudinal); MAP rose significantly in T_3 ($P = .015$)
Smith, 2004	Normotensive pregnant women, n = 53; nonpregnant women, n = 10	Longitudinal (same women followed prospectively)	Applanation tonometry	AIx, CBP	17−20, 25−28, and 33−36 weeks	AIx and CBP were lower in pregnant compared to nonpregnant women ($P < .05$); AIx decreased from T_2 to T_3 ($P < .01$)

Franz, 2013	Healthy pregnant women, n = 53	Longitudinal (same women followed prospectively)	Oscillometric (TensioClinic TL1 Arteriograph)	cfPWV, AIx	11–13, 14–16, 19–21, 24–26, 29–30, 33–35, 37–38, and 3–6 months postpartum	Significant AIx decrease from T_1 to end of T_2 and increase from T_3 to postpartum ($P = .041$ and $P < .001$, respectively); cfPWV values lowest at 20 weeks gestation and peaked at 35 weeks ($P = .015$)
Gomez, 2016	Women with low-risk, singleton uncomplicated pregnancy, n = 63	Longitudinal (different women at different gestational ages; 11 followed across all trimesters)	Applanation tonometry	cfPWV, crPWV, AIx, CBP, MAP, SEVR, PPA	7–13, 14–17, 18–21, 22–25, 26–29, 30–33, 34–40, and 6.5 weeks postpartum	MAP ($P = .04$) and CPP ($P = .03$) decreased during pregnancy; PPA and crPWV decreased in T_2, then increased steadily until delivery ($P = .01$ and $.04$, respectively); PPA sharply decreased postpartum ($P = .01$); AIx and SEVR significantly increased postpartum ($P = .03$ and $.02$, respectively); no differences in cfPWV, AIx, SEVR, or CBP across pregnancy
Macedo, 2008	Women with normal singleton pregnancies, n = 193; nonpregnant controls, n = 23	Cross-sectional	Applanation tonometry	cfPWV, crPWV, AIx, CBP, MAP	11–41 weeks (all 3 trimesters)	Pregnant women had lower MAP ($P = .01$), CPP ($P = .03$), central SBP ($P = .001$), central DBP ($P = .008$), and AIx ($P < .001$); metrics changed significantly with gestation, reaching nadir at midpregnancy ($P = .001$ to 0.02); cfPWV and crPWV not significantly different across pregnancy or compared with controls
Robb, 2009	Healthy primigravida women with uncomplicated singleton pregnancy, n = 22	Longitudinal (same women followed prospectively)	Applanation tonometry	cfPWV, crPWV, AIx75, CBP, MAP	16, 24, 32, 37, and 7 weeks postpartum	AIx75 rose from 16 weeks to term ($P < .01$) and remained elevated postpartum ($P = .0002$); cfPWV rose from 24 to 7 weeks postpartum ($P = .0008$); crPWV rose from 24 weeks to term ($P < .05$) and remained similar postpartum ($P = .07$); MAP and CBP increased from 24 weeks to term ($P < .0001$)
Mahendru, 2014	Normal pregnant women with previous healthy pregnancies, n = 54	Longitudinal (same women followed prospectively)	Applanation tonometry; Innocor® inert gas rebreathing technique	cfPWV, AIx, CBP, MAP, CO	Preconception; 6–7, 23–24, 32–34, and 14–17 weeks postpartum	Adjusted change in cfPWV not significant; AIx, MAP, and central SBP reached nadir in T_2 and increased in T_3 and postpartum ($P < .001$); AIx significantly higher postpartum than preconception ($P = .01$); postpartum central SBP remained significantly lower than at preconception ($P < .001$); CO peaked in T_2 ($P = .001$), returned to baseline postpartum

TABLE 42.1 Longitudinal studies assessing arterial stiffness and hemodynamic parameters throughout healthy pregnancy and postpartum.—cont'd

First author, year	Population	Design	Method	Metrics	Gestational timepoints	Results
Mersich, 2005	Normotensive pregnant women, n = 12	Longitudinal (same women followed prospectively)	Echo—wall tracking; applanation tonometry	cfPWV, AIx, β stiffness index, carotid CC, carotid DC, MAP	12, 20, 33, and 13 weeks postpartum	Carotid DC and CC decreased and β stiffness increased during pregnancy and reversed after delivery ($P < .05$); cfPWV and AIx decreased from T_1 to T_3, then increased in postpartum period ($P < .05$); no significant changes in MAP
Fujime, 2012	Healthy women with normal singleton pregnancies, n = 830	Longitudinal (different women at different gestational ages; 69 followed across all trimesters)	Applanation tonometry	AIx75, central SBP	12−14, 17−20, 23−27, and 34−36 weeks (cross-sectional); 12−14, 23−27, 34−36 weeks, within a few days of delivery and 4 weeks postpartum (longitudinal)	AIx75 and central SBP decreased to a nadir around midpregnancy ($P < .05$), then increased to T_1 levels toward term and continued rising after delivery ($P < .05$)

AIx75, augmentation index corrected for a heart rate of 75 beats per minute; *aoAIx*, aortic augmentation index; *AP*, augmentation pressure; *baPWV*, brachial-ankle PWV; *BrAIx*, brachial augmentation index; *CBP*, central blood pressure; *CC*, compliance coefficient; *cfPWV*, carotid-femoral PWV; *CO*, cardiac output; *CPP*, central pulse pressure; *crPWV*, carotid-radial PWV; *DBP*, diastolic blood pressure; *DC*, distensibility coefficient; *MAP*, mean arterial pressure; *PPA*, pulse pressure amplification; *SBP*, systolic blood pressure; *SEVR*, subendocardial viability ratio; T_1, first trimester; T_2, second trimester; T_3, third trimester.

As discussed in detail in Chapters 3, 8, and 11, the propagative and reflective properties of the arterial tree can be assessed with pulse wave analysis. Specifically, augmentation index (AIx) is a measure of pulse wave reflection, and as such depends on the diameter and elasticity of the small muscular arteries/arterioles at the major sites of pulse wave reflection. AIx is estimated to decrease by 3%–15% in pregnancy,[33] and to be negatively associated with birth weight.[31] The majority of studies have shown a nadir in AIx midpregnancy[16,30,43,45,46,48,49,51] or at the end of the second trimester,[17,44] while one study showed that the lowest AIx was noted in the third trimester.[50] Of note, a study by Khalil et al. in 541 women recruited at different gestational ages noted no significant difference in AIx standardized to a HR of 75 bpm (AIx75) or augmentation pressure (AP) across the three trimesters; however, when 45 of those pregnant women were assessed prospectively once per trimester, a significant decrease in AIx75 was noted in the second trimester (23–24 weeks).[46] That same study also demonstrated that there was no difference in AIx75 or AP in any trimester throughout pregnancy between Caucasian and Afro-Caribbean ethnic groups. Furthermore, in a cross-sectional study of 830 pregnant women who were recruited at different trimesters, a similar nadir was shown in AIx75 in midpregnancy; this association was confirmed in 69 of the women who were followed longitudinally.[51] Seven studies assessed AIx postpartum between 4 weeks and 9 months[16,30,43,44,47,50,51]; compared with third trimester AIx values, the postpartum AIx was significantly higher in five of these studies,[16,30,44,47,51] significantly lower in one study,[50] and no different in another one.[43] These postpartum AIx values were significantly higher than the first trimester value in four studies[30,44,47,51] and no different in two other studies.[16,50] In the only study that assessed AIx from preconception to postpartum prospectively in the same group of women, the AIx adjusted for HR reduced to a nadir in the second trimester and rose above preconception values postpartum.[16] Some debate also exists as to whether AIx is increased or decreased during early pregnancy with respect to nonpregnant controls,[45,48,49] as normative values of AIx across gestation are not available. Of note, there is no evidence of significant diurnal variability for the majority of arterial stiffness parameters, including cfPWV and pulse wave analysis, suggesting that their measurements do not need be performed at a specific time of day.[52]

Other important hemodynamic indices have also been assessed during pregnancy. Pulse pressure amplification, a measure of the progressive increase in pulse pressure from central to peripheral arteries, was found to decrease early in the second trimester (14–17 weeks) followed by a steady increase until delivery ($P = .01$), and finally a sharp decrease at 7 weeks postpartum ($P = .01$).[47] The subendocardial viability ratio was not found to change during pregnancy but significantly increased at 7 weeks postpartum.[47]

Several mechanisms have been proposed to explain the decrease in arterial stiffness in early and midpregnancy. As previously discussed, there is a gradual reduction in total peripheral resistance despite a gradual increase in CO. This occurs in response to vasodilation of the peripheral vasculature and structural remodeling to accommodate the volume expansion of pregnancy.[33] These changes could be due to the alterations of vasoactive substances, such as NO, prostacyclin, endothelium-derived hyperpolarizing factor, estrogen, progesterone, and relaxin.[24,29] This state of high flow-low resistance circulation is accompanied by increased aortic compliance and distensibility, providing optimal coupling between the heart and the vasculature. In late pregnancy, the increased arterial stiffness from midpregnancy to term could be due to the inhibition of NO, increased CO, and increased circulatory volume.[17]

Importantly, vascular compliance and distensibility may vary depending on the vascular bed. For example, aortic compliance and distensibility increases gradually from the first to the third trimester, along with an increase in its diameter, by about 12%; the aortic compliance and distensibility decrease postpartum compared to late gestation.[50] On the other hand, in order to protect the cerebral circulation from excessive blood flow/volume during pregnancy, carotid compliance and distensibility have been shown to decrease from the first to third trimester of pregnancy, coupled with reduced arterial baroreceptor reflex sensitivity.[53] The arterial smooth muscle cells express both estrogen receptors (causing vasodilation and decreased production of collagen) and angiotensin II receptors (causing vasoconstriction). Given that the relative density of these receptors on the vascular smooth muscle varies in different segments of the arterial tree, it can produce contraction in the carotid artery and relaxation in other arteries, such as the aorta, which has been shown to have higher density of estrogen receptors. Therefore, although the carotid artery increases in diameter during pregnancy, it may gradually become up to 30% stiffer compared to the aorta. Indeed, it has previously been shown that the carotid end-diastolic diameter is increased by 8% across pregnancy, while the pulsatile distension is decreased by 23%; consequently, strain is decreased by 28%.[50] Therefore, compliance and distensibility change approximately in parallel. These alterations were found to reverse in the postpartum period; however, it may take over 6 months for the aortic diameter and 3 months for the carotid artery diameter to return to prepregnancy levels.

Pregnancy complications

Pregnancy acts as a natural cardiometabolic "stress test" that can reveal underlying predispositions to vascular dysfunction.[54] Pregnancy complications are most likely to manifest in the late stages of pregnancy, with the demands

of the growing fetus steadily increasing throughout gestation. In this context, PrE, a common hypertensive disorder of pregnancy (HDP), is a progressive multisystem syndrome characterized by systemic endothelial dysfunction. Other HDPs include gestational hypertension, chronic hypertension, and PrE superimposed chronic hypertension. HDPs remain leading causes of maternal and neonatal morbidity and mortality worldwide,[55] affecting as many as 10% of pregnancies and contributing to 343,000 maternal and around 1.5 million fetal and neonatal deaths annually.[56–58] The health burden imposed by HDPs extends beyond pregnancy, as afflicted women are at significantly increased cardiovascular risk in the postpartum period and later in life.[59,60] Importantly, HDP incidence is on the rise, given the obesity and diabetes epidemic, as well as more advanced maternal age in recent years to accommodate career and life choices.

PrE is the most severe form of HDP, occurring in 5%–8% of pregnancies annually worldwide. It typically manifests as new onset or worsening of hypertension, new-onset proteinuria, and/or signs and symptoms of end-organ dysfunction after the 20th week of gestation.[61] While the majority of PrE cases occur in late gestation (late-onset PrE), approximately 10% occur before 34 weeks, termed early-onset PrE. The latter typically represents a more severe form of PrE, with greater placental dysfunction and a higher risk for maternal and fetal complications.[62] PrE occurring after the 37th week is called term PrE, while before the 37th week preterm PrE. In 5% of cases, PrE is diagnosed postpartum.[63] Diagnosis of PrE is also associated with an increased risk of premature cardiovascular disease, at a relative risk of 2.0 for mild PrE (95% CI 1.8–2.2) and up to 9.5 for severe PrE (4.5–20.3). Women with a history of PrE have a 3.7-fold increased risk (2.7–5.1) of chronic hypertension and a 1.8-fold increased risk of developing type 2 diabetes (1.3–2.6) within 10 years postpartum. The risk for developing hypertension is increased >3.5-fold after mild PrE and >6-fold after severe PrE.[64–68]

Given that PrE is a heterogeneous syndrome, multiple pathways have been proposed for both the causal and exacerbating factors leading to maternal vascular dysfunction. Below, we present changes occurring during pregnancy complicated with HDPs, with a particular focus on PrE.

Blood volume

Plasma volume expansion occurs gradually across gestation but is lower in pregnancies complicated by pregnancy-induced hypertension, PrE, or fetal growth restriction than in healthy pregnancy, and hemoconcentration is often present. According to a metaanalysis, plasma volume is significantly lower by 13% than in healthy pregnancies in the third trimester. Specifically, a 0.8 L volume expansion is noted in PrE (total increase of 32% in the third trimester) as opposed to the >1 L volume expansion seen in healthy pregnancies (a 45% increase in the third trimester).[2] It appears that the decrement in volume precedes the onset of hypertension.

The role of the RAAS and intrarenal renin–angiotensin system (iRAS) is complex in PrE, with several different theories proposed. It has been suggested that abnormal placental development causes dysregulated expression of the placental RAS through oversecretion of renin and other proteins/angiotensin peptides by the placenta released into the maternal circulation.[5] Shallow placentation and alterations in uteroplacental perfusion in PrE are also accompanied by increased levels of AT1 receptor autoantibodies, which act as agonists on the AT1 receptor. These molecules, or their combination, may cause activation of maternal iRAS and failure of the circulating RAAS to be activated and respond to the homeostatic demands.[5] As such, plasma concentrations of angiotensin II are reduced in PrE, largely due to reduced active octapeptide angiotensin. There is correspondingly enhanced pressor sensitivity to angiotensin II in PrE. Plasma aldosterone concentrations (PACs) are also reduced in PrE compared with normal pregnancy. The reduction is proportionally less than that of plasma renin activity and plasma renin concentration (PRC), and thus the PAC:PRC ratio rises.[69] Overall, compared with the increase in RAAS components in normotensive pregnancy, the circulating levels of renin, Angiotensin I, Angiotensin II, Angiotensin (1–7), and aldosterone are much lower, with little fluctuation in ACE levels.[70] In sum, most components of the circulating RAAS are downregulated in PrE and the condition associates with a relatively low degree of RAAS activity compared to normal pregnancy.[71]

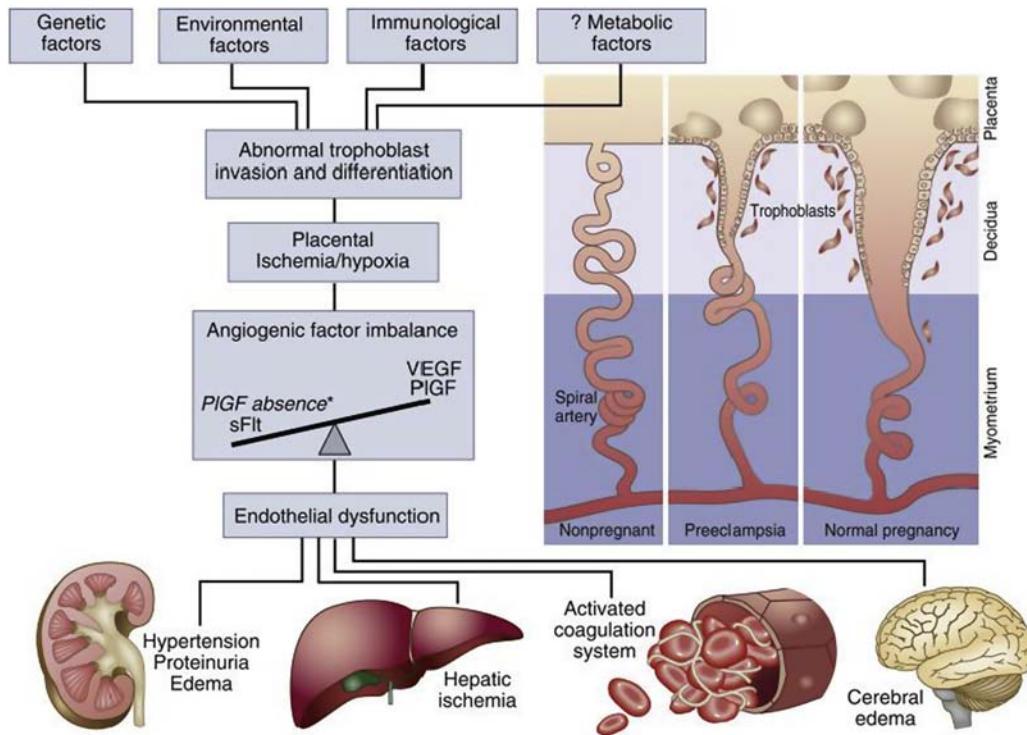
Cardiac output

CO has divergently been described as decreased, unchanged, and increased in this disease. It has been suggested that PrE is characterized by variations in hemodynamic status, ranging from a hyperdynamic high-CO–low-resistance state with increased left ventricular function in the preclinical phase of PrE to a low-CO–high-resistance vasoconstrictive state with decreased left ventricular function during PrE.[72] However, conflicting results have been reported. Specifically, it was shown that those who subsequently developed PrE without small for gestational age infants had increased CO and MAP at 11–14 gestational weeks compared to a control group.[73] Increased CO was also shown by others when measured at 24–40 weeks in cases of PrE but without fetal growth restriction.[74] Conversely, others have observed that women who subsequently developed PrE have decreased CO and

increased total peripheral resistance, even before conception, when compared with healthy pregnancies.[75]

Most studies report that cardiovascular adaptations are compromised in PrE, including a 13% reduction in plasma volume expansion and decreased CO (5.5 ± 1.5 vs. 6.2 ± 1.9 L/min)[2,76]; central venous and pulmonary wedge pressures are also reduced and may vary inversely with the severity of the disease.[77] Moreover, higher impedance to flow in the uterine arteries is inversely related to gestational age at delivery.[72] Furthermore, it has been demonstrated that CO in PrE is significantly lower in the early-onset PrE (<34 weeks) compared with late-onset PrE ($\geq$34 weeks)[78] and is positively associated with birth weight.[74]

The evidence on HR is equally mixed. Lower HR in the third trimester with a lower SV have been reported in PrE and gestational hypertension.[79] The SV index has also been shown to be reduced by a mean of 9.7% between early- and late-onset PrE.[80] Conversely, others have observed no significant differences in HR between women with PrE and gestational age-matched healthy controls as well as between early- and late-onset PrE groups.[81] HR variability has been shown to be higher in PrE groups compared to healthy pregnant controls, although not consistently in the literature; HR variability and baroreceptor reflex sensitivity were found to be significantly higher in late-onset PrE compared to gestational age-matched controls, but not between early-onset PrE and controls.[81] A study performing 24-h ambulatory BP monitoring suggested that the odds of developing an HDP increased by 1.5 times for every 1 bpm increase in the 24-h ambulatory BP monitor HR, when measured at 14−24 weeks' gestation. This became nonsignificant at 24−32 weeks and was reversed by 33 weeks to delivery.[82]

In general, it is thought that sympathetic activity is greater in PrE and gestational hypertension than in healthy pregnancy and in nonpregnant women with hypertension.[83] Although a decrease in baroreceptor reflex sensitivity is also seen in healthy pregnancy, this is further impaired in PrE.[81,83] Interestingly, PrE appears to be associated with decreased vagal control of the heart.[81−83] More broadly, sympathetic overdrive and adrenergic receptor−induced vasoconstriction are elevated in PrE.


Finally, evidence suggests that PrE is associated with abnormal cardiac geometry.[84,85] Women who subsequently develop PrE show evidence of left ventricular concentric remodeling at midgestation. Importantly, reduced SV, diastolic dysfunction, and left ventricular remodeling can occur before clinical manifestations of PrE and are most affected in severe and early-onset PrE.[1,84] Indeed, women who develop preterm PrE exhibit a high resistance−low volume hemodynamic state and demonstrate asymptomatic left ventricular diastolic or systolic dysfunction as well as segmental impaired myocardial relaxation at midgestation.[85] Both early and late PrE are characterized by increased left ventricular

mass and relative wall thickness. However, concentric hypertrophy and diastolic dysfunction are significantly more prevalent in early- rather than late-onset PrE.[86] Furthermore, longitudinal, radial, and circumferential strain are significantly worsened in women with PrE compared to those with gestational hypertension or without HDP; however, their ejection fraction is not significantly different, unless there is decompensation.[80,87,88] Autopsy data have shown that, compared with deaths in pregnancy from other causes, there is a 10-fold prevalence of myocardial contraction band necrosis in PrE cases.[80]

Vascular remodeling and vascular resistance

Although PrE symptoms typically appear in the second-half of pregnancy, disease processes can be detected in the first trimester. PrE has been associated with the failure of the maternal cardiovascular system to undergo normal adaptations (Figs. 42.2 and 42.4).[23,89] As such, insufficient remodeling of the uteroplacental arteries results in a 21%−42% increase in uterine artery resistance in women who develop PrE, leading to a reduction in uterine blood flow, which can be observed as early as 16 weeks' gestation.[33] To this end, an increased uterine artery pulsatility index in the second trimester is correlated with an increased risk of PrE. Together, these changes lead to abnormal placentation, angiogenic imbalance, and maternal vascular dysfunction, which are implicated in the development of PrE and alter the delivery of blood, oxygen, and nutrients to the fetus, which can impair fetal growth and development.[33]

Due to inadequate remodeling of the spiral arteries, the myometrial segments retain vasoreactivity, leading to intermittent placental perfusion and a cascade of events that result in PrE.[90,91] Postulated mechanisms include imbalance in the bioavailability and activity of endothelium-derived contracting and relaxing factors and oxidative stress.[92] Consistent with ischemia-reperfusion injury, fluctuating oxygen supplies result in oxidative stress−induced endothelial dysfunction.[93] Although reactive oxygen species are required and upregulated for normal physiology during gestation, an imbalance of oxidative species and antioxidative defense mechanisms are implicated in PrE.[94] As a result, a decrease in NO bioavailability and the associated endothelial dysfunction occur such that endothelial-dependent vasodilation is reduced without concurrent changes to endothelial-independent vasodilation. Furthermore, hormonal alterations and exaggerated immune and systemic inflammatory responses occur with production of proinflammatory cytokines (tumor necrosis factor-α, interleukin [IL]-6, and IL-17) and a decrease in antiinflammatory cytokine (IL-10, IL-4) levels.[95] Moreover, it appears that, unlike in healthy pregnancies, increased sensitivity to angiotensin II and vasoconstrictor

FIGURE 42.4 The current understanding of the pathogenesis of preeclampsia. *PlGF*, placental growth factor; *sFlt*, soluble fms-like tyrosine kinase; *VEGF*, vascular endothelium growth factor. *Reproduced from Almaani SJ. Placental growth factor in pre-eclampsia: friend or foe?* Kidney Int. 2019;95:730—732.

responses are enhanced in PrE.[91] To this end, placenta-derived factors, including antiangiogenic factors, microparticles, and cell-free nucleic acids, are released into the maternal circulation and act on the vascular wall to modify the secretory capacity of endothelial cells that alter the responsiveness of vascular smooth muscle cells to constricting and relaxing stimuli.[92] Indeed, the trophoblastic stress caused by placental hypoperfusion and hypoxia triggers excess release of sFlt-1 at the placental surface into the circulation (Fig. 42.3).[23,91] Up to a threefold increase in sFlt-1 has been noted in PrE, resulting in up to a 90% decrease in VEGF and PlGF.[33] Together, this imbalance of angiogenic/antiangiogenic factors negatively affects angiogenesis and placentation in PrE.[96] It is noteworthy that the sFlt-1/PlGF ratio correlates with severity of PrE, while a greater reduction in PlGF is associated with early-onset PrE.[97,98] A sFlt-1:PlGF ratio of 38 or lower has been shown to have a negative predictive value (no occurrence of PrE) of 99.3% in the subsequent week, and thus can be used as a cutoff value to predict the short-term absence of PrE.[99]

Hormonal alterations associated with PrE also play an important role in vascular remodeling. Estrogen levels have been shown to be decreased by 30%—40% in PrE, contributing to the observed endothelial dysfunction.[33,100] Low estradiol (E2) levels reduce angiogenesis and vasculogenesis, leading to insufficient placental development and maternofetal exchange,[100] in turn, leading to lower E2 levels and triggering a vicious circle between hormonal imbalance and disrupted implantation. Both severe and mild PrE have been associated with low E2 concentrations. In pregnancy complicated by PrE and/or fetal growth restriction, lower placental aromatization and E2 levels and higher progesterone inactivation have been noted.[101] Indeed, E2 and progesterone levels have been shown to be significantly reduced in PrE at the time of diagnosis compared to gestation-matched normotensive pregnant women.[102] However, relaxin levels in women with PrE do not seem to be significantly different from that of healthy pregnancies during the third trimester, at delivery, and up to 2 weeks postpartum.[103,104]

It is generally believed that PrE is associated with increased total peripheral resistance, while aortic diameter is inversely proportional to total peripheral resistance.[33,92] As such, the aortic diameter in pregnancies complicated with hypertension is lower compared to healthy pregnancies; however, this is not consistent in the literature. Contrary to this principle, the carotid artery's diameter is up to 20% larger in women with PrE in the third trimester; this increase is related to the severity of PrE and is greater in early- versus late-onset PrE.[105] The increased diameter of the carotid artery is accompanied by a decrease in its

compliance. Furthermore, carotid intima—media thickness has been shown to be increased by up to 10% in women with PrE, a finding that endures postpartum. These alterations in the carotid artery seem to be proportional to BP.[33] In contrast, the resting diameter of the brachial artery has been found to decrease or remain unchanged in PrE.[33] At the microcirculatory level, a decrease in the density of skin capillaries of up to 17% has been noted in women who develop PrE.[106,107] This decrease may precede the development of PrE and may persist up to 15 weeks postpartum. These microcirculatory alterations further contribute to the increased vascular resistance and decreased peripheral blood flow observed in PrE.[106,107]

PrE is a very complex disorder and manifests with different patterns. For example, PrE that occurs earlier in gestation and is associated with fetal growth restriction is likely related to low CO, low inotropy, and high peripheral vascular resistance,[108] while cases of later and term gestation PrE involve babies who tend to be larger, and there is a predominantly high CO, low peripheral vascular resistance, and increased intravascular volume in midgestation.[109] Moreover, early- and late-onset PrE are both characterized by increased total vascular resistance at term.[110]

Blood pressure

Altered BP trajectories in gestation have been reported in women who develop HDP (gestational hypertension and PrE), whereby SBP and DBP are higher throughout pregnancy compared to normotensive women. Specifically, unlike women with healthy pregnancies, women with HDP have generally stable BPs during the first-half of pregnancy, which then increase until delivery.[111] Indeed, in 13,016 women from the Avon Longitudinal Study of Parents and Children, the rate of change in SBP and DBP from 18 weeks' gestation onward was higher in women with PrE compared to women with healthy pregnancies.[112] While DBP increases by about 7% between midgestation and delivery in women with healthy pregnancies, this increment is around 12%—15% in those with HDPs.[111] Additionally, greater BP variability, especially systolic coefficient of variation, in the second to third trimester is independently associated with higher odds of severe hypertension and PrE.[113]

Similarly, MAP has demonstrated an increasing trend from the second trimester onwards in both early- and late-onset types of PrE; in early-onset PrE, its highest value was observed at 20 weeks of gestation compared to a control group. Whereas in late-onset PrE, absolute MAP and increases in MAP were higher from 20 to 27 weeks and 28—37 weeks into gestation compared to controls. Further, while an increment of 5% in MAP was noted in women with healthy pregnancies, this was observed to be increased by 13% in those with late-onset PrE.[111]

Nonsevere hypertension in pregnancy is defined as an SBP of 140—159 mmHg and/or DBP 80—109 mmHg, while severe is characterized as SBP $\geq$160 mmHg and/or DBP$\geq$ 110 mmHg.[114] Notably, when measured in the first trimester (8—11 weeks), the incidence of PrE was found to be significantly higher, in a graded manner, in women with high-normal BP (clinic SBP: 120—129 mmHg and DBP <80 mmHg), temporary hypertension (clinic BP $\geq$140/90 mmHg, with clinic BP <140/90 mmHg in midgestation), white coat hypertension, high BP (clinic SBP: 130—139 mmHg and/or DBP: 80—89 mmHg), and chronic hypertension than in normotensive women.[115] In a recent cohort study analyzing data of 137, 389 pregnancies, it was found that using the lower diagnostic threshold for hypertension recommended in the 2017 ACC/AHA guideline (130/80 mmHg) increased the prevalence of chronic and gestational hypertension, markedly improved the appropriate identification of women who would go on to develop PrE, and was associated with improved identification of adverse fetal/neonatal risk.[114]

As previously stated, PrE significantly increases the risk of chronic hypertension later in life, which increases with increasing severity of PrE.[64–68] Interestingly, longitudinal assessment of PrE revealed that $\approx$50% of women have persistent hypertension and increased rates of nocturnal, ambulatory, and masked hypertension at 12 weeks postpartum.[1]

Arterial stiffness

Increased systemic arterial stiffness and wave reflection have been reported among women with HDP.[116–118] In a systematic review, our group has demonstrated that PrE is associated with increased arterial stiffness during and after pregnancy, more so than gestational hypertension.[116] Our metaanalyses showed that a significant weighted mean increase of 1.04 m/s in cfPWV was noted at the time of PrE diagnosis, as well as a sizable 15% increase in AIx.[116] The magnitude of the increase in arterial stiffness appears to be greater in early-onset PrE and is proportional to the severity of PrE.[116,119,120]

The limited number of longitudinal studies with data preceding PrE onset generally showed that arterial stiffness and wave reflection parameters were increased as early as 11 weeks among pregnant women who subsequently developed PrE and remained elevated throughout pregnancy compared to healthy pregnant women or women with gestational or chronic hypertension (Table 42.2).[118,121] More severe PrE was associated with a greater increase in arterial stiffness. Furthermore, women who developed gestational diabetes mellitus were also shown to have increased arterial stiffness starting in the first trimester compared to healthy controls.[122] Specifically, cfPWV has been shown to be increased in PrE pregnancies

TABLE 42.2 Longitudinal studies assessing arterial stiffness and hemodynamic parameters throughout pregnancy subsequently complicated with preeclampsia and postpartum.

First author, year	Population	Design	Method	Metric	Gestational timepoints	Results
Franz, 2013	Healthy pregnant women, n = 19; women presenting with PrE, n = 21	Longitudinal cohort trial	Oscillometric (TensioClinic TL1 Arteriograph)	cfPWV, AIx	Onset of disease (mean 28 (early-onset) and 36 (late-onset) weeks) and 3—6 months postpartum	No differences in cfPWV during pregnancy; AIx significantly greater in early- and late-onset PrE during pregnancy ($P < .001$); cfPWV ($P = .006$) and AIx ($P = .001$) elevated in early-onset PrE postpartum; no differences between late-onset PrE and controls postpartum
Robb, 2009	Healthy primigravida women with uncomplicated singleton pregnancy, n = 22; singleton primigravida women with PrE, n = 15	Longitudinal	Applanation tonometry	cfPWV, crPWV, AIx75, CBP, MAP	At diagnosis (mean 30 (early-onset) and 38 (late-onset) weeks) and 7 weeks postpartum	All metrics greater in both PrE groups ($P \leq .01$); cfPWV, AIx75, CBP, and MAP remained elevated 7 weeks postpartum ($P \leq .02$)
Khalil, 2010	High-risk women with singleton pregnancy, n = 252 (42 PrE)	Nested case—control	Applanation tonometry	AIx75	11—13 weeks	AIx75 significantly higher in all PrE, early-onset PrE and PrE + SGA compared to controls ($P \leq .002$)
Khalil, 2014	High-risk women with singleton pregnancy, n = 245 (44 PrE)	Prospective longitudinal	Oscillometric (Arteriograph, TensioMed Ltd.)	cfPWV, AIx, aortic SBP	11—13 weeks and every 4 weeks until delivery	cfPWV, AIx, and aortic SBP significantly higher in the preterm PrE group ($P \leq .033$), but not in the term PrE group
Savvidou, 2011	Healthy women with singleton pregnancy, n = 140 (29 PrE)	Prospective	Applanation tonometry	cfPWV, crPWV, AIx75, MAP, CBP, T1R	22—24 weeks	Adjusted cfPWV/crPWV, MAP, and CBP higher and T1R lower in PrE group ($P \leq .02$); adjusted AIx75 not significantly different between PrE and non-PrE groups; adjusted cfPWV not different between early- and late-onset PrE
Khalil, 2012	Women with singleton pregnancy, n = 6947 (181 PrE)	Longitudinal	Oscillometric (Arteriograph, TensioMed Ltd.)	cfPWV, AIx75, aortic SBP	11—13 weeks	Significantly greater cfPWV, AIx75, and aortic SBP in PrE ($P < .0001$)

Khalil, 2009	Low-risk women with singleton pregnancy, n = 210 (14 PrE)	Prospective longitudinal	Applanation tonometry	AIx75, MAP	11–13 weeks	AIx75 had a detection rate of 79% for all PrE and 88% for early-onset PrE, with an FPR of 11%; no differences in MAP
Carty, 2014	High-risk pregnant women, n = 140 (17 PrE)	Longitudinal	Applanation tonometry, peripheral arterial tonometry	AIx75, peripheral AIx, CBP	16 and 28 weeks; 6–9 months postpartum	Central DBP higher in PrE at week 16 ($P = .013$); no difference in other metrics
Katsipi, 2014	High-risk pregnant women, n = 118 (21 PrE)	Longitudinal	Doppler ultrasound	cfPWV, MAP	22–26 weeks	cfPWV showed a detection rate of all PrE of 81% and of early-onset PrE of 82% at a fixed 10% FPR; MAP elevated in PrE ($P < .01$)
Khalil, 2012	Women with singleton pregnancy, n = 6814 (337 PrE + SGA and 48 SGA)	Prospective longitudinal	Oscillometric (Arteriograph, TensioMed Ltd.)	cfPWV, AIx75, aortic SBP	11–13 weeks	In PrE + SGA, AIx75, and aortic SBP were increased ($P \leq .001$) but not cfPWV; no differences between SGA and controls

AIx75, augmentation index corrected for a heart rate of 75 beats per minute; *CBP*, central blood pressure; *cfPWV*, carotid-femoral pulse wave velocity; *DBP*, diastolic blood pressure; *FPR*, false-positive rate; *MAP*, mean arterial pressure; *PrE*, preeclampsia; *SBP*, systolic blood pressure; *SGA*, small for gestational age; *T1R*, timing of the reflected wave.

by approximately 20% (1 m/s) above normotensive pregnant values and remain elevated at 7 weeks postpartum; importantly, this increase was shown to be independent of BP values.[33,43,123–126] Only two studies measured cfPWV in the first trimester of pregnancy, one showed that cfPWV was significantly higher in those destined to develop PrE and the other noted a significant increase only in early-onset PrE.[126,127] Another small study (n = 20, three developed PrE) also found a significant increase in brachial PWV in the first trimester using ultrasound.[128]

When measured in the second trimester, cfPWV was found to be significantly increased by 17%[124] or 30% (10.2 ± 1.9 m/s vs. 7.2 ± 1.1 m/s)[125] in women who subsequently developed PrE compared with healthy pregnancies. It was also shown that for every 1 m/s increase in cfPWV, there was a 3.9-fold (95% CI 2.2–7.0) increased risk for PrE, which was even higher when an increase in sFlt-1 levels was also considered.[125]

Limited evidence suggests an increase in crPWV of around 10%–15% above healthy pregnancy values can be detected in the third trimester in women with PrE, with no difference postpartum.[33,43,123] The difference in central versus peripheral PWV could be due to the fact that the aorta undergoes more adverse adaptations in PrE, while the brachial artery structures remain generally unaltered.[33]

Measures of wave reflection have also shown unique changes in complicated pregnancy. AIx may be increased by up to 20% in PrE, although there is no universal agreement.[124,129] The four studies that measured AIx/AIx75 in the first trimester showed that these parameters were increased in women destined to develop PrE,[126,127,130,131] although one study found that this increase was significant only for preterm PrE.[126] However, studies that measured AIx later in pregnancy (in the second[124] or second and third[129] trimester) showed no significant difference between those who did and did not develop PrE, while some evidence suggests that AIx remains elevated up to 6 months postpartum.[43,44] These mixed results highlight the lack of systematic research in this area and the need for more comprehensive examinations of arterial stiffness and wave reflection parameters during and after pregnancy.

Overall, in a metaanalysis of a limited number of eligible studies that assessed arterial stiffness and wave reflection parameters, it was shown that, in the first trimester, mean AIx75 was significantly higher in the PrE group, with an estimated standardized mean difference (SMD) of 0.90 [95% CI 0.07–1.73; $P = .034$]. In the second trimester, the PrE group had significantly higher cfPWV with an estimated SMD of 1.26 m/s (95% CI 0.22–2.30; $P = .018$).[121]

Interestingly, one study that measured AIx, cfPWV, and central SBP throughout high-risk pregnancies found the arterial stiffness measures to be significantly higher only in the preterm PrE group from 16 weeks onwards, but not in the term PrE group, and the difference increased with gestational age.[126]

A study of high-risk pregnant women by our group demonstrated that arterial stiffness was significantly increased throughout pregnancy and that a first-trimester 1 m/s increase in cfPWV was associated with 64% increased odds of developing PrE ($P < .05$), while a 1 m/s increase in time to wave reflection (T_{1R}) was associated with 11% decreased odds for PrE ($P < .01$) (unpublished data). Furthermore, a changepoint in cfPWV and crPWV was detected at 14–17 weeks gestation, at which time cfPWV started increasing in women who developed PrE but decreasing in women who did not; at 22–25 weeks' gestation, a 1.2 m/s difference in cfPWV was observed. Furthermore, women who subsequently developed PrE showed an increase in AIx at 18–21 weeks that was not seen in women who did not develop PrE until 30–33 weeks.[132] This study further highlighted the importance of changes in arterial stiffness early in pregnancy.

Regarding early-onset versus late-onset PrE, all markers of arterial stiffness and hemodynamics have been shown to be elevated at the time of PrE diagnosis compared to healthy pregnancies,[116,117] with two studies showing no significant differences between the different types of PrE.[43,44] While there are limited studies examining postpartum measurements, one group showed that all measures except crPWV remained elevated 7 weeks postpartum in both types of PrE,[43] while others showed that cfPWV and AIx were elevated 3–6 months postpartum only in early-onset PrE,[44] or that PWA parameters were not significantly different 6–9 months postpartum from the values during pregnancy.[129] When cfPWV measurements were performed in the second trimester, prior to PrE onset, they were found to be either similar in early- and late-onset PrE[124] or significantly higher in early-onset PrE.[125] Overall, evidence suggests that the early-onset PrE shows more significant alterations in arterial stiffness, but more studies are needed to confirm the differences between the two types.

In terms of prediction of early- versus late-onset PrE, AIx75 had a prediction rate of 79% for all PrE cases and 88% for early-onset PrE in the first trimester, while MAP was not found to be predictive.[131] Measurement of PWV, among other markers in the second trimester, showed that cfPWV had the highest prediction rate, at 81% for all PrE cases and 82% for early-onset PE; when combined with sFlt-1 measurements, these rates increased to 90% and 92%, respectively.[125] To this end, a study of high-risk pregnant women by our group has demonstrated that a combination of arterial stiffness and wave reflection indices (cfPWV, AIx75, and T_{1R}) measured between 10 and 13 weeks' gestation predicted PrE earlier and with greater accuracy than BP, ultrasound indices, and/or angiogenic

biomarkers alone. The area under the curve of arterial stiffness, BP, ultrasound indices, and angiogenic biomarkers was 0.84, 0.68, 0.66, and 0.64, respectively (unpublished data). Importantly, we found that BP had a sensitivity of 14% for PrE prediction, whereas that of arterial stiffness was 36%, demonstrating the clinical value of these measurements.

Peripheral vascular stiffness and resistance in women with PrE has been associated with decreased resting blood flow,[133] decreased capillary density,[107] and impaired vascular compliance and endothelial function. A meta-analysis has demonstrated that women who develop PrE have reduced FMD not only at the time of diagnosis but also prior to diagnosis in the first or second trimester compared to controls.[134] Moreover, women who subsequently developed PrE had similar FMD values at 16–19 weeks compared to 24–28 weeks, indicating that, unlike in healthy pregnancy, PrE is linked to a failure of endothelial function to improve.[135] Furthermore, FMD values were shown to be up to 75% lower in women with PrE in the third trimester. Interestingly, the impaired FMD values remained up to 3 years postpartum, thus contributing to increased future cardiovascular risk.[33]

It is also clinically relevant that increased arterial wave reflections may affect fetal growth in pregnant women even in the absence of hypertension. Specifically, a significant inverse association between AIx and AIx75 and birth weight has been suggested.[136] Furthermore, an increase of 1 m/s in cfPWV was associated with a decrease in birth weight centiles by 17.6% and a catch-up growth after birth of 22.3% in weight centiles, independent of MAP; this association was even stronger for pulse pressure.[137] However, these associations are not universally noted; a large study measuring AIx and PWV in the first trimester observed no difference in these parameters in women who subsequently delivered small for gestational age infants versus unaffected controls, unless PrE was also present.[138]

Overall, in contrast to women with healthy pregnancies, women with PrE appear to have an impaired vascular response to hemodynamic changes that occur during pregnancy. As such, arterial stiffness and vascular resistance may be early indicators of PrE development.

Fetal growth restriction

Fetal growth restriction (previously termed intrauterine growth restriction) has also been independently associated with increased markers of arterial stiffness and impaired vessel hemodynamics. Pregnant women destined to develop fetal growth restriction exhibited decreased SV and CO, as well as increased peripheral vascular resistance compared to their healthy counterparts.[139] Furthermore, in women who went on to develop fetal growth restriction, but not superimposed PrE, AIx75 was significantly elevated.[140]

Moreover, aortic AIx75 was found to be the only significant independent determinant of birth weight in a cohort of pregnant women with chronic hypertension.[140]

Pregnancies complicated by fetal growth restriction had greater MAP and reactive hyperemia index, measured in the second or third trimester, than unaffected controls.[141] In high-risk pregnant women followed longitudinally from the first to third trimesters, unaffected pregnancy was associated with reduced vascular resistance and increased CO until midpregnancy, while pregnancies complicated by fetal growth restriction showed no change across gestation with lower CO and higher peripheral vascular resistance. Fetal growth restriction is thus linked to a persistent failure of maternal hemodynamic adaptation in pregnancy.[142]

It has been noted that screening and predictive tools for fetal growth restriction tend to underperform in high-risk groups compared with general pregnant populations.[143] Hemodynamic indices which have shown independent predictive potential for fetal growth restriction when measured in the first trimester in high-risk women include peripheral vascular resistance, and to a greater extent, CO.[143]

Exercise in pregnancy

Due to concerns and uncertainty around the safety of pharmacological regimens in pregnancy, there is currently a lack of specific treatments to prevent pregnancy complications. Thus, prevention of pregnancy complications through lifestyle modification is that much more essential to ensuring a healthy pregnancy. Physical exercise, in particular, appears to enhance the beneficial adaptations that occur in healthy pregnancy.

Overall, placental angiogenesis and endothelial function are enhanced in women who are active prior and during pregnancy compared to those who are not.[33] Indeed, regular aerobic training in the year before conception and/or during early pregnancy (up to 24 weeks of gestation) has been found to decrease the overall risk of developing HDPs by 30%; specifically, risk of gestational hypertension was reduced by 20%–40%, and PrE by 20%–60%.[33,144,145] Prepregnancy physical activity in general was associated with a 28% reduced risk of PrE for every 1 hour of physical activity per day, plateauing at 5–6 h per week, while leisure-time physical activity in early pregnancy decreased the risk of PrE by 17% for every hour per day with no plateau. Higher intensity activity and increased walking in early pregnancy were also beneficial and reduced PrE risk.[146] In patients with diagnosed PrE, supervised training was shown to lower BP and proteinuria over time.[145] The beneficial effects of exercise on PrE have been further examined in a transgenic mouse model, where exercise training both before and during gestation led to normalization of MAP, proteinuria, cardiac hypertrophy, vascular reactivity, and placental VEGF expression.[146]

Regular exercise also reduces the risk of gestational diabetes by 20%−40%; it has been shown to ameliorate glycemic control and reduce insulin resistance (improve skeletal muscle insulin sensitivity) and leptin levels in both normal weight and obese women.[144,146−148] Exercise and physical activity, in general, during pregnancy can prevent excessive gestational weight gain and have been shown to improve lipid profiles.[146,148] Additionally, regular exercise has been associated with reductions in preterm birth by 20%−50% and the risk of large-for-gestational-age infants, or macrosomia, by 30%−50%. The odds of having a small newborn were not found to be affected by exercise.[148,149]

Exercise in early pregnancy enhances placentation by enabling the invasion and proliferation of trophoblast cells, in part through changes in perfusion pressure and oxygen supply. Exercise may be beneficial to placental growth and vascular development as brief bouts of mild hypoxia and a reduction in placental perfusion may promote cell proliferation and angiogenesis.[33] The increase in shear stress produces a state of hyperemia, while an increase of blood flow during exercise results in improved endothelial function.[150] Indeed, repeated bouts of exercise effectively improve vascular function (a) directly by exerting shear forces on the vascular wall, which activates endothelial NO synthase (eNOS) and reduces NAD(P)H oxidase activity, decreasing reactive oxygen species and increasing NO bioavailability and (b) indirectly through the release of antiinflammatory and anabolic mediators in response to increased energy demands from muscles.[33,145,151,152] To this end, a significant increase in FMD during the third trimester of pregnancy has been observed in pregnant women who participated in controlled exercise programs.[153]

Exercise may also lead to improved antiangiogenic/angiogenic balance, with an approximately 40% decrease in sFlt-1 and approximately 50% increase in PlGF and VEGF in active versus inactive pregnant women. Exercise was also found to improve placental vessel formation and density without affecting placental size.[33] Regular weight-bearing exercise in pregnancy lowers the level of plasma proinflammatory cytokine tumor necrosis factor-α, and reduces oxidative stress through reduction of lipid peroxidation and thromboxane levels, while increasing iron-binding capacity, antioxidant enzyme levels, and prostacyclin.[145,146]

The evidence on the effect of exercise on arterial stiffness and vessel hemodynamics is limited. In a prospective cohort study, control brachial-ankle PWV (baPWV) at 1 month after delivery was significantly higher than the control baPWV in the early second trimester, while baPWV remained essentially the same in healthy pregnant women who performed vigorous exercise three or more times per week. These results indicate a relative decrease in arterial stiffness after healthy pregnancy associated with exercise.[154] Lastly, a randomized controlled trial found that regular aerobic exercise starting in the second trimester lasting 16 weeks led to greater cardiorespiratory fitness, lower HR at rest, and 44% greater FMD at the end of the intervention than that observed in a control group without regular aerobic activity, as assessed by the 6-min walk test and VO_{2max}.[153]

Worldwide guidelines encourage women without contraindication to begin or continue regular moderate intensity exercise during pregnancy, recommending 60−150 min/week.[33,145] The majority of pregnant women currently do not reach this target and continue to be inactive, especially as the pregnancy progresses.[145] Regular moderate intensity exercise during pregnancy is safe and the beneficial effects are numerous for the mother and developing fetus.

Concluding remarks

The complexity of changes during gestation and in HDP (and particularly PrE) have not allowed to fully unravel the physiology of pregnancy and the pathophysiology of its complications. Overall, it is accepted that during healthy pregnancy there is systemic vasodilation and decreased vascular resistance to accommodate the increase in blood volume and CO and meet the metabolic needs of the growing fetus. These changes lead to a U-shaped curve in BPs, arterial stiffness, and wave reflection, reaching a nadir in the second trimester. In contrast, in HDP and particularly in PrE, there are relatively lower increases in blood volume and CO, with marked elevation in peripheral vascular resistance, leading to continuous increases in BPs as well as in arterial stiffness and wave reflection throughout pregnancy.

Pregnancy is a cardiometabolic "stress test" that can uncover vascular abnormalities that manifest later in life as hypertension, diabetes, and premature cardiovascular disease. In this context, HDP and PrE constitute sex-specific, pregnancy-related cardiovascular disorders that share similar risk factors and have similar long-term adverse cardiovascular outcomes as the conventional cardiovascular disease. Therefore, it is important to accurately predict and prevent HDP from happening. To this end, the optimization of health care to prevent and treat women with HDPs continues to be a top priority on the global health agenda.[155] The American Heart Association in its "Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women" recommends including a history of pregnancy complications as part of the cardiovascular risk evaluation and screening of women.

At present, there are no accurate clinical tools to predict early HDP and PrE. Arterial stiffness and hemodynamic parameters hold promise and they should be systematically investigated as early predictive tools for HDP and PrE.

Currently, the evidence examining arterial stiffness and hemodynamic alterations, although encouraging, is still sparse; limited number of studies of typically small sample sizes, mainly cross-sectional study designs, methodological differences, and measurement at different timepoints do not allow to capture the continuum of acute vascular changes that occur during the short timeline of pregnancy. Furthermore, first trimester or postpartum baselines may underestimate the magnitude of pregnancy and HDP-related changes. Prospective studies from preconception to postpartum, as well as identification of reference and normative values of arterial stiffness and hemodynamic parameters, will help reveal the magnitude of cardiovascular maladaptations during pregnancy and their long-term cardiovascular effects.

Thus, more comprehensive investigations to establish the ability of arterial stiffness and hemodynamics to predict early and accurately HDP and PrE are necessary. As such, arterial stiffness−related parameters may serve to address the current lack of effective and accurate screening methods for predicting HDP and PrE risk in early pregnancy with the potential to ultimately be incorporated into obstetric clinical practice.

Chapter 43

Arterial stiffness and pulsatile hemodynamics in pediatric populations

Andrew H. Tran[1,2] and Elaine M. Urbina[3,4]

[1]The Heart Center, Nationwide Children's Hospital, Columbus, OH, United States; [2]The Ohio State University, Columbus, OH, United States; [3]Division of Cardiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States; [4]University of Cincinnati, Cincinnati, OH, United States

Introduction

Measures of arterial stiffness have been measured in adults for many years resulting in a large body of literature and established normal values for many parameters. Contrasting this, the study of arterial stiffness in children has received less attention and data are limited on normal values. One of the difficulties with studying arterial stiffness in children is the change in arterial physiology with growth. Aortic length progressively increases in childhood until reaching adult proportions, which affects the wave reflection sites. In addition to changes in aortic length, structural aortic changes occur during development. As discussed in Chapters 7 and 19 in detail, elastin is a major structural component of large arteries, with elastogenesis starting at mid-gestation and continuing after birth until adolescence.[1,2] This means that essentially no de novo elastin fibers are made during adulthood. The most elastic the aorta will be is during childhood with subsequent increasing stiffness as the integrity of the elastin fibers degrade over time. These physiologic changes over time make studying arterial stiffness in children a unique and interesting challenge. In this chapter, we present the currently available literature on arterial stiffness in children, encompassing various disease states and measurement modalities.

Vascular effects of various disease states

Obesity

Pulse wave velocity

Obesity increases the risk for comorbidities even during childhood.[3] The effects of obesity also extend to aortic stiffness, with obese children having increased aortic stiffness compared to lean children.[4–6] A recent large meta-analysis of 15 studies found that 10 out of the 12 studies measuring central pulse wave velocity (PWV) and all of the studies that evaluated carotid and aortic β-stiffness demonstrated higher values in obese children compared to controls.[4] The studies measured central PWV in various ways including assessment of carotid-femoral PWV (cfPWV), Doppler ultrasound of the aorta, or local PWV measured at the carotid artery. Another meta-analysis also found that PWV was higher in obese children compared to nonobese children but found no significant differences in Augmentation Index (AIx).[5] A significant limitation is that PWV was also measured in various ways in the included studies encompassing assessment of cfPWV, carotid-radial PWV (crPWV), Doppler ultrasound of the aorta, upper and lower limb PWV measured by Doppler ultrasound and photoplethysmography, or local PWV measured at the carotid artery. Cardiac magnetic resonance imaging (MRI) may be an even more sensitive technique to evaluate obesity-related arterial stiffening in youth. Caterini et al. found that mean aortic PWV by cardiac MRI was higher in obese/overweight youth compared to controls despite no differences in cfPWV measurements by applanation tonometry.[7] Sletner et al. examined the relative contributions of fat mass and lean mass and found that increasing lean mass attenuated the effect of fat mass on cfPWV such that subjects with the lowest cfPWV had low fat mass and high lean mass. These findings suggest that lean mass may have a vascular protective effect.[8]

Pulse wave analysis

Available studies regarding the effect of obesity on arterial wave reflections in children are mixed. A large multiethnic

study found that AIx was significantly higher in obese youth compared to lean controls.[9] However, a study examining African-American youth found no differences in AIx between obese youth versus lean controls.[10] Another study found that AIx was significantly lower in obese children compared to lean controls but noted that the forward pulse wave amplitude (Pf) and backward pulse wave amplitude (Pb) of the aortic pressure wave were significantly higher in obese children.[11] Pierce et al. also found that Pf was significantly higher in obese children compared to lean controls but saw no difference in AIx or Pb between groups.[12] It is possible that the difference in conclusions regarding AIx, Pf, and Pb between the studies can be explained the various age ranges of the studies. Urbina et al. had the largest age range and included subjects up to 24 years old[9] whereas Castro et al. had the youngest subjects with a mean age of approximately 10 years.[11] The differences between studies may be related to the well-known changes in arterial wave reflections over time as subjects age and progress toward adulthood. Nevertheless, it appears that arterial wave reflections are altered in obese subjects, suggesting vascular changes in this condition.

Distensibility

Arterial distensibility appears to decrease in states of obesity. Overweight children have significantly decreased carotid distensibility compared to normal weight children.[13] To our knowledge, no studies of aortic distensibility and obesity in children currently exist. However, in a study of predominantly normal weight subjects, Mikola et al. found that systolic blood pressure (SBP) and low-density lipoprotein cholesterol (LDL-C) were independent determinants of aortic distensibility while body mass index (BMI), SBP, LDL-C, and homeostasis model of insulin resistance influenced carotid distensibility.[14] Brachial distensibility was also decreased in obese children when compared to lean controls.[9] Adding to these findings, adolescents and young adults classified as severely obese exhibited significantly lower brachial distensibility compared to subjects classified in the nonsevere obesity category.[15] Indeed, Whincup et al. found that as measures of adiposity increase, brachial distensibility decreases, and that the effects of adiposity on brachial distensibility emerge around 13−15 years of age.[16] The findings of these various studies are important because they suggest that increasing obesity leads to further impaired arterial distensibility and that these effects worsen with age even during the pediatric period.

Global measures

Global measures of arterial function such as pulse pressure (PP) and stroke volume (SV) are also affected by obesity. SV is increased in obese children[11,17] and adults[17] compared to normal weight subjects. If necessary, correction of SV using BSA can be performed in order to remove the expected effect of body size in measurements.[17] PP is also increased in obese children. Chandramohan et al. examined NHANES data from 1988 to 1994 and found that obesity was associated with increased PP with waist circumference, rather than BMI, being a significant predictor of PP.[18] Zachariah et al. reexamined NHANES data more recently including data up to 2008 and found that PP has increased over time paralleling the increase in childhood obesity.[19]

Dyslipidemia

Pulse wave velocity

Dyslipidemia influences PWV in children. Riggio et al. evaluated children with elevated LDL-C and found that they had significantly increased local PWV measured at the carotid artery compared to controls.[20] A more recent study of youth with familial hypercholesterolemia (FH) using cardiac MRI showed significantly increased ascending-to-descending aortic PWV.[21] However, other studies of subjects with familial hypercholesterolemia (FH) involving greater age ranges (adults and children) showed no differences in ascending-to-descending PWV as assessed by cardiac MRI[22] or in cfPWV as assessed by applanation tonometry.[23] Differences in outcomes of PWV between the studies may be explained partially by differences in method of measuring PWV, but the predominance of adult subjects in the latter two studies may suggest possible age-related changes in PWV. Triglyceride to HDL-C ratio (TG:HDL-C) also influences cfPWV with cfPWV increasing across TG/HDL-C tertiles.[24] Taken together, the above studies show the impact of dyslipidemia on large artery stiffness even in children.

Pulse wave analysis

The impact of dyslipidemia on arterial wave reflections in children has been less well studied. However, children with elevated LDL-C had significantly higher AIx compared to controls.[20] Additionally, triglyceride levels were found to be an independent determinant of AIx,[25] and children in the highest tertile of TG:HDL-C had significantly higher AIx compared to the lowest tertile.[24]

Distensibility

The effect of dyslipidemia on arterial distensibility is mixed. Multiple studies show that lipid levels are independent determinants of arterial distensibility.[14,16,24] LDL-C levels were noted to be associated with both aortic and carotid distensibility[14] while another study found that total cholesterol and LDL-C were inversely related to brachial distensibility in youth.[16] Brachial distensibility was also noted to decrease across increasing TG:HDL-C tertiles.[24]

These studies primarily looked at the general pediatric population. However, studies specifically examining youth with FH show a more nuanced picture. Lehmann et al. studied young FH patients (age <24 years) and found a significantly more compliant aorta when assessed by ultrasound compared to controls even after correction for age and sex.[26] LDL-C:HDL-C ratio and duration of disease were independent predictors of aortic compliance in this study. Evaluation of FH subjects by cardiac MRI support these findings of increased aortic compliance as Tran et al. found significantly increased aortic distensibility in adolescents with FH and Soljanlahti et al. found a trend toward significance in increased aortic compliance in their study including adults and children with FH. On the other hand, Aggoun et al. found decreased carotid compliance and distensibility in children with FH as assessed by ultrasound.[27] The varied findings between studies are important as they highlight decreased distensibility in the carotid and brachial arteries but *increased* distensibility in the aorta in the setting of hypercholesterolemia in children. By adulthood, this effect disappears with aortic distensibility in FH subjects being significantly higher than normolipidemic controls.[28]

Global measures

Study of global measures of arterial function in children with dyslipidemia are scarce. Adult data reveal significantly higher central PP in hypercholesterolemic subjects compared to normolipidemic controls.[29] While specific SV data for hypercholesterolemic children is unavailable, there was no difference in ventricular function in two cardiac MRI studies of FH subjects compared to norms.[21,22]

Hypertension

Pulse wave velocity

Hypertension is associated with increased PWV in children. Kulsum-Mecci et al. studied 159 children and found that cfPWV was increased in children with hypertension, obesity, or those with both hypertension and obesity compared to controls.[30] The differences seen in the hypertensive group were independent of obesity. Another study found that obese children with hypertension had significantly higher PWV estimated by oscillometry compared to lean controls and obese children without hypertension[31] suggesting that blood pressure has an effect on arterial stiffness beyond that explained by obesity alone. Incremental increases in blood pressure also appear to be associated with PWV elevation (estimated by oscillometry) with PWV rising for each unit of increase in SBP or DBP independent of BMI.[32] However, these studies are limited since oscillometry is not a reliable method to estimate

PWV. In another study, cfPWV (a well-validated measure of large artery stiffness) also exhibited increases across blood pressure categories in normotensive to prehypertensive to hypertensive youth.[33]

Pulse wave analysis

Measures of arterial wave reflections appear to be worse in hypertensive children than normotensive youth. When comparing AIx across blood pressure categories of normotensive, prehypertensive, and hypertensive youth, there was a significant increase in AIx between groups with increasing blood pressure.[33] Differences in AIx are also seen when comparing central blood pressures. Adolescents and young adults (16−24 years) with high central blood pressure (but normal peripheral blood pressure) had higher AIx compared to subjects with normal central blood pressures.[25]

Contrasting the above studies, Wójtowicz et al. found no significant difference in AIx between lean controls, obese subjects without hypertension, and obese subjects with hypertension.[31] No difference in AIx was also seen in a study by Garcia-Espinosa et al., but Pf and Pb were significantly higher in the high blood pressure group compared to normotensive controls.[34] A later follow-up study from the same group found that high blood pressure was associated with higher Pf, Pb, and AIx.[35]

Distensibility

Arterial distensibility is impaired in states of elevated blood pressure. Brachial distensibility was significantly lower in a graded fashion when compared between hypertensive to prehypertensive to normotensive youth.[33] Adolescents and young adults with higher central blood pressure but normal peripheral blood pressure also exhibited similar findings of lower brachial distensibility when compared to controls with normal central blood pressure.[25] Adding to these findings, both SBP[13] and diastolic blood pressure[16] were found to be independent determinants of arterial distensibility.

Global measures

Global measures of arterial function such as PP are increased in high blood pressure states in children. Children with high blood pressure were found to have significantly higher peripheral and central PP values compared to normotensive youth.[34,35] Furthermore, youth with isolated systolic high normal blood pressure and systolic hypertension had significantly higher peripheral and central blood pressure compared to normotensive controls.[36] Subjects classified as having high central blood pressure also exhibit higher peripheral and central PPs compared to normotensive subjects.[25]

Diabetes

Pulse wave velocity

Large artery vascular changes are present in children with diabetes mellitus. Differences in PWV are evident between type 1 diabetic (T1D) subjects and controls across measurement modalities such as tonometry[37,38] and oscillometry.[39] When compared to nondiabetic controls, T1D adolescents and young adults had significantly higher cfPWV even after adjusting for cardiovascular risk factors such as blood pressure, adiposity, lipid levels, and microalbuminuria.[37] Another study found significantly higher crPWV in T1D subjects compared to controls.[38] While cfPWV was higher in T1D subjects in this study, it did not reach statistical significance.

Large artery vascular changes are also present in subjects with Type 2 diabetes (T2D). Shah et al. evaluated the arterial stiffness of young adults with youth-onset T2D and found increased arterial stiffness in approximately half of the subjects.[40] PWV was significantly higher in the T2D group compared to lean controls. Treatment assignment for T2D between metformin, metformin + intensive lifestyle intervention, or metformin + rosiglitazone did not predict arterial stiffness.

Contrasting the findings in subjects with T1D and T2D, subjects with prediabetes do not appear to have significant large artery changes compared to controls. Shah et al. compared the vascular health of 102 obese youth with prediabetes to 139 obese youth without prediabetes. While the prediabetic obese youth had higher carotid intima-media thickness and lower brachial distensibility, there was no significant difference in PWV between the two groups.

Diabetes duration and insulin resistance influence arterial stiffness. crPWV, cfPWV, and lower extremity PWV in diabetic youth at five year follow-up were significantly higher than their baseline values.[41] Putarek et al. found that diabetic disease duration was the strongest independent determinant of arterial stiffness with BMI, blood pressure, and HbA1c also influencing local PWV measured at the carotid artery.[42] Diabetes duration was also a significant determinant of PWV in another large pediatric study of 1809 T1D youth[43] which also found that subjects with a HbA1c ≥9% had significantly higher crPWV, cfPWV, and lower extremity PWV compared to youth with lower HbA1c. Adding to these findings, Shah et al. found that lower insulin sensitivity was associated with a higher rate of change in cfPWV in their study of diabetic youth.[44]

Pulse wave analysis

Arterial wave reflections are altered in diabetic children. Multiple studies of T1D subjects found significantly higher AIx in T1D youth and young adults compared to nondiabetic controls.[37,39,43] Shah et al. found similar findings in T2D subjects.[40] These subjects diagnosed with T2D as children had vascular assessment obtained as young adults (mean age 20.8 ± 2.5 years). AIx was significantly higher in the T2D subjects when compared to obese nondiabetic controls. Prediabetic youth did not show significantly higher AIx compared to nondiabetic youth in contrast to the aforementioned studies in T1D and T2D subjects.[45] Similar findings are seen in studies of T1D[37,42] and T2D subjects[40] with significantly lower arterial distensibility and compliance compared to controls. MRI evaluation of T2D diabetic youth found a trend toward significance in decreased aortic distensibility compared to controls.[46] Insulin resistance appeared to contribute to distensibility as the children in the lowest two tertiles of insulin resistance had significantly lower descending aortic strain and distensibility.

Global measures

Studies of global measures of vascular health in diabetic children are very limited. Dost et al. studied peripheral PP data of 46,737 children with T1D in Germany and found that peripheral PP in T1D was significantly higher than the nondiabetic control population.[47] Notably, diabetes duration, insulin dose, BMI, age, and male sex were independent determinants of PP in this study. Suláková et al. also evaluated children with T1D but used ambulatory blood pressure monitor data to find that diabetic subjects with white coat hypertension or true hypertension had significantly higher PP compared to normotensive diabetic subjects.[48] These findings suggest that diabetic subjects have impaired arterial health especially in the setting of concurrent cardiovascular risk factor such as hypertension.

Other conditions

Individuals with congenital heart disease (CHD) demonstrate abnormal large artery characteristics. Multiple studies have shown that PWV is significantly higher in subjects with Tetralogy of Fallot (TOF) compared to controls both before[49] and after[49−51] repair. Similar findings are seen in children after heart transplantation[52] and transposition of the great arteries (TGAs).[51,53] Subjects with aortic coarctation (CoA) have significantly higher PWV after repair both during childhood[51] and as adults[54] compared to controls. Measures of pulse wave analysis (PWA) are also abnormal with significantly higher AIx in adult subjects with cyanotic CHD[55] and children with TOF after repair.[50] Adult subjects with repaired with CoA had higher central SBP and lower arterial compliance compared to controls,[54] and children with TGA had higher central SBP compared to controls[53] though no difference in central SBP was found in children with TOF after repair.[53] The findings described above are important because they demonstrate that individuals with CHD have impaired arterial health even after repair which

may put them at increased risk above and beyond their CHD. However, there is evidence that physical activity may lower PWV in subjects with CHD.[56] Therapies to address these large artery impairments in individuals with CHD deserve more exploration. For a detailed review regarding arterial stiffness and pulsatile hemodynamics in CHD, the reader is referred to Chapter 47.

Renal disease is also known to affect arterial health. Children with end-stage renal disease (ESRD) requiring dialysis have significantly higher PWV[57,58] and aortic AIx[58] compared to controls. These findings persist when comparing measurements before and after dialysis[58] and continue to be elevated even 6 months after renal transplantation[59] suggesting that the vascular changes that occur in ESRD are more structural rather than functional. Acute cases of renal disease can also cause elevations in PWV that normalize after resolution of renal disease as seen in children with poststreptococcal glomerulonephritis.[60] Contrasting the findings of the previous studies, children with mild to moderate chronic kidney disease do not appear to have significant differences compared to reference values[61] or controls.[62] However, PWV does not appear to be linked merely to glomerular filtration rate as children with nephrotic syndrome but normal renal function had significantly higher PWV compared to controls. Instead, differences in arterial parameters may be explained by blood pressure.[62,63] The changes in arterial stiffness seen in children with renal disease are important to note as adult data in ESRD subjects demonstrate that PWV is an independent predictor of all-cause and CV mortality.[64]

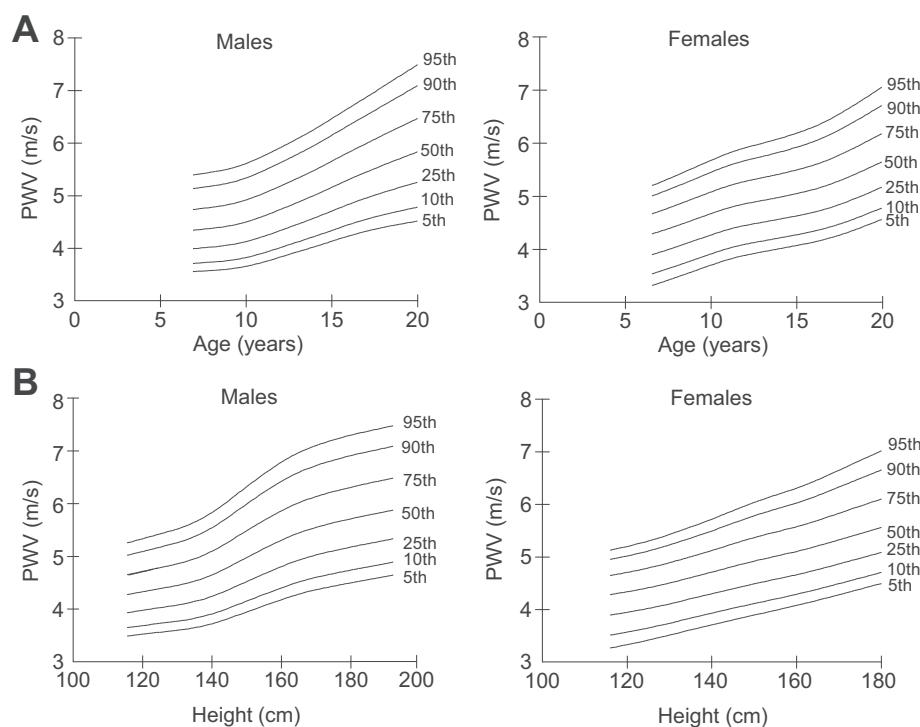
Arterial parameters are altered in numerous other disease states. AIx is increased in subjects with cystic fibrosis,[65] and PWV is higher in adults with childhood asthma compared to nonasthmatic subjects.[66] Pulmonary arterial hypertension influences aortic stiffness with significantly higher PWV and decreased distensibility in subjects versus controls.[67] Kawasaki disease subjects have significantly increased PWV compared to controls,[68–70] and PWV was lower and AIx higher in sickle cell disease patients.[71] Subjects with Turner syndrome and bicuspid aortic valve had decreased aortic distensibility but no difference in PWV compared to controls in one study[72] whereas another study found significantly higher PWV and lower distensibility versus controls.[73] The variety of these studies demonstrates how large artery parameters can provide information regarding possible cardiovascular risk across a range of disease conditions.

Methods and normal values in children

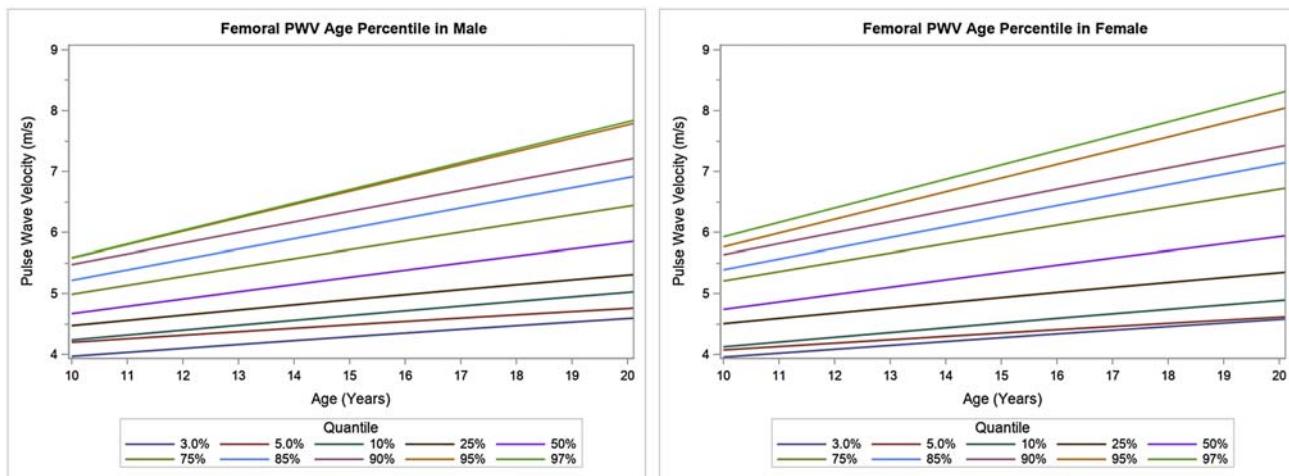
General principles regarding methods of measurement of arterial stiffness in vivo are discussed in Chapter 7. This section deals with aspects unique or particularly relevant to measurements in children.

Pulse wave velocity

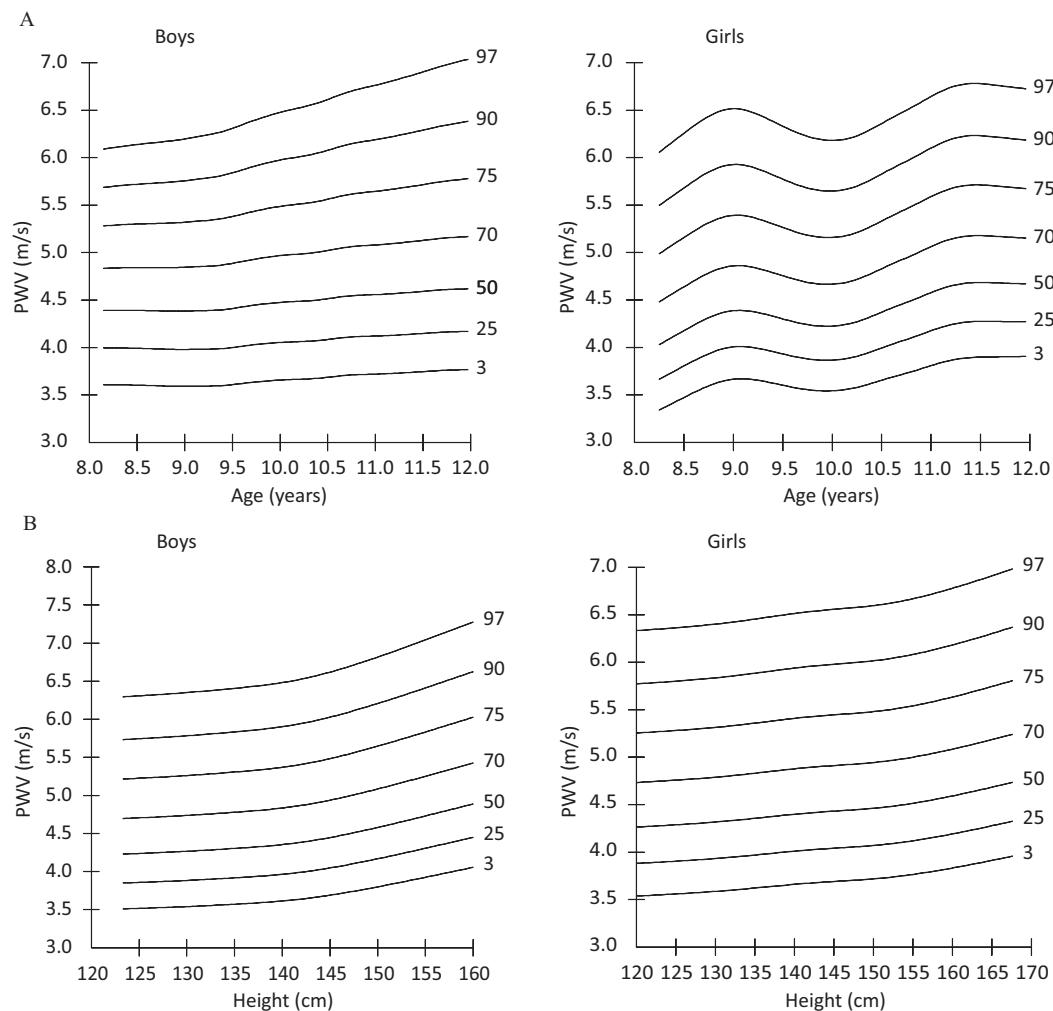
Similar to adults, measurement of PWV can be obtained through various methods. cfPWV can be assessed by placing tonometers or ultrasound probes over the carotid and femoral regions and using ECG tracings to determine the pulse time delay between measurement points with the R wave as a reference point. Another approach is to use a tonometer over the carotid and a blood pressure cuff over the thigh. To approximate the distance the pulse travels, the measured carotid-to-femoral distance can be multiplied by 80% or the sternal notch-to-carotid distance can be subtracted from the notch-to-femoral distance.[74] Brachial-ankle PWV can be assessed using blood pressure cuffs on both arms and ankles with the distance from the brachial artery to the ankle calculated by height and pulse time delay directly computed.[74] Aortic flow measurements and direct aortic measurements can also be performed using cardiac MRI to determine aortic PWV. Sinus arrhythmia in children can be a challenge when measuring the pulse wave using tonometry, and usage of the thigh cuff in assessing cfPWV may not be as accurate for children as for adults. Use of calipers in determining pulse wave distance in obese children helps to improve accuracy. The faster heart rate in children can also impact readings and depending on the age of the patient, sedation may be required for PWV measurement using MRI.

Large datasets of normative data are available in adults providing thresholds to define clinical abnormality. However, these large datasets are not available in children. The European Network for Noninvasive Investigation of Large Arteries published a large dataset of normal PWV values in 2010.[75] This study spanned eight European countries and included 11,092 subjects to determine reference values. Because the centers involved in the study obtained cfPWV through applanation tonometry using a variety of devices, measurements were then standardized prior to generating reference values. Ages were classified by decade for these values: <30, $30-39$, $40-49$, $50-59$, $60-69$, and ≥70 years. While the study included some pediatric patients (age range $15-97$ years), these patients were in the adolescent age range and the proportion of the subjects aged <18 years in the study was not specified. Nevertheless, this large study demonstrated that PWV increases progressively with age and that those in the <30 year age category had a mean (±2 SD) cfPWV of 6.2 (4.7–7.6) and median (10–90 percentile) cfPWV of 6.1 (5.3–7.1).


In adults, a PWV cut-off of 10 m/s was proposed, above which there is an increased risk for cardiovascular events.[76]

Unlike adult guidelines, there is no set threshold value for PWV in children as there are no longitudinal data sets tying the measurements in children to hard outcomes. There have been multiple attempts at defining age- and sex-specific reference values in children and adolescents.[77−84] However, these studies used varying techniques and devices in measuring PWV such that determining a standard set of values is difficult.


Applanation tonometry

Applanation tonometry is considered the gold standard noninvasive method of measuring PWV. The largest study in children thus far using this method was performed by Reusz et al. in 2010.[78] In this study, age- and sex-specific percentile curves were developed form measurements performed on 1008 children and adolescents measured by applanation tonometry using the PulsePen device (Fig. 43.1). cfPWV increased with age though values were similar in both boys and girls in the first two age quartiles. In the third and fourth age quartiles, cfPWV increased for boys more than for girls; however, this effect disappeared when subjects were matched for age and height. cfPWV also increased with increasing height. The population for the study consisted of Hungarian, Italian, and Algerian children so this should be considered when generalizing these values for other races/ethnicities. The Reusz et al.


values are similar to American data adapted from Urbina et al. (unpublished data) (Fig. 43.2).[6] The 50th percentile curve is similar in both studies, but the 5th and 95th percentile curves are slightly higher in the Urbina et al. data. A smaller study by Curcio et al. used applanation tonometry to obtained cfPWV in Uruguayan children.[85] Similarly to Reusz et al., the authors found that cfPWV was similar in boys and girls during the prepubescent age range but that PWV increased more in boys after that period. Mora-Urda et al. also used applanation tonometry to measure cfPWV and create percentile curves for healthy Spanish children aged 8−11 years based on 350 subjects (Fig. 43.3).[80] Compared to the percentiles curves by Reusz et al. and Urbina et al., the 50th percentile curves are similar, but the 90th and 97th percentile curves are slightly higher. Additionally, there is a mild decrease in cfPWV in girls around age 10 years in the Mora-Urda et al. study that is not evident in the Reusz et al. curves. When comparing cfPWV by height, the values from Mora-Urda et al. rise with increasing height similarly to the values from the Reusz et al. study. The 50th percentile curves for boys and girls are similar at the shorter heights but are less in the Mora-Urda et al. study with increasing height. Boys and girls at the 90th percentile of height in the Mora-Urda et al. study have higher cfPWV at shorter heights but then are similar at 160 cm to values from Reusz et al.

Oscillometric devices

Oscillometric devices for measuring PWV have also become popular due to relative ease of use compared to applanation tonometry.[81–84] Two German studies used the Vicorder device to determine cfPWV in a pediatric cohort using a carotid and femoral cuff[82] and a combined group of adults and children using a carotid plethysmograph and a femoral cuff.[86] Elmenhorst et al. studied German children with the Mobil-O-Graph, which use a single brachial cuff, to measure PWV in 1445 subjects (Fig. 43.4). The authors found that while PWV increased with age and height, there were different trajectories between boys and girls that were potentially explained by different growth patterns. Two other large studies used the Arteriograph device to determine normal values with Hidvégi et al. obtaining PWV measurements in 3374 Hungarian children (Fig. 43.5)[81] and Diaz et al. measuring PWV in 1000 Argentinean children

FIGURE 43.4   Pulse wave velocity percentile curves by brachial oscillometry using Mobil-O-Graph device according to age, displayed separately for girls and boys. *Reprinted from Elmenhorst J, Hulpke-Wette M, Barta C, Dalla Pozza R, Springer S, Oberhoffer R. (Fig. 43.6).[84] The 50th percentile values from Diaz et al. and Hidvégi et al. are similar, but the 90th and 10th percentile lines are slightly higher in the Hidvégi et al. study. The percentile curves obtained by Elmenhorst et al. are lower overall than the other two studies which may be a function of using the Mobil-O-Graph device instead of the Arteriograph. Despite the availability of normative data from these methods, it should be noted that single site oscillometry is not a reliable method to estimate aortic PWV.

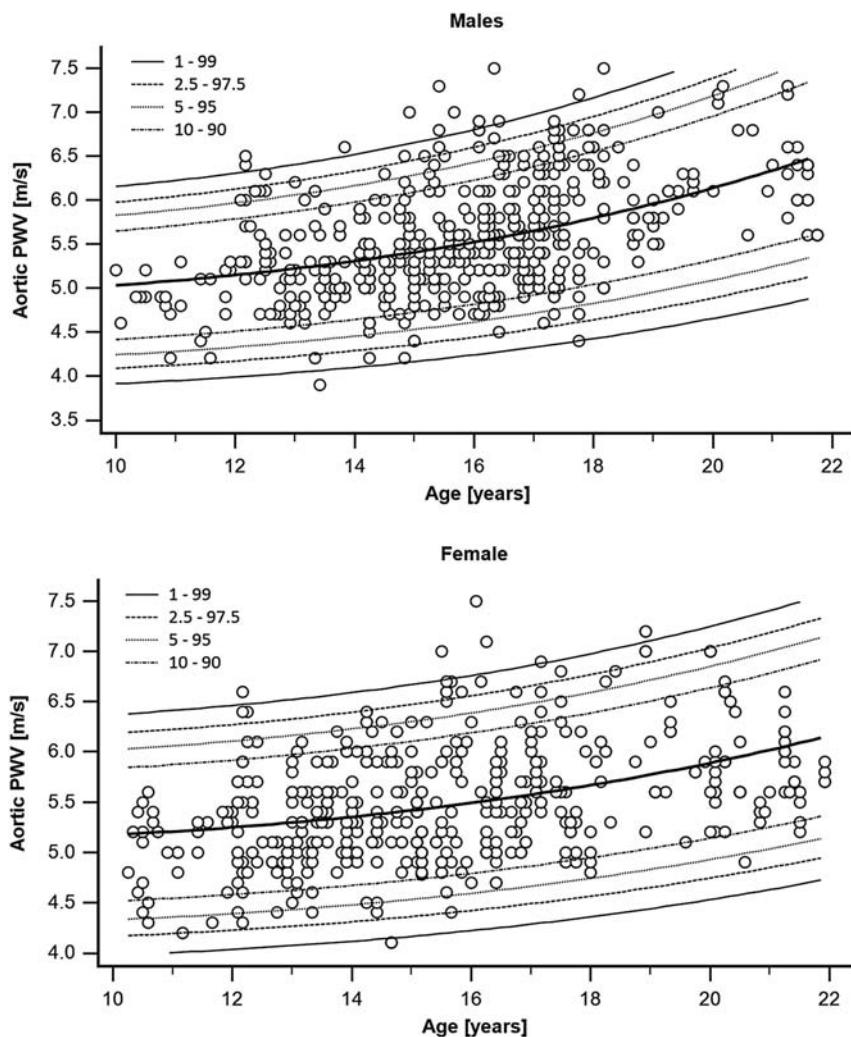
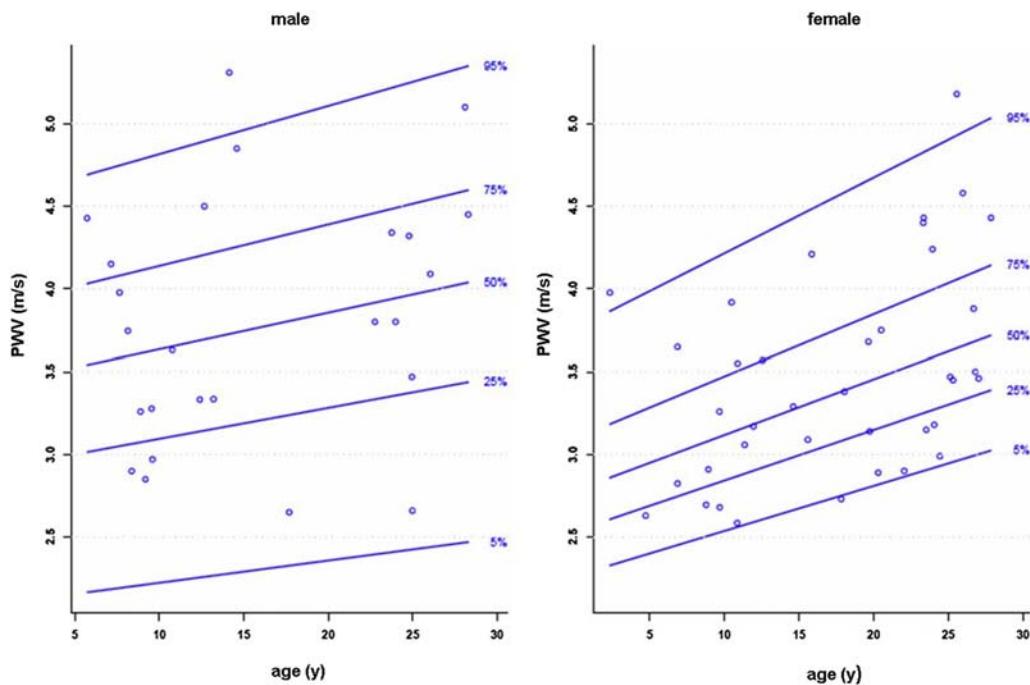
Cardiac magnetic resonance imaging

Cardiac MRI measures of PWV in children are limited. Voges et al. used MRI flow data to develop normative curves for aortic PWV in children and young adults

(Fig. 43.7).[77] In addition to using a different modality, the PWV measurements obtained in this study were of the aortic arch only (ascending-to-descending aorta) which may contribute to the overall lower measurements compared to PWV values by applanation tonometry or oscillometry. Additionally, the study was relatively small (n = 71) compared to studies measuring PWV by applanation tonometry or oscillometry.

Sex-specific differences in pulse wave velocity


In prepubescent children, there appears to be no difference in PWV between males and females. However, after puberty, PWV is higher in males. These findings have been replicated in multiple studies encompassing PWV measurements by applanation tonometry[78] and oscillometry[82−84] though one large oscillometric study found no significant difference in PWV values between sexes.[81] The higher PWV values in males after puberty can be explained by the overall greater height and weight at those ages compared to females.[78,83,84] Indeed when subjects were matched by age and height[78] or by age, anthropometric values, and hemodynamic values,[84] no sex-specific differences were evident.

Race-specific differences in pulse wave velocity


cfPWV in African-American men has been noted to be higher compared to cfPWV measurements in white men.[87] These findings are mirrored in children as well with Lefferts et al. comparing cfPWV by applanation tonometry in 54 African-American children compared to 54 white children.[88] While the African-American children were taller and heavier than the white children, cfPWV was higher in the African-American children even after multivariable adjustment that included height. A large study of 791 children by Zaniqueli et al. studied Brazilian children and adolescents comparing the cfPWV by applanation tonometry in Blacks (n = 211) versus Non-Blacks (n = 560).[89] There was no difference in cfPWV between groups during the prepubescent time period, but cfPWV was significantly higher in blacks during the pubescent and postpubescent phases after adjustment for sex, age, height, BMI, SBP, and heart rate.

Conclusions about pulse wave velocity normal values

Measurement of arterial stiffness in youth is now established as a robust method for evaluating CV risk, but there is still a lack of normative data across age, population, and device. More research into defining this normative data is needed before arterial stiffness can be incorporated into care for pediatric patients.

Normal values of aortic dimensions, distensibility, and pulse wave velocity in children and young adults: a cross-sectional study.* **J Cardiovasc Magn Reson**. *2012; 14:77. https://doi.org/10.1186/1532-429X-14-77.*

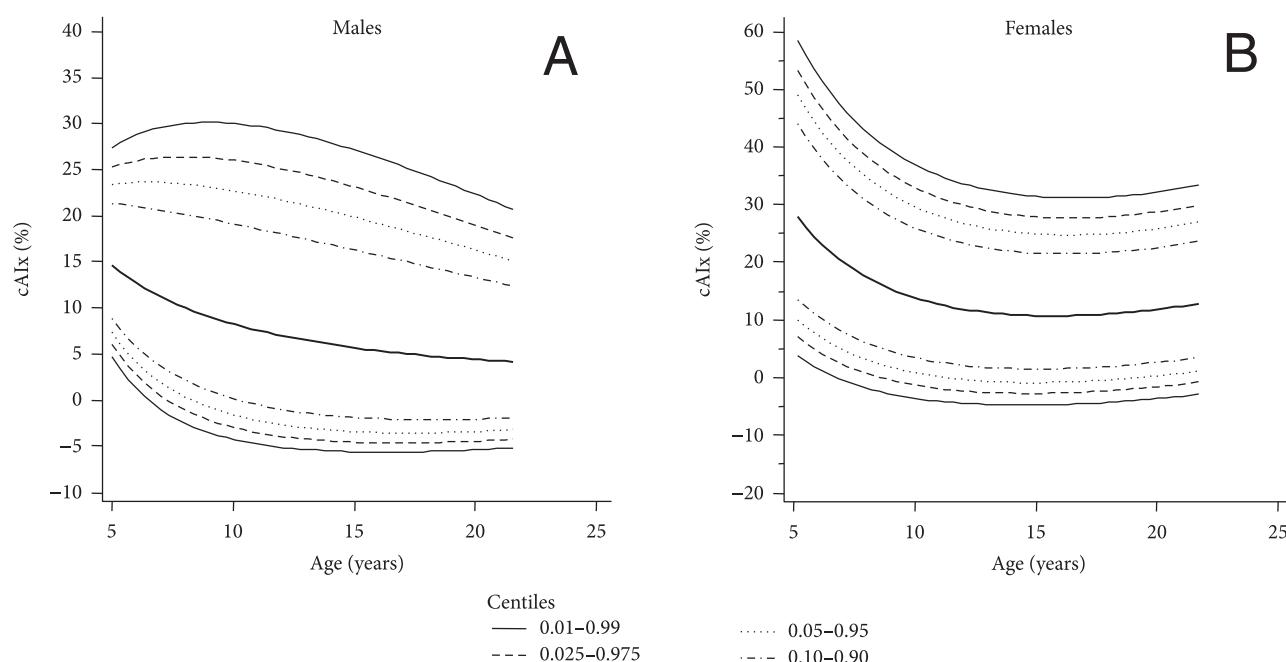
Pulse wave analysis

PWA is typically obtained in children, similarly to adults, by using oscillometric or tonometric devices to determine the central arterial PP waveform. However, invasive measurement of the central waveform by cardiac catheterization is also performed. Using the central PP waveform, augmentation index and other parameters such as augmentation pressure (AP), component waveforms (Pf, Pb), and central blood pressure can be determined as measures of arterial health. The faster heart rate in children and heart rate variability with respiration (sinus arrhythmia) can make measurements challenging in children. Additionally, it may be more technically challenging to take radial artery measurements using a tonometer due to the smaller size of the artery. Appropriate cuff sizing for younger children is another potential challenge as the devices are typically designed for adults.

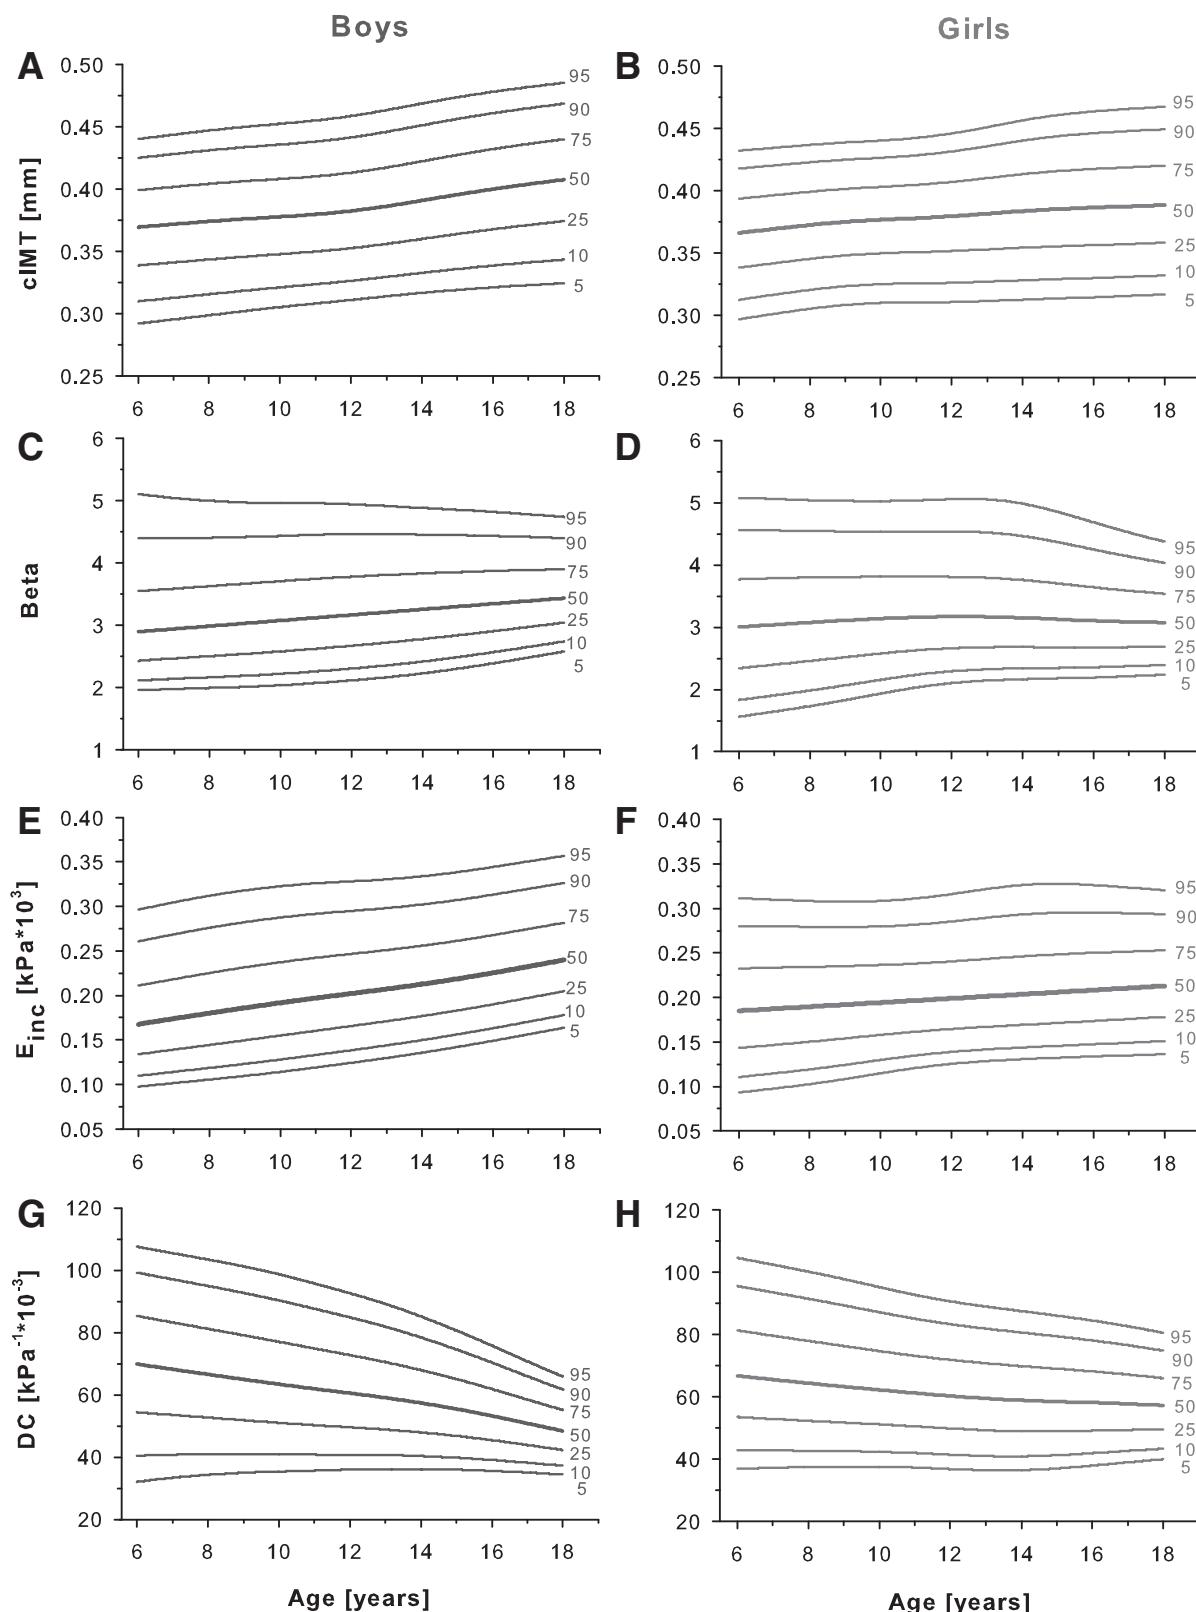
More robust literature exists in children for reference values of augmentation index whereas there are no established reference values for Pf or Pb. Murakami et al. assessed AIx by direct cardiac catheterization measurements in Japanese subjects and found that AIx was highest in infancy and early childhood and that it steadily decreased until approximately age 15 years when values then plateaued and then increased afterward in early adulthood.[90] These findings were confirmed using oscillometry by Hidvegi et al. in a large study of 4619 Hungarian subjects (age range 3−18 years) with AIx decreasing from early childhood until subjects reached puberty.[91] Return time of the systolic wave reflection was also found to be shorter in younger children due to shorter aortic length. This finding explains the greater AIx values in younger children as the sooner return of the systolic wave reflection results in greater wave augmentation. Reference curves for AIx from Hidvegi et al. are shown in Fig. 43.8.

Influence of body height on aortic systolic pressure augmentation and wave reflection in childhood.* **J Hum Hypertens.** *2015; 9:495−501.* https://doi.org/10.1038/jhh.2014.118.

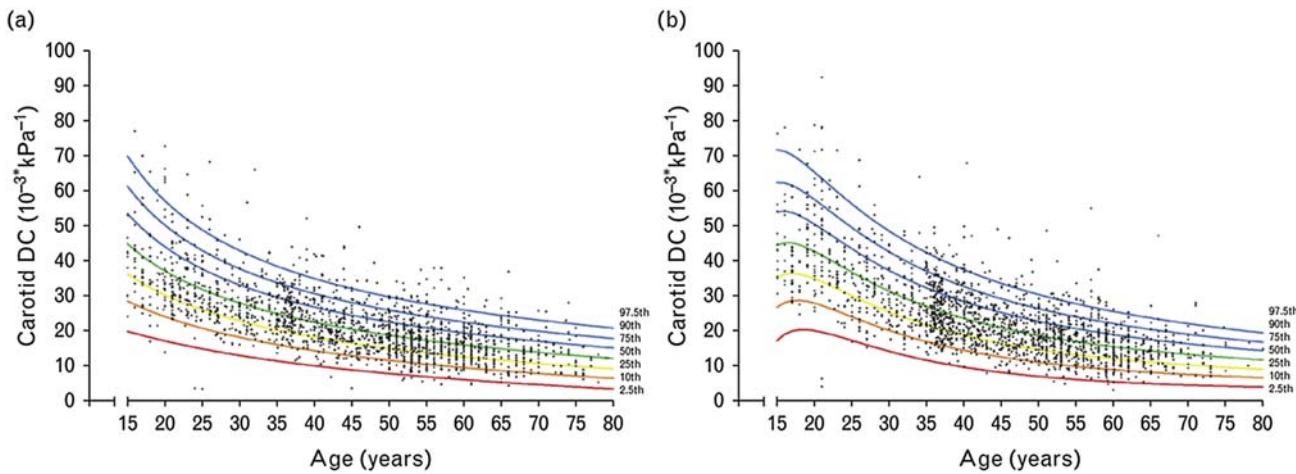
Diaz et al. also determined normal AIx values in children but used applanation tonometry in a large study of 1038 Argentinean subjects (age range 5−22 years).[92] Their findings mirrored those of Murakami et al. and Hidvégi et al. with reference curves shown in Fig. 43.9. AIx values for girls were higher than in boys for both studies. It is important to note the different racial/ethnic backgrounds of the subjects in the previously mentioned studies when attempting to generalize findings to other races/ethnicities.

Distensibility


Arterial distensibility can be assessed through multiple methods ranging from oscillometry, ultrasound, and MRI. Challenges in children with these methods are similar to those seen in determining PWV and PWA and include difficulty with correct cuff sizing due to younger/smaller subjects, children having faster heart rates and potential sinus arrhythmia, technical challenges of children having smaller arteries and potentially having more compressible arteries, and the possible need for sedation if using MRI.

Reference data for arterial distensibility in children exist for ultrasound and MRI modalities. Doyon et al. created sex-specific reference charts for carotid distensibility coefficient determined by ultrasound that are normalized to age using data from 1051 children (age range 6−18 years). The general trend appears to be that carotid distensibility decreases with age in both boys and girls (Fig. 43.10G and H). The authors noted that age- and sex-specific differences


started to appear at age 15 years and with carotid distensibility for boys decreasing more steeply than girls after that age.

Mikola et al. assessed carotid and abdominal aortic distensibility longitudinally in children by ultrasound and found that distensibility was significantly lower in boys compared to girls in both regions and that distensibility significantly decreased with age. Measurements were taken at 11, 13, 15, 17, and 19 years of age.[93] However, when adjusted for PP, the differences between sexes disappeared suggesting that PP may be driving the differences rather than arterial diameter.


Engelen et al. compiled carotid distensibility coefficient values assessed by echo-tracking across 24 studies to create age- and sex-specific reference curves from 3601 healthy individuals.[94] While the majority of the data were of adult subjects, data from late adolescents were included and can be seen in Fig. 43.11. The same group also compiled data from seven studies with femoral artery distensibility values to create age-specific reference curves from 1489 healthy individuals.[95] Again, the majority of the data were from adults but data from late adolescents were also included. Contrasting the findings of the carotid distensibility coefficient data, femoral artery distensibility appears to be stable over time without major changes until the 6th decade of life. When comparing the carotid distensibility coefficient values between the Doyon et al. study and the Engelen et al. data, the carotid distensibility coefficient values were higher overall for both males and females in the Doyon

et al. study. These differences may be explained by the use of ultrasound to measure distensibility in Doyon et al. group versus the echo-tracking technique used in the Engelen et al. study.

Cardiac MRI data are limited regarding reference values of aortic distensibility in children. However, Voges et al.

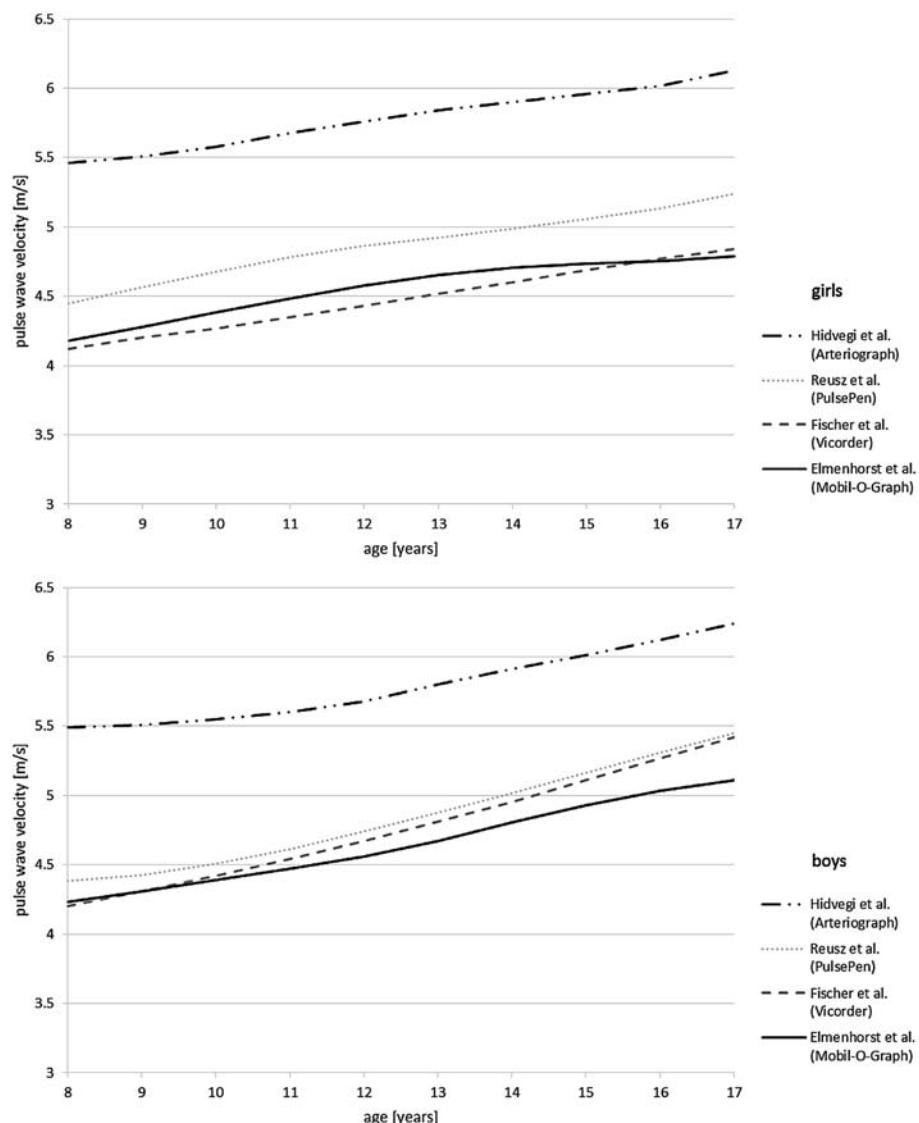
created gender-specific reference percentiles for aortic distensibility in multiple regions of the aorta as seen in Fig. 43.12.[96] While distensibility decreases with increasing age similarly to the findings by ultrasound, the ascending aortic distensibility in males appears to decrease more drastically with age compared to that seen in females, and


FIGURE 43.12   Gender-specific reference percentiles for aortic distensibility at four locations: (A) ascending aorta, (B) aortic arch, (C) aortic isthmus, and (D) descending aorta above the diaphragm. *Reprinted by permission from Springer Nature. the aortic isthmus distensibility undergoes a steeper decline in both males and females compared to the aortic arch and descending aortic regions.

Future directions

As more advanced and direct methods of assessing arterial health have been developed such as PWV, PWA, and arterial distensibility, global measures of arterial health such as PP are used less often in favor of the other modalities mentioned above. As demonstrated in this text, while there are some pediatric data on reference values for measures of arterial health, they are limited in comparison to adult data. More normative data are needed across race,

sex, and ethnicity in children to provide better understanding of normal differences. Calibration of measurements between devices for children is also an area of potential focus as this will allow easier conversion/comparison of readings for patients. Some of the considerable differences in PWV by device can be seen in Fig. 43.13. Additionally, longitudinal data of arterial measures in children are needed to show what normal change in arterial stiffness is in children. The need for accurate assessment of arterial health in children remains with the hope that increased and better normative data will allow use of these measures to more accurately risk stratify patients with CV risk factors and be a tool toward helping children live longer, healthier lives.

FIGURE 43.13   Comparison between the 50th percentiles for pulse wave velocity (PWV) obtained with different devices (Arteriograph [79], PulsePen [76], Vicorder [80], and Mobil-O-Graph [81]) displayed separately for girls and boys. *Reprinted from Elmenhorst J, Hulpke-Wette M, Barta C, Dalla Pozza R, Springer S, Oberhoffer R. Aortopathies and arteriopathies

Reed E. Pyeritz

Perelman School of Medicine, University of Pennsylvania Health System, Philadelphia, PA, United States

Introduction

Disorders primarily affecting large and medium caliber arteries, the aorta, or both can arise in people of all ages, from fetuses to the elderly. Except in severely affected individuals, the age of onset is typically overestimated due to a failure to diagnose earlier. Some of these disorders occur or are influenced because of strong environmental and other conditions, such as smoking, hypertension, and lipidopathies. While genetic factors usually play a role in the modulation of blood pressure and cholesterol levels, the focus of this chapter is on genetic conditions that primarily cause arteriopathies and aortopathies (Box 44.1).

BOX 44.1 Human genetic complement

Nuclear DNA

6.4 billion nucleotides arranged on 23 pairs of chromosomes. There are 22 pairs of autosomes (numbered 1−22) and two sex chromosomes, X and Y. Females have two X chromosomes and males have an X and a Y.

The genome consists of all of this nuclear DNA. All of these sequences are arrayed when whole genome sequencing is performed.

The exome consists of the DNA that encodes approximately 22,000 genes, the exons (coding sequences) and introns (sequences between each exon). The exons constitute 1.5%−2% of the nuclear DNA. When exome sequencing is performed, only these sequences are examined.

Mitochondrial DNA

Each cell has multiple mitochondria in its cytoplasm. Each mitochondrion has multiple copies of a small, circular chromosome composed of 16,569 nucleotide pairs that encode 37 genes. Mitochondria, utilizing its own genes and some encoded by the nuclear chromosomes, are essential for oxidative metabolism.

Three decades or so ago, anyone with a dilated ascending aorta, especially if there was a positive family history, was labeled as "Marfan syndrome," which led to an inflated estimate of the prevalence of this condition and inaccurate expectations as to the prognosis of each patient. Since then, not only is there improved understanding of true Marfan syndrome, but that many dozens of genes are, individually, associated with arteriopathies and aortopathies. Fortunately, what we learned about the medical and surgical management of aortic disease in Marfan syndrome generally applies to aortopathies due to most genes.

What is meant by the term "genetic" is a trait primarily caused by a pathogenic variant (previously termed a "mutation") in one gene. The term "hereditary" refers to a condition or predisposition that is due to a genetic variant that is, or can be, evident in multiple members of the same family. While all hereditary disorders are genetic, the reverse is not necessarily the case. Disorders may not be identified as hereditary because of small families or minimal clinical information of previous generations. Autosomal recessive and X-linked conditions may appear as isolated cases in a family because people with only one of two copies of the aberrant gene show no clinical effects. In the case of autosomal dominant conditions not recognized as hereditary, the affected person will have unaffected parents (or more distant relatives) because the pathogenic variant arose for the first time in the patient, typically in the oocyte or spermatocyte that led to his or her fertilization. For example, at least one-quarter of patients with Marfan syndrome have parents neither of whom has the pathogenic variant in *FBN1* present in the patient. Of course, nonpaternity can confuse this interpretation (Box 44.2).

Several other terms deserve note. "Phenotype" refers to the outward manifestations of a genetic variant while "genotype" is the specific variant (a change in a single or multiple nucleotides) that causes the condition. "Genetic heterogeneity" refers to multiple pathogenic variants that cause the same condition. These multiple variants can be

Textbook of Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease. https://doi.org/10.1016/B978-0-323-91391-1.00044-3
707

within the same gene (intragenic) or in more than one gene (intergenic). For example, only variants in *FBN1* cause Marfan syndrome, but there are more than a 1000 of them. On the other hand, multiple variants in at least two genes (*TGFBR1* and *TGFBR2*) cause Loeys−Dietz syndrome, which reflects both intra- and intergenic heterogeneity. "Variability" defines differences in phenotype among people with the same genotype, often relatives. Variability can be due to multiple causes, such as differences in age of expression of the phenotype, influences of one or more other genes, even environmental factors. "Nonpenetrance" is one end of the spectrum of variability, in which a person with a clearly pathogenic variant does not show any manifestations. All of these concepts are highly relevant to both the investigation and management of arteriopathies and aortopathies.

Last, "natural history" and "clinical history" are often used interchangeably but should be distinguished. Natural history defines the evolution of a phenotype if no therapy, effective or not, is employed for a specific trait. On the other hand, clinical history refers to how the phenotype is altered by therapy. For example, the clinical history of ascending aortic disease in Marfan syndrome has been remarkably altered by medical and surgical therapy. However, the improved life span has resulted in the emergence of a host of features (such as sleep apnea, cardiomyopathy, and central adiposity) that expand the scope of natural history.[1]

Approaches to defining the genetic contributions to arterial and aortic disease

Two general approaches are employed to define how variation in one or more genes determine a particular disease. These are defined as "phenotype first" and "genotype first." In the former, a specific disease, well characterized and readily identifiable, is the basis for searching for pathogenic variation in a specific gene or genes that are causative. One of the first such successes was identification in 1991 of variants in the gene for fibrillin-1, *FBN1*, as causative of the Marfan syndrome.[2] Since then, dozens of successes have been achieved, often by first understanding the pathology and protein defects of the arterial lesion and then systematically examining the genes that encode the relevant proteins. Another example is the vascular form of Ehlers−Danlos syndrome for which mutations in *COL3A1* were identified based on the known importance of type 3 collagen in the arterial wall. As more genes predisposing to thoracic aortic disease are discovered, then they can be assessed for pathogenic variants in patients.[3]

The more recent but expanding approach is defined as "genotype first." Here one, several, many or all genes are examined for pathogenic variants, which are then associated with a specific disorder. For example, we examined patients in the Penn Medicine Biobank for one of a dozen pathogenic variants in *FBN1* and found that ** subjects had such a variant.[4] Only two of these subjects had been diagnosed with Marfan syndrome, but many of the others had thoracic aortic disease. Variations in all genes can be determined by sequencing the 1.5%−2% of the genome known to encode proteins, termed whole exome sequencing. Increasingly, because of markedly improved and rapid techniques, the entire 6.4 billion nucleotides that comprise our 23 pairs of chromosomes are being sequenced, whole genome sequencing. Then, many programs[5] that screen any variation from "normal" are used to assess whether it is likely to be harmful. Likely pathogenic variants are then screened for their association with a

phenotype of interest. Because of statistical applications to large databases, such as biobanks, potential causes of specific diseases can be established. For example, all pathogenetic variants in large numbers of subjects in a biobank can be identified and the phenotypes of people with each variant can be investigated to understand if they have a disease for which the cause is undetermined.[5,6] The genetic cause of a specific Mendelian condition can be searched. Alternatively, a common phenotype, such as type A aortic dissection can be examined based on appropriate ICD-10 codes in a biobank. The results can include specific genetic variants predisposing to type A dissection either in specific Mendelian conditions or in subjects without a known underlying condition.

Pathogenic mechanisms

Four major classes of proteins are abnormal in arteriopathies and aortopathies: extracellular, transmembrane, cytoplasmic, and nuclear. These result in conditions that affect many organs or mainly one. These disorders are typically classified as connective tissue disorders, smooth muscle disorders, and signaling disorders. Some conditions that have been classified as connective tissue disorders, the Marfan syndrome termed that for half a century, are now recognized as resulting primarily from defects in signaling. As a general example, vascular smooth muscle function is the principal determinant of arterial contraction. Mutations in a number of genes, for example, *FBN1* and *ACTA2*, disrupt the mechanosensing of the elastin-contractile unit. This can result in numerous downstream detrimental effects that lead to aortic aneurysm and dissection.[7] As an example, some variants increase aortic stiffness, which increases the rate of sinuses of Valsalva dilatation and poor outcomes in Marfan syndrome.[8]

Arteriopathies with limited aortic involvement

Arterial aneurysms and dissections appear in young people in the absence of any obvious syndrome. Occasionally, relatives have the same disorders, so a strong genetic component to cause is likely. For example, people, usually women, can present with bilateral carotid or vertebral artery dissections. In some cases, there is a family history of similarly affected relatives. To date, screening for pathogenic variants in genes known to cause aortic conditions is likely uninformative. Such conditions are ideal for a genotype-first approach.

A few Mendelian conditions are associated with arteriopathy (Table 44.1). Most are rare, with the exception of hereditary hemorrhagic telangiectasia (HHT) which occurs in about 1 in 5000.

The diagnosis of HHT is established by documenting three or the following four signs: recurrent epistaxis, mucocutaneous telangiectases, pulmonary arteriovenous malformations, and a family history of HHT.[9] Finding a pathogenic variant in *ENG*, *ACVRL1*, or *SMAD4* confirms the diagnosis.[10] In HHT, the telangiectases are connections between arterials and venules bypassing capillaries. In addition, however, patients are at risk for arterial aneurysms and arteriovenous malformations in the nervous system (brain and spinal cord) and arteriopathy in the liver. Pulmonary AVMs are the most common serious problem, but when diagnosed can be treated by embolization of the feeding artery.[11]

Vascular Ehlers–Danlos syndrome	130050

[a]Number of disorder in On-line Mendelian in Man (omim.org; accessed October 17, 2020).

Vascular Ehlers—Danlos syndrome is a serious but fortunately uncommon autosomal dominant condition due to pathogenic variants in *COL3A1*, the gene encoding type 3 collagen, an important component of skin and the walls of muscular arteries, the intestine, and the uterus.[12,13] Any of the latter can spontaneously rupture, with pregnancy being the only predisposing condition. Other than keeping blood pressure as low as reasonable, there is no effective therapy, although beta-adrenergic blockade and inhibiting oxytocin or androgen effects are still being investigated.[14] Occasionally the aorta minimally dilates. Dissection of the aorta or peripheral arteries is not associated with histopathology showing medial degeneration.

Disorders that primarily involve the aorta with arterial involvement

The most common and well-known of these conditions in the Marfan syndrome. Diagnosis is based on findings in multiple organ systems and pathogenic variants in *FBN1*, the gene encoding the connective tissue protein fibrillin-1.[2,15] Patients are typically disproportionately tall of stature, develop deformity of the anterior chest and vertebral column, are prone to dislocation of the ocular lens, and have enlargement of the lumbosacral spinal canal (dural ectasia). At least 50% have mitral valve prolapse, and mitral regurgitation often develops. Aortic dilatation begins in the sinuses of Valsalva, is typically gradually progressive and rarely progresses above the proximal ascending aorta. With increasing diameter, the valve attachments are stretched with the development of aortic regurgitation. Most important, as the diameter increases so does the risk of a type A dissection. This can be prevented with a prophylactic valve-sparing ascending aortic replacement. The appropriate diameter for recommending repair varies, with a dimension of 45 mm if the family history includes relatives with dissection at early ages, a rapidly increasing dimeter (>5 mm in a year), or a diameter >50 mm. As soon as the diagnosis of Marfan syndrome is made, oral beta-adrenergic blockade or angiotensin receptor blockade should be stared. Patients should be counseled to avoid vigorous exertion (especially isometric) and contact sports. The mitral valve should be assessed because of the high prevalence of prolapse and regurgitation. About 10% of acute dissections are type B and is the most common form in peripartum women. Today, acute dissection remains the most common cause of premature death.

The recommendations of beta-adrenergic blockade, restricting exertion and contact sports, and prophylactic ascending aortic repair were developed in patients diagnosed with Marfan syndrome in the 1970s and 1980s. Angiotensin receptor blockade is equally effective as beta-adrenergic blockade.[16] Subsequently, more than two dozen

genetic predispositions to aortic disease like that in Marfan syndrome have been defined (Table 44.2), and more are sure to follow. However, the approaches to reducing aortic dilatation and the risk of dissection delineated from Marfan syndrome are completely appropriate today.

Involvement of other arteries in Marfan syndrome most often occurs as a result of aortic dissection. However, primary dilatation or frank aneurysms of aortic branches can occur, so it is wise to image the vascular system from the neck to the pelvis in an adult at least once.

Some of the other aortopathies listed in Table 44.2 are syndromic (the various Loeys—Dietz syndromes and some mutations in *ACAT2*), while others involve mainly the aorta. All are autosomal dominant. While management of the aortic disease is the same as in Marfan syndrome, based on the specific gene and pathogenic variant surveillance and treatment need to be more aggressive. Variants at one specific codon in *ACTA2*, normally encoding an arginine at position 179, lead to more rapidly progressive aortic disease and involvement in other arteries.[17] In most of these disorders, peripheral arteries may be involved as in Marfan syndrome. In most, including the Marfan syndrome, arteries may be unusually tortuous.[18] Additionally, shining a bright light through the distal phalanges of the hand (transillumination) often reveals both vascular tortuosity and dilatations. These tend to correlate with the severity of the arteriopathy and are invariably asymptomatic.[19]

The underlying causes involve components of the extracellular matrix or vascular smooth muscle and signaling pathways such as for TGF-β. Knowing the genetic variant underlying aortic disease in a particular patient enables predicting the course of their condition and the diagnosis of disease, often undetected, in relatives. Additionally, understanding how a signaling pathway is involved may lead to the development of specific therapies, such as angiotensin receptor blockade.

Disorders that primarily affect the aorta

The most common cause of dilatation of the ascending aorta is its association with bicuspid aortic valve (BAV). Postductal coarctation may also occur. The aortic valve,

ascending aorta, and periductal aorta all derive from the same embryologic origin. Rarely do the sinuses of Valsalva, which are distinct embryologically, dilate. The severity of ascending aortic dilatation may not correlate with the severity of the aortic valve pathology.[20] In most instances, the dilatation of the aorta is not as rapidly progressive or prone to dissection as in the Marfan syndrome.[21] Because transthoracic (i.e., standard) echocardiography often does not visualize the midascending aorta, patients with BAV should have a CT or MR of the thorax to establish if dilatation is present, and if so, to be followed by an adequate imaging modality. The histopathology of the aortic wall typically shows medial degeneration, indistinguishable from MFS.

About one-quarter of patients with BAV give a family history of a relative with BAV or at least aortic valve disease. Thus, a strong genetic predisposition must be contributory. Despite this evidence, there has been surprisingly little success in defining specific genes with pathogenic variants that cause BAV.

Concern about the possible diagnosis of MFS is a common reason for referral to medical genetics clinics. Many such probands have one or more features of MFS but fail to meet strict criteria. The acronym MASS represents common (but not essential) involvement of the mitral valve, the aorta, the skin, and the skeleton.[22]

MVP as an echocardiographic entity occurs in perhaps 2.5% of the general population, is more common among women, and is more common in adolescence and young adulthood than in childhood or old age. MVP is an autosomal dominant trait in many families. Based on standard transthoracic echocardiographic evaluation, two classes of MVP can be defined: those with abnormal leaflet motion but normal leaflet morphology; and those with both prolapse and thickening of the leaflets, which correlates with the degree of myxomatous degeneration. The latter is sometimes termed primary MVP; is typical of the MVP in most heritable disorders of connective tissue, including MASS phenotype; and is more likely to be associated with clinical complications. In some people, MVP is associated with deformity of the chest wall or the vertebral column, or both. These patients also often have an aortic root dimension near or slightly above the upper limit of normal for age and body surface area (but no dissection or apparent progressive enlargement), myopia (but by definition no ectopia lentis), joint hypermobility (in addition to pectus excavatum and scoliosis), pneumothorax, and striae atrophicae. Some probands have a family history of similarly affected relatives. Thus, the MASS phenotype is not Marfan syndrome, although in some instances it certainly resembles what one would expect a mild variant of MFS to be. The MASS phenotype seemingly has a good prognosis, with the worst manifestation being a predisposition to progressive MVP and mitral regurgitation. Whether and how "familial

TABLE 44.3 Disorders affecting primarily the aorta.

Disorder	OMIM entry[a]
Bicuspid aortic valve	109730; 190198; 314400; 614823; 618496
MASS phenotype	157700
Tuberous sclerosis 2	613254
Turner syndrome and X-linked Alport syndrome	301050

[a]Number of disorder in On-line Mendelian in Man (omim.org; accessed 3 Dec 2021).

MVP" and MASS phenotype should be distinguished have not been clarified (Table 44.3).

The MASS phenotype is likely heterogeneous in etiology, hence the term "phenotype," rather than syndrome. A very few patients with a mutation in *FBN1* qualify for a MASS phenotype diagnosis. One example is a patient with a mutation that results in little abnormal fibrillin monomer and is close to a null allele. In general, mutations near the 3′-terminus of *FBN1*, little expression of the mutant allele, and in vitro deposition of fibrillin in the ECM greater than 70% of normal are all associated with a milder MFS-like phenotype. However, other patients with missense mutations near the 3′ end of *FBN1* have had a severe, classic MFS phenotype. Meanwhile, other pedigrees that could be characterized as MASS are not linked to *FBN1*. Moreover, three loci for familial MVP have been mapped, Xq28, 13q31.3−q32.1, and 16p11.2−p12.1.

Precision medicine

Many factors go into determining who receives what therapy when. From a purely phenotypic perspective, issues such as age, gender, effectiveness of pharmacologic therapies, even institutional expertise can be major factors. For example, in the absence of useful genetic markers for BAV, these factors are major determinants of choosing the vessel diameter at which to recommend replacement of the ascending aorta.[23]

Understanding the genetic cause, the pathogenic mechanism, or both can lead to the development of a targeted therapy for a specific disease. For example, beta-adrenergic blockade was used for decades to reduce dP/dt in Marfan syndrome, learning that a defect in TGFβ signally is the pathogenic mechanism led to angiotensin-receptor blockade as an alternative therapy.[16] As another example, the arteriopathy in vascular Ehlers−Danlos was always assumed to be a straightforward connective tissue disorder resulting in weakness of the vessel wall. Recently, however, attenuation of androgen and oxytocin signaling was discovered to reduce vascular risk.[14]

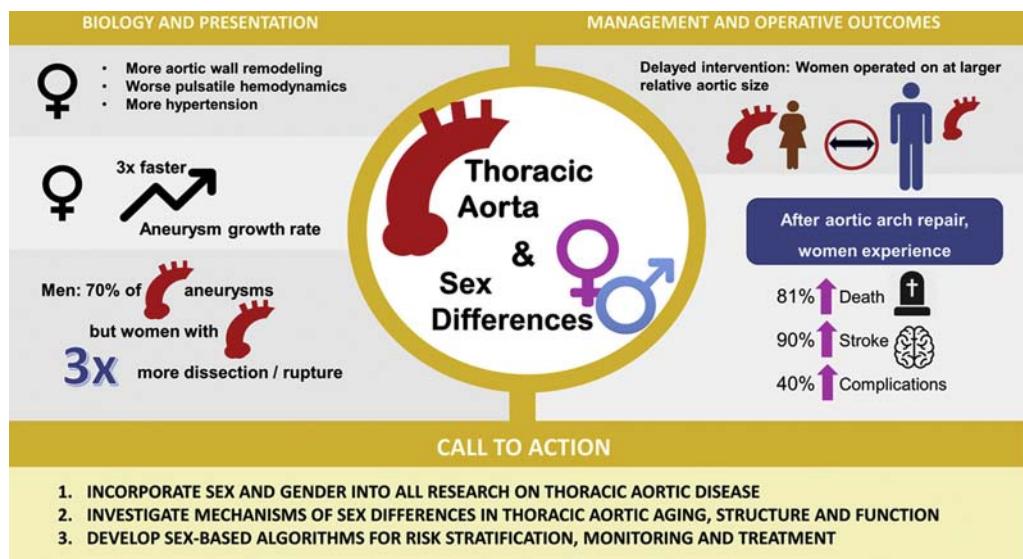
Aortopathy refers to a family of structural pathologies of the aorta, which can have life-threatening consequences. These include aortic aneurysm, dissection, rupture, penetrating aortic ulcer, aortic intramural hematoma, and aortitis. For epidemiological and clinical purposes, diseases of the aorta are typically categorized as involving the thoracic and/or abdominal segments of the vessel. For the purpose of this chapter, we will focus on thoracic aortic aneurysms (TAAs) given that most studies have focused on this segment.

Epidemiology and sex differences of thoracic aortic disease


TAAs are clinically silent conditions associated with high morbidity and mortality when complicated by acute aortic syndromes.[1–4] Most TAAs can be broadly categorized as being degenerative or heritable in nature. Patients with degenerative aortic aneurysms are typically older, and commonly have atherosclerotic risk factors, particularly hypertension (HTN). HTN has the highest population-attributable risk for acute aortic syndromes,[5] and is present in over two-thirds of patients with TAA (61%—78%).[6,7]

TAAs identified in younger patients are commonly associated with a number of heritable/genetic disorders, including bicuspid aortic valves (BAVs), Marfan's syndrome, familial TAA, Loeys—Dietz, Turner and Ehlers—Danlos syndrome (EDS) (vascular form).[8] Other etiologies, such as aortitis, posttraumatic or mycotic, are rare.

Given its predominantly silent nature, it is difficult to precisely estimate the incidence and prevalence of TAA. According to the published data, the annual incidence of TAA is estimated to be 5.6—10.4 cases per 100,000 patient-years.[6,9] However, these numbers are undoubtedly underestimated, given the lack of screening strategies for TAA and the fact that most TAAs are discovered incidentally (1% of all imaging studies).[10] Recent population data from Canada[11,12] and Sweden[13] suggest that incidence of thoracic aortic disease (aneurysms and dissections) has increased over the past decade, especially in women, which may relate to the aging population and the increased utilization of imaging techniques.

All in all, the incidence of ruptured aortic aneurysm reported in the literature is approximately 5—10 per 100,000 person-years, and that of aortic dissection is estimated to be 2—4 per 100,000 person-years.[14] However, similarly to TAA statistics, the incidence of acute aortic syndromes is also underestimated and expected to be 3—5 times higher than reported,[15] since individuals who die suddenly from these conditions are often misclassified as dying from heart attacks or strokes,[16–19] and 60% of cases of aortic dissection are missed clinically and first identified at autopsy.[20] Importantly, contemporary mortality rates of nondissected TAA and of acute aortic syndromes parallel those of other known and more commonly recognized killers such as heart disease and cancer.[12]

It is important to highlight the observed sex differences in thoracic aortopathies (Fig. 45.1).[21,22] Similar risk factors for

FIGURE 45.1   Sex differences in thoracic aortic aneurysms and dissections. Sex differences exist in the epidemiology, biology, management and outcomes of patients with thoracic aortic disease. *Adapted, with permission, from Chung J, Coutinho T, Chu MWA, Ouzounian M. Sex differences in thoracic aortic disease: a review of the literature and a call to action.* **J Thorac Cardiovasc Surg.** *2020; 160:656−660.*

developing TAA exist for men and women,[23] including age, HTN, atherosclerosis, and genetic factors/family history. However, while TAAs are 2−4 times more prevalent in men than women,[24] women with this condition carry a significantly worse prognosis.[21,24−26] Compared to men, women with TAA have twice as fast aneurysm growth rates,[25] three times higher risk of acute aortic syndromes[27−30] and 40% higher mortality. In addition, acute aortic syndromes occur at smaller aneurysm sizes in women than men, despite correction of aneurysm size to body size.[27] Further, prognosis is also worse for women undergoing TAA repair, who experience 81% higher mortality and 90% higher risk of stroke as compared to their male counterparts.[26]

Causes for these sex differences remain incompletely understood. The lower TAA prevalence in women may be partly due to the protective effects of estrogen during the reproductive years, which is believed to mediate its protective effect on the aorta through modulating matrix metalloproteinases (MMPs).[31] MMPs are enzymes that play an important role in arterial wall remodeling and have been shown to predispose to aortic aneurysm formation and dissection. The activity of MMPs is mainly regulated by tissue inhibitors of metalloproteinases (TIMPs).[32] It has been found that high levels of circulating estrogen protect against aortic aneurysm formation by reducing inflammation and MMP activity in aortic tissue.[33] While it is true that women with TAA tend to be older and harbor more comorbidities than men with TAA, the aforementioned sex differences in outcomes are independent of age, body size, and comorbidities. However, one study that included aortic specimens from men and women undergoing elective TAA repair has demonstrated greater MMP and lower TIMP

activity, indicating greater extracellular matrix (ECM) remodeling in the arterial wall, in women.[34] This was reflected in stiffer aortic walls in women than men.[34] Thus, it is possible that while women may be naturally protected against aortic aneurysm development, those that go on to develop a TAA may have greater burden of disease and remodeling in the aortic wall, which, in turn, may contribute to the worse aortic-related outcomes in women.

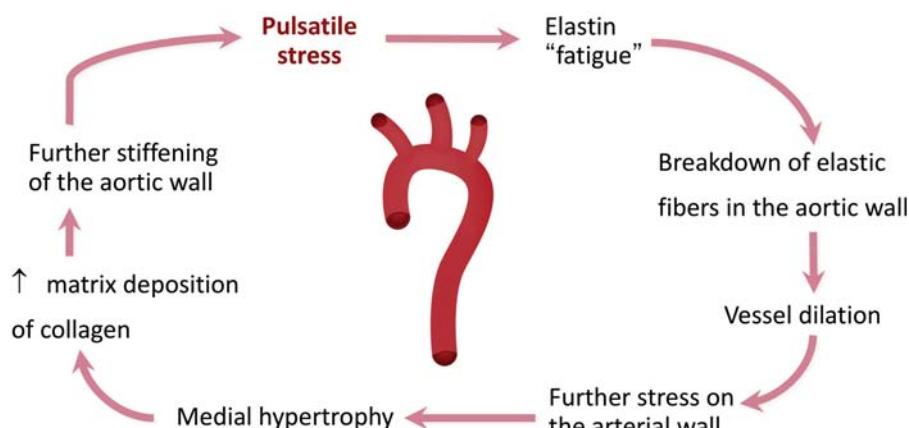
Clinical management of thoracic aortic aneurysm

Among patients with TAA, the risk of acute aortic syndromes is influenced by a number of factors including patient characteristics (age, sex, HTN, history of smoking, family history of aortic disease) and disease-related factors (aortic size, rate of aneurysm growth, connective tissue disorder, BAV, among others). Clinical management consists of blood pressure control for those who are hypertensive, beta-blocker or angiotensin-receptor blocker for those with Marfan syndrome, and yearly imaging surveillance with expectant management until critical aneurysm size is met.[8,35,36] As such, clinical management centers upon the absolute size of the aneurysm in light of the etiology and location of aortic disease, with recommended TAA size cut-offs for surgical repair based on these characteristics, and a watchful-waiting approach with serial imaging surveillance for those not yet meeting TAA surgical size criteria. While this strategy is adequate for many patients, it is imperfect, as several individuals suffer acute aortic syndromes with aneurysm sizes that are smaller than the guideline-recommended cut-offs for prophylactic

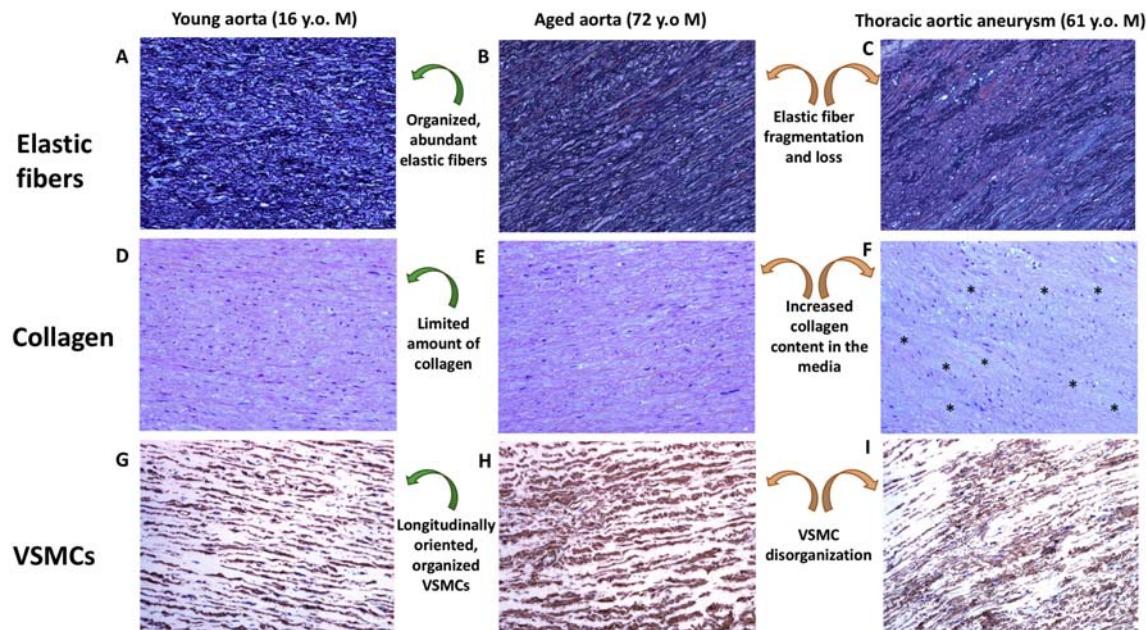
surgery.[30,37] Additionally, individuals experience different rates of aneurysm expansion and aortic complications despite having similar aneurysm sizes. These findings highlight the fact that aneurysm size alone fails to capture all of the complexity of the aorta, and motivate us to turn our attention to novel aortic parameters to better understand disease activity, risk and prognosis among TAA patients.

Histopathological links between thoracic aortic aneurysms and arterial aging

Aging plays a major role in the process of aortic disease.[38] Arterial aging is the age-associated change in arterial structure and function,[39] and is reflected in aortic stiffness and measures of aortic function. With aging, and even in the absence of aortopathy, aortic lumen increases, while the thickness of the arterial wall triples between the ages of 20 and 90 years, mainly due to intimal and subintimal thickening.[39]

As discussed in detail in Chapter 19, with increasing age, the repetitive pulsatile stress imposed upon the aorta by the beating left ventricle over time leads to fatigue and breakdown of the elastic fibers in the aortic wall. These fibers consist primarily of the structural protein elastin (90%) as well as elastin-associated glycoproteins (10%) including fibrillins. In arterial aging, there is an accelerated depletion of elastin and deposition of collagen as a result of the repetitive cyclic stress (i.e., arterial wall distension and elastic recoil)[39,40] (Fig. 45.2).


By disrupting this elastic architecture, this normal "wear and tear" of the aortic wall due to aging causes increased aortic stiffness and wall stress[41−44] and decreased aortic ability to buffer the pulsatile pressure generated by the heart. Importantly, loss of elastic fiber integrity reduces

aortic resilience, which allows the artery to dilate uniformly with aging.[45] Importantly, the process of age-related aortic stiffening is not a passive process, but involves multiple active mechanisms, discussed in detail in Section III of this textbook (Chapters 19−25).


The aging process also affects the vascular smooth muscle cells (VSMCs) in the aortic wall. It has been demonstrated that aging promotes VSMC proliferation, migration, and apoptosis, in addition to a phenotypic change leading to a secretory behavior by the aortic VSMCs, which in turn promote vessel inflammation, calcification and further alterations in the ECM.[46] These changes cause additional alterations to aortic wall structure, further impairing pressure-buffering function. The role of VMCs in aortic stiffening is discussed in detail in Chapter 22.

Aneurysms are characterized by the localized yet permanent dilatation and weakening of the arterial wall.[47] Its underlying pathophysiology is multifactorial: inflammation of the aortic wall, modulation of the ECM, apoptosis of VSMCs, complex atherosclerosis, and oxidative stress.[48] Importantly, several of the structural abnormalities observed in histological examination of TAAs closely resemble those observed in aged, stiff aortas (Fig. 45.3). For example, the main histological findings of human TAA specimens include elastic fiber thinning, disorganization, fragmentation and loss; medial fibrosis (collagen deposition); and VSMC disorganization.[49] The main difference is that such histological abnormalities found in TAA tend to be focal, more severe, and occur at younger ages as compared to the normal arterial aging process.[50] As such, experts have suggested that TAA represents a focal, accelerated aging of a segment of the aortic wall.[45]

Importantly, the loss of elastic fiber integrity that occurs with both natural aging and TAA allows the wall to dilate either uniformly, as in aging when the loss is diffuse or locally, as in TAAs when the loss is focal. Realizing the

FIGURE 45.2 Arterial aging and aortic stiffness. With the repetitive stretch and recoil of the aorta over the years, there is fatigue of the elastic fibers in the aortic wall. This pulsatile stress leads to a series of structural alterations in the aortic wall's extracellular matrix that culminates with elastic fiber disruption, wall fibrosis (collagen deposition), and vessel remodeling. This promotes aortic wall stiffness and exacerbates pulsatile stress. This process occurs naturally with aging but is exacerbated in the presence of hypertension, cardiovascular risk factors, renal insufficiency, and systemic inflammatory conditions.

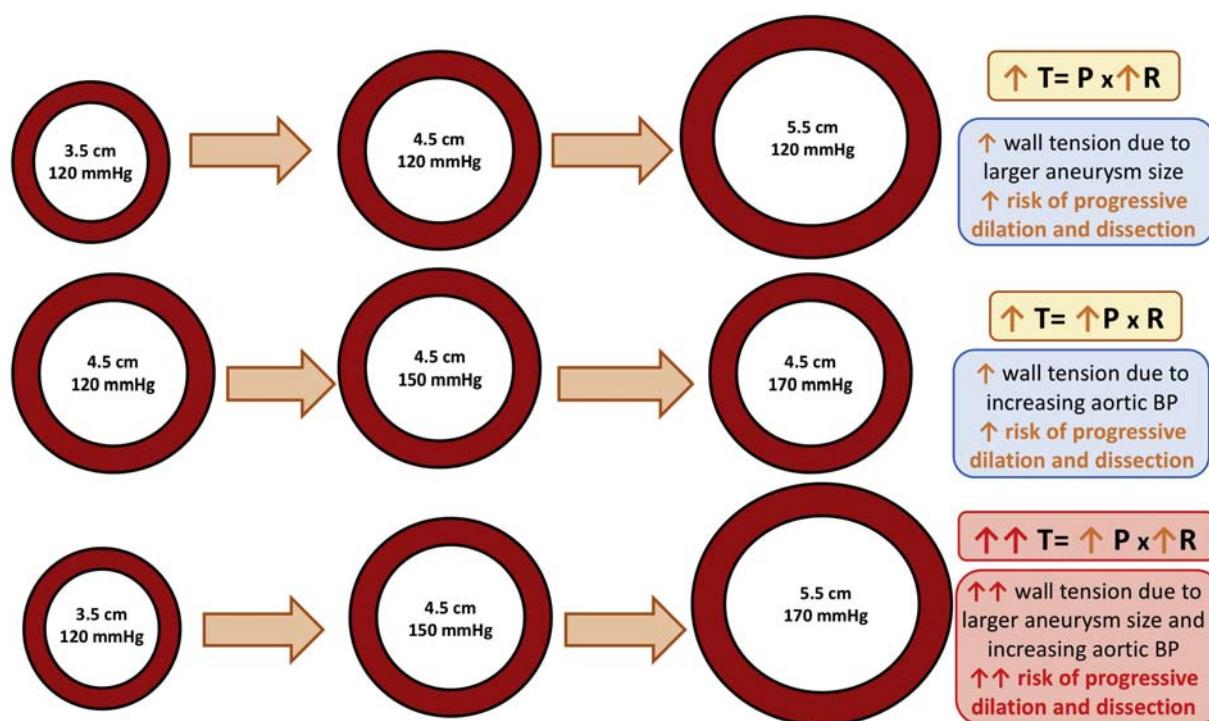
FIGURE 45.3   Structural similarities between natural aortic aging and thoracic aortic aneurysms. This figure demonstrates the structural alterations of the aortic wall that occur as a result of natural arterial aging (middle panels) and a thoracic aortic aneurysm (right-sided panels). Notably, even though the patient with a thoracic aortic aneurysm (TAA) is a decade younger than elderly patient without an aneurysm, he displayed even greater disruptions to aortic wall architecture and composition, suggesting exacerbated and accelerated arterial aging associated with the thoracic aortic aneurysm. These structural alterations are expected to lead to abnormalities in aortic stiffness, function, and pulsatile arterial hemodynamics. (A) Movat Pentachrome stain in an autopsy aortic specimen of a 16-year-old male who died of noncardiovascular causes. Elastic fibers are seen stained in black, and are abundant, intact and organized in the wall of a young, healthy aorta. (B) Movat Pentachrome stain from a 72-year-old male's aorta, demonstrating some sparsity and mild fragmentation of elastic fibers as compared to the young aorta specimen from panel A. (C) Movat Pentachrome stain from a surgical aortic specimen from a 61-year-old male with TAA. Note the significant fragmentation and sparsity of elastic fibers, leading to substantial disruption of arterial wall architecture. (D) Hematoxylin phloxine saffron (HPS) stain in the aortic specimen from the same 16-year-old male as in panel A. The areas stained in light blue, corresponding to collagen deposition in the extracellular matrix (ECM), are minimal. (E) HPS stain in the same aortic specimen from the 72-year-old male as in panel (B). Note the increase in the portions stained in light blue, corresponding to increased ECM collagen. (F) Hematoxylin and eosin stain from the same 61-year old male with TAA as in panel C. There is a substantial increase in ECM collagen deposition, highlighted by the *. (G) Muscle actin immunohistochemistry stain of the 16-year-old male's aorta. Vascular smooth muscle cells (VSMCs) are seen stained in dark red, and their nuclei are stained in blue. In this young aorta, the VSMCs and their nuclei are well organized along the aortic wall. (H) Muscle actin immunohistochemistry stain of the aged aorta (72-year-old male), demonstrating VSMC hypertrophy, distortion, and mild disorganization of the cells and their nuclei. (I) Muscle actin immunohistochemistry of a TAA in the 61-year-old male. There is extreme disorganization of VSMCs and their nuclei in the TAA wall, and the white "empty" spaces between the VSMCs represent areas of increased collagen and glycosaminoglycan deposition. *Images courtesy of Dr. John Veinot, Department of Pathology & Laboratory Medicine, The Ottawa Hospital − Ottawa, ON, Canada.*

close similarities between structural aortic alterations occurring in natural aging and in TAAs, and understanding the hemodynamic consequences resulting from aortic aging, we anticipate a significant potential for evaluating the hemodynamic consequences of aortic aging in the clinical evaluation of patients with TAA.

Aortic wall structure, aortic stiffness, and arterial biomechanics in thoracic aortic aneurysm

In animal models studying aortic aneurysm formation, blockade of plasmin formation by overexpression of plasminogen activator inhibitor-1 prevents the formation of aneurysms and aortic rupture by inhibiting MMP activation.[50] Aneurysm rupture correlates with an increase in MMP levels, local overexpansion of tissue inhibitor of MMPs can prevent aneurysmal degeneration and rupture,[51] confirming that enhanced and deleterious matrix remodeling contribute to structure alterations in the aortic wall, rendering it prone to dilation and rupture.

Per Laplace's law, wall tension (T) equals pressure (P) multiplied by radius (R), or $T = PR$. Aneurysm formation increases wall tension, causing further expansion of the aneurysmal segment.[52,53] As the aorta enlarges, distensibility of the aortic wall decreases.[52,53] At a diameter of 6 cm in size, the tensile limit is reached, and at this point, the aorta loses its natural elasticity and becomes a relatively rigid tube.[52,53] As a result, the aneurysmal aortic wall cannot further "stretch" during systole, so the critically enlarged aorta stays rigid and thus the full energy of the pulse wave is translated into wall stress.[52,53] This results in the enlarged aorta demonstrating lower distensibility and

higher wall stress, which may predispose to dissections as a result.[52,53] Fig. 45.4 illustrates a conceptual framework highlighting the potentially incremental effects of changes in aortic diameter and hemodynamics in increasing dissection risk.


Based on the histopathological similarities between arterial aging and TAAs outlined in Section 3, it is possible that similar hemodynamic derangements observed as a consequence of an aged aorta may be observed in thoracic aneurysmal disease. This has been demonstrated in several forms of thoracic aortopathy, as summarized below.

Marfan syndrome

For a discussion of general concepts regarding genetic aortopathy, the reader is referred to Chapter 44. Marfan syndrome (MFS) is an autosomal dominant disorder caused by mutations in the FBN1 gene coding for a large glyco-protein called fibrillin-1.[54] Fibrillin-1 is a protein that forms one of the major components of microfibrils of elastin and is found at the periphery of elastic fibers in the medial layer of the ascending aorta.[52,54] The mutations in MFS result in a decrease in the amount of elastin in the aortic wall and a loss of elastin's normally highly organized structure.[55] As a consequence, the Marfan aorta exhibits abnormal elastic properties, including lower aortic distensibility[55–57] and greater aortic wall stiffness[58,59] than non-Marfan controls. As a result of these alterations in distensibility and stiffness, aortic pressure-buffering function is impaired in MFS, evidenced by the higher central pulse pressure and lower pulse pressure amplification in this population as compared to controls.[60] In addition, the age-related increases in aortic pulse wave velocity (the gold-standard measure of arterial stiffness and the hallmark of arterial aging) were greater in MFS patients as compared to non-Marfan controls.[61,62] Importantly, given their correlation with aortic wall structure and health, measures of aortic elasticity at baseline are associated with aneurysm growth rate in MFS. In a study of 608 people with MFS, above-median aortic root elastic modulus (assessed by transthoracic echocardiography) was associated with faster root growth, and top quartile aortic root elastic modulus was associated with greater risk of a composite outcome that included aortic root surgery, aortic dissection or death.[63]

Given the reported benefits of atenolol and losartan in curbing aneurysm expansion in patients with MFS, these two medications have been compared in a small randomized clinical trial in terms of their effects on the

FIGURE 45.4 Role of aortic size and pressure on wall tension and possible aortic dissection risk. Conceptual framework demonstrating the potentially incremental effects of aneurysm size and aortic pressure on potential risk of progressive aortic dilation and dissection resulting from increased wall tension. Larger aneurysms with the greatest alterations in aortic wall structure, resulting in impaired aortic pressure-buffering function and increased central blood pressure, may have the highest risk for progressive aneurysm expansion and aortic dissection. This conceptual framework illustrates the need to consider both aortic size and aortic hemodynamics to improve estimation of disease activity and risk of acute aortic syndromes in patients with thoracic aortic aneurysms. *BP*, blood pressure.

biomechanical properties of the aorta. Although there were group imbalances in terms of participant sex and baseline aortic root size, the main finding was that losartan therapy led to more favorable changes in measures of aortic stiffness (pulse wave velocity) and pulsatile arterial hemodynamics (aortic impedance, total arterial compliance) as compared to Atenolol.[64] These findings highlight measures of aortic stiffness and pulsatile hemodynamics as potential therapeutic targets in MFS patients with TAA.

Loeys−Dietz syndrome

Although MFS has been most vastly studied, alterations in aortic stiffness and pulsatile hemodynamics have also been reported in individuals with other heritable forms of aortopathy, helping prove the concept that the deleterious structural alterations in the aortic wall that simulate the natural aging process may be responsible for hemodynamic abnormalities in this population. Among patients with Loeys−Dietz syndrome (LDS), an autosomal dominant disease characterized by mutations in transforming growth factor beta receptor 1 or 2, there is increased transforming growth factor beta signaling[65] in the arterial walls, which culminates in disorganization of elastic fibers and enhanced deposition of collagen in the aortic media (again, similar to the processes observed with natural aging, but in these cases occurring much earlier in life, and in an exacerbated fashion).[65] Unlike MFS, literature reporting arterial hemodynamic alterations in LDS is scant. In a study of 31 patients with heritable aortopathies that included five participants with LDS, aortic distensibility and strain (estimated with transthoracic echocardiography) was lower in aortopathy patients as compared to controls, even when their aortas were not dilated.[66] Aortopathy patients with dilated aortic root had the worse values of aortic distensibility and strain.

Familial thoracic aortic aneurysms and dissections

Familial thoracic aortic aneurysms and dissection (FTAAD) describes a spectrum of heritable disorders associated with aortopathy in the absence of identifiable syndromes or other characteristic phenotypical features. Several gene mutations have been reported in FTAAD, including SMAD3, ACTA2, MYH11, MYLK, and PRKG1. Description of aortic specimens from individuals with FTAAD caused by MYH11 mutation also demonstrates focal medial degeneration, with increased proteoglycans, decreased elastic fibers, and disorganized VSMCs.[67] Similarly, in six individuals with FTAAD due to ACTA2 mutation, aortic tissue examination showed loss of elastic fibers, marked medial smooth muscle cell proliferation, and increased proteoglycan accumulation.[68] At the time of writing of this chapter, human hemodynamic data from FTAAD remain extremely scant. In a study of eight asymptomatic subjects with a mutation of the MYH11 gene but without aortic aneurysms, MRI-derived aortic compliance and distensibility were significantly lower, and aortic pulse wave velocity was higher when compared to 21 controls without this mutation.[69]

Bicuspid aortic valve

BAV is the most common form of congenital heart disease, affecting 0.5%−2.0% of the population. As a result, aortopathy associated with BAV is the most common form of heritable aortopathy. Being relatively common, BAV aortopathy has benefited from abundant research with regards to aortic elasticity and hemodynamics. The body of available data is fairly concordant in identifying abnormal aortic material properties and adverse pulsatile hemodynamics in patients with BAV. Similar to what was described above for MFS, LDS, and FTAAD, histological examination of BAV-TAA also demonstrates varying degrees of elastic fiber fragmentation and smooth muscle cell abnormalities,[70] also resembling abnormalities found in the naturally aged aorta. Importantly, advanced histological abnormalities in BAV-TAA can be found even when the aorta is not severely dilated,[70] confirming the notion that the absolute size of the aorta is an imperfect predictor of aortic wall disease and subsequent risk. Another important observation is that, in BAV-TAA, the greatest severities of aortic wall histological abnormalities were found in younger individuals,[70,71] giving rise to the notion that the arterial age may be more relevant than chronological age for understanding TAA disease activity and risks.

These structural abnormalities of the aortic wall in BAV predispose patients to impaired aortic biomechanics and function. Compared to individuals with TAA but who have trileaflet aortic valves, aortas from BAV-TAA have greater collagen-related stiffness.[72] Perhaps as a result of this, the elastic module of BAV-TAA aortas has been shown to be higher than in trileaflet aortic valve TAA and in normal aortas, translating into greater wall stiffness in BAV-TAA.[72] The aortic energy loss, a size-independent measure defined as hysteresis normalized to total stored strain energy, represents the relative amount of energy absorbed by the aorta during the cardiac cycle. Higher energy loss highlights greater aortic inefficiency in expanding to act as a capacitor during systole, and in recoiling to return the stored energy to the circulation in diastole. The aortic energy loss correlates with elastin and collagen composition in the aortic wall, increasing with lower elastin and greater collagen content.[72] As such, aortic energy loss directly reflects aortic health by corresponding to the aorta's pressure-buffering function and efficiency in performing Windkessel functions. Aortic energy loss is higher in BAV-TAA than in normal aortas, reflecting abnormal aortic

pressure-buffering function in BAV aneurysms, but not as high as in trileaflet aortic valve TAAs, who have the greatest aortic energy loss and, therefore, the worst aortic function.[72]

The BAV-TAA abnormalities in aortic stiffness and aortic function identified in the fundamental studies above have also been demonstrated in clinical studies that have used imaging techniques to estimate aortic stiffness and hemodynamics. Even in the absence of an aneurysm, the aortas of patients with BAV already display lower distensibility and higher stiffness index, estimated by transthoracic echocardiography, as compared to controls with trileaflet aortic valves.[73,74] In addition, lower aortic distensibility and higher stiffness index correlate with larger aneurysm sizes in BAV.[74] Among 50 BAV patients, 28% of whom had dilated ascending aortas, carotid-femoral pulse wave velocity (cfPWV), central augmentation index, and central pulse pressure were higher, whereas pulse pressure amplification was lower than in age- and sex-matched trileaflet aortic valve controls without aortopathy.[75]

There appears to be a gradient of aortic hemodynamic abnormalities based on clinical involvement of the aorta in patients with BAV. As demonstrated by the aforementioned studies, measures of aortic stiffness and function are abnormal in BAV patients when compared to trileaflet aortic valve controls. But even within the group of BAV subjects, further deterioration of aortic function is observed based on degree of aortic involvement. In 32 men with BAV, 16 of whom also had a TAA, cfPWV, augmentation index, central systolic, and pulse pressures were higher, and pulse pressure amplification was lower among patients with BAV-TAA as compared to those with BAV alone, despite similar ages, body sizes, and brachial blood pressures.[76] BAV-TAA participants also exhibited greater circulating levels of matrix metalloproteinase-2 (MMP-2) than those with BAV alone, likely reflecting a greater degree of adverse arterial wall remodeling among those with an aneurysm.

Measures of aortic stiffness and pulsatile arterial hemodynamics also appear to carry potential to serve as gauges for disease activity and risk in BAV. We have previously shown that higher cfPWV, aortic characteristic impedance (Z_c) and amplitude of the forward pressure wave (P_f), and lower total arterial and proximal aortic compliances are independently associated with faster TAA expansion among individuals with BAV.[77] Subsequently, Longobardo and colleagues evaluated 47 BAV patients who underwent echocardiographic evaluation of ascending aorta longitudinal strain (LS), finding that lower aortic LS was independently associated with progressive aortic dilation and need for aortic surgery after a 48 ± 11 month follow-up.[78]

Turner's syndrome

Turner's syndrome is a genetic disorder caused by the presence of a single X chromosome (typically 45X0), and associated with cardiovascular abnormalities in approximately half of affected patients.[79] Although aortic dissection is relatively uncommon in Turner's syndrome,[79] at least one predisposing factor to aortic dissection including BAV, HTN, or aortic coarctation is present in 90% of patients. A few patients with Turner's syndrome also have dilation of aortic root, although the true prevalence is unknown. Aortic root diameters have been shown to be significantly larger for Turner's syndrome patients with 45XO karyotype (complete absence of the second X chromosome in all cells), as compared to those with either mosaic (when some cells have a second X chromosome, and some do not), isochromosome (when one of the X chromosomes is composed of mirror images of one of the arms of the chromosome, resulting in deletion of the opposite arm) or deletion (when the individual has two X chromosomes, but one of them has a deletion) forms of the disorder, and to controls.[80] These differences were observed despite similar body sizes among groups. Aortic dilation has been reported as present in 29%[81]−46%[81] of TS patients. It appears that abnormalities of aortic function may be most prominent among Turner's syndrome patients with some degree of aortopathy, confirming the link between aortic pathology and aortic function. Aortic distensibility, assessed by echocardiography, has been reported to be significantly lower in Turner's syndrome patients with aortic dilation as compared to those with normal aortas, and controls without Turner's syndrome or TAA.[81] Similarly, Turner's syndrome patients who have aortic coarctation have much lower MRI-derived descending aorta distensibility than age-matched female controls and Turner's syndrome patients without coarctation.[82] In this study, lower aortic distensibility in Turner's syndrome resulted in higher central systolic blood pressure.

Ehlers−Danlos syndrome

Patients with vascular EDS (EDS type IV) have very different aortic pathology as compared to MFS, BAV, FTAAD, and LDS. Instead of disruption of elastic fiber integrity promoting collagen deposition in the aortic wall, as seen in other heritable aortopathies, vascular EDS is an autosomal dominant condition characterized by mutation in the gene encoding type III procollagen (COL3A1), which leads to deficits in the most abundant type of collagen found in the aorta's ECM. This results in excessive vessel fragility and predisposition to rupture. In contrast to MFS, vascular EDS most often involves the descending thoracic

and abdominal portions of the aorta and can be complicated by arterial rupture even in the absence of vessel dilation. As could be expected by the different type of insult to the aortic wall, it appears that EDS leads to normal to increased arterial elasticity. In a study of 12 individuals with EDS from six families, four of whom had vascular EDS, EDS participants did not have different aortic or carotid pressure strain elastic modulus or beta stiffness index as compared to controls.[83] Conversely, in a study of 60 EDS patients (eight of whom had vascular EDS), patients with this condition had lower cfPWV when compared to age-based reference values from normal subjects.[84]

Degenerative aortopathy

Patients with degenerative TAAs are typically older, with high prevalence of HTN and other cardiovascular risk factors. Considering the significant similarities between natural aortic aging and pathological alterations of the aortic wall in TAAs, perhaps degenerative thoracic aortopathy may represent the ultimate manifestation of aortic aging. By adding further structural disruptions to an aortic wall that may already be abnormal from aging, patients with degenerative TAAs may exhibit the greatest abnormalities in measures of aortic health and function. Concordant to this hypothesis, in a recent study, Chung et al. performed extensive biomechanical testing of human aortic tissue and demonstrated that S_d, the force required to mechanically tear apart the aortic sample, was the lowest among dissected aortas, and lower in patients with non-dissected TAAs with trileaflet aortic valves (91% of whom had degenerative TAAs) than in patients with nondissected BAV-TAA.[72] In the same study, the authors also showed that aortic energy loss is much higher in the trileaflet TAA patients (again, 91% of whom had degenerative aneurysms) than in BAV-TAA and nonaneurysm controls, and that aortic energy loss was inversely correlated with S_d. The interpretation of these findings is that degenerative TAAs have the greatest disruption to elastin/collagen balance in the wall, leading to the greatest impairments to the aorta's pressure-buffering function and the highest susceptibility to dissection.

In a separate biomechanical study, surgical aortic specimens from 26 subjects with degenerative TAA (average aneurysm size: 59 ± 3 mm) were examined and compared to fresh postmortem control aortic specimens from 15 age-matched individuals without aortopathy.[85] TAA specimens had lower elastin density in the aortic wall when compared to control aortas, as well as lower wall thickness and failure strain values, and higher peak elastic modulus. Failure stress (i.e., tensile strength) was not different between TAA and control aortic specimens. These findings confirm that aortas affected by degenerative TAA have greater structural disruption to wall architecture (lower elastin fiber density) and are considerably stiffer than aortas of age-matched control subjects, once again highlighting the accelerated vascular aging affecting the aortic wall of patients with aortopathy. In addition, since the tensile strength of TAAs does not appear to be different than that of unaffected aortas, with only weak negative correlations between maximum aneurysm diameter and tensile strength, findings from this study also corroborate the notion that aneurysm size (the universally acknowledged criterion considered for prophylactic surgical intervention) may not be the most representative parameter for the quality of aortic tissue. Rather, the rupture risk of TAAs (in the case of this study, degenerative TAAs) may be better ascribed to the increased wall stresses caused by tissue stiffening and vessel enlargement. Importantly, and particularly relevant for degenerative TAAs (whose main risk factor is HTN), a study that focused on the effects of HTN and wall stiffness found that stiffer TAAs were correlated with the most altered distribution of wall stress, and an acute change of peripheral vascular resistance could significantly increase the risk of rupture for a stiffer aneurysm.[86]

Measures of aortic stiffness and pulsatile hemodynamic as markers of disease activity and thoracic aortic aneurysm—related risk

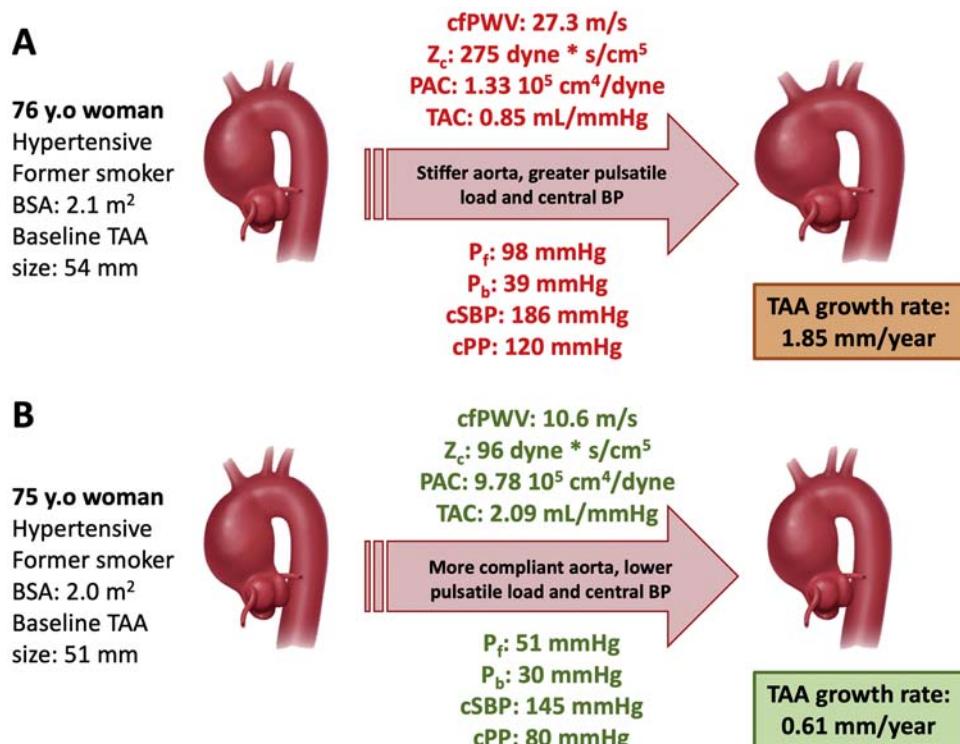
The natural history of TAA is one of slow expansion with an increasing risk of aortic dissection as the aorta enlarges. The rate of aneurysm growth gives insights into disease activity, highlighting potential adverse processes occurring in an unstable aortic wall that ultimately promotes growth. Expansion rates range from 0.1 to 1.0 cm per year, depending upon TAA etiology diameter and location within the aorta.[1−3,87−89] A recent meta-analysis reported that the average TAA expansion rate is ∼0.60 mm/year, being faster for those with BAV (∼0.76 mm/year) and those with trileaflet aortic valves (∼0.34 mm/year).[90] Although sex-based data have historically lacked, we have demonstrated that TAA expansion is twice as fast in women than men, which seems to be unique to individuals with degenerative forms of TAA.[25]

Given the direct links between aortic wall structural and functional abnormalities, leading to accelerated vascular aging and alterations in the aorta's mechanical properties in the presence of TAA, it is reasonable to consider that alterations in aortic function (aortic stiffness and pulsatile hemodynamics) may present a window to better understand aortic health, disease activity, and risk (Fig. 45.5).

At the time of writing of this chapter, this remains a relatively new area for research but with significant potential to positively impact the field. To date, a few studies have evaluated the role of measures of aortic stiffness and

FIGURE 45.5 Potential mechanisms linking aortic stiffness, central blood pressure, and pulsatile arterial load to thoracic aortic aneurysm expansion. The compliance and pressure-buffering function of the aorta are intrinsically linked to the health of its wall. According to this premise, it is possible that thoracic aortic aneurysm patients with more active disease in the wall (i.e., greater degree of inflammation, elastic fiber disruption, and matrix remodeling) may be identified by greater aortic stiffness and impaired pressure-buffering capacity. This, in turn, marks an individual whose aneurysm is more likely to expand over time, and highlights a window to identify disease activity, increase surveillance, and develop targeted therapies to control the disease. *cfPWV*, carotid-femoral pulse wave velocity; *PP*, pulse pressure; *SBP*, systolic blood pressure. *Adapted, with permission, from Boczar KE, Boodhwani M, Beauchesne L, et al. Aortic stiffness, central blood pressure, and pulsatile arterial load predict future thoracic aortic aneurysm expansion. **Hypertension**. 2021; 77:126−134.*

hemodynamics as potential predictors of aneurysm size, expansion or acute aortic syndromes. Research from our group has focused on noninvasive assessment of aortic stiffness (cfPWV), central blood pressure, and pulsatile hemodynamics (assessed with pressure-flow analyses that integrate pressure data from arterial applanation tonometry with flow and volume data from transthoracic echocardiography, as described in detail in Chapters 1−3). In an initial cross-sectional study, we demonstrated that aortic stiffness, measured by cfPWV, as well as measures of higher pulsatile arterial load (central systolic blood pressure, central pulse pressure, proximal aortic compliance global reflection coefficient, and reflected pressure wave amplitude in univariable analyses; central systolic blood pressure and global reflection coefficient retained statistical significance in multivariable analyses) are correlated with larger aneurysm sizes in women, but not in men,[91] suggesting a greater role for aortic structural and functional abnormalities in women with TAA. In accordance to his topic, in a retrospective evaluation, we have shown that greater aortic stiffness (cfPWV) is independently associated

with a faster rate of aneurysm growth, and that this association is stronger in women than men.[92] Also in a retrospective analysis, we focused on the subgroup of participants who had a TAA associated with a BAV and showed that a stiffer aorta (higher cfPWV) with higher measures of pulsatile arterial load (higher aortic characteristic impedance and forward pressure wave amplitude, as well as lower proximal aortic, and total arterial compliances) was associated with faster aneurysm expansion rates in the BAV-TAA population.[77]


In prospective studies that have included participants with all TAA etiologies (58% degenerative TAA, 42% heritable TAA with the majority having a BAV), we have demonstrated the independent value of baseline aortic stiffness and aortic function assessment for the evaluation of future aneurysm growth. Higher aortic stiffness (cfPWV) and greater pulsatile arterial load (higher central systolic and pulse pressures, amplitude of the forward and reflected pressure waves, and lower total arterial compliance) at baseline were not only independently associated with faster TAA expansion in the future, but some of the hemodynamic

measures (namely cfPWV, forward pressure wave amplitude, and central pulse pressure) were even stronger correlates of future TAA growth than the current clinical standard of care (aneurysm size).[93] Fig. 45.6 illustrates a comparison of two real-life examples of patients with similar clinical characteristics and baseline TAA sizes, but with very different aortic stiffness and pulsatile hemodynamic measures, resulting in different rates of aneurysm expansion.

Further, it appears that undertaking an aortic evaluation that takes into account both aortic size and function may be a superior strategy for assessment of TAA disease activity, as the combination of aneurysm size with variables reflecting aortic stiffness and pulsatile hemodynamics were more strongly associated with future TAA expansion than aneurysm size or aortic function measures alone.[94] This is directly in line with the concepts proposed in Fig. 45.4, whereby combined abnormalities of aortic diameter and hemodynamics/pressure have potential to cause the greatest increases in aortic wall tension, which, in turn, may lead to unstable aneurysmal disease.

The role of assessing the aorta's function and elastic properties has also been demonstrated in the specific population of patients with TAA due to MFS. In a study of 78 unoperated MFS patients who underwent aortic stiffness and distensibility assessment by MRI, both larger aortic diameter and lower aortic distensibility were found to be independent predictors of future aneurysm expansion.[95] In this study, a 10^{-3} mmHg^{-1} decrease in aortic distensibility was associated with a fourfold increase in the risk of experiencing progressive aortic dilation, independent of baseline aortic diameter. Most recently, a separate study of 117 unoperated MFS patients followed patients prospectively after MRI, showing that lower proximal aorta LS at baseline was independently associated with faster aneurysm growth rate in the future, and aortic events (composite of aortic dissection and elective aortic surgery).[96] Confirming the notion that including information about aortic health/function/elasticity improves risk stratification in TAA (in this case, in MFS-TAA), the authors compared the receiver-operating characteristic curves for aortic diameter alone (C-statistic: 0.80), aortic LS alone (C-statistic: 0.74), and a full model that included age, sex, aortic diameter, and aortic LS (C-statistic: 0.95) in the prediction of aortic events, demonstrating that combining aortic size and function is better than each parameter alone in this prediction.

FIGURE 45.6 Comparison of two patients with similar clinical characteristics and baseline thoracic aortic aneurysm (TAA) sizes, but with different rates of aneurysm expansion. Despite similar age, clinical characteristics, and baseline aneurysm sizes, Patient A has a stiffer aorta, with greater pulsatile load and central pulse pressure (cPP) leading to faster aneurysm expansion compared to Patient B who has a more compliant aorta (albeit, with the same baseline aneurysm size). This highlights the fact that measures of aortic stiffness, central blood pressure, and pulsatile arterial load could potentially be clinically useful office-based markers for TAA risk assessment and determination of disease activity in TAA. *BSA*, body surface area; *cfPWV*, carotid-femoral pulse wave velocity; *cSBP*, central systolic blood pressure; *PAC*, proximal aortic compliance; *Pb*, reflected pressure wave amplitude; *Pf*, forward pressure wave amplitude; *TAC*, total arterial compliance; *Zc*, characteristic impedence of the aorta. *Adapted, with permission, from Boczar KE, Boodhwani M, Beauchesne L, et al. Aortic stiffness, central blood pressure, and pulsatile arterial load predict future thoracic aortic aneurysm expansion.* **Hypertension**. *2021; 77:126−134.*

When it comes to assessing disease activity and risk in TAA, it also makes sense to include HTN as a potential prognostic factor in patients with this condition. Arterial HTN is the greatest population-attributable risk factor leading to the development of TAAs.[97–99] Being highly prevalent among TAA patients, HTN is a predictor of acute aortic syndromes in these patients and negatively influences their overall survival.[7,97,98,100,101] Importantly, HTN increases hemodynamic forces on the ascending aorta.[102] In these cases, the aortic VSMC's mechanosensing is stressed by the increased forces on the wall, leading to misperceptions of high stress as low stress and resulting in maladaptive remodeling.[102,103] Importantly, wall stress increases almost linearly with systolic blood pressure.[104,105] Thus, controlling HTN is particularly important in TAA in order to reduce aortic wall stress[104] and, in turn, target disease prevention.[45,103] Understanding the importance of HTN in TAA, we must acknowledge that HTN is typically diagnosed based on brachial blood pressure, which does not perfectly reflect central blood pressure and may better predict cardiovascular events.[106] To address this, we have prospectively studied patients with TAA and found that occult central HTN (i.e., central systolic blood pressure ≥ 130 mmHg in the presence of brachial blood pressure < 140 mmHg and no previous clinical diagnosis of HTN) is relatively common, affecting 15% of TAA patients.[107] Furthermore, among all patients, while baseline brachial BP was not associated with aneurysm size or aneurysm growth, higher central blood systolic and pulse pressures were independently associated with larger aneurysms among those without a clinical diagnosis of HTN, and with faster future aneurysm expansion in all participants regardless of previous HTN diagnosis. Similar to our findings, in the aforementioned study of 117 MFS-TAA, brachial blood pressure was not included in multivariable statistical models for prediction of aortic growth and aortic events, as it was not associated with these outcomes.[96] Therefore, although HTN diagnosed by brachial artery measurement remains an important risk factor for TAA and acute aortic syndromes, it appears that central BP and central HTN may carry even higher potential for improving risk stratification of TAA patients. In addition, central blood pressure may present a viable therapeutic target aimed at controlling TAA expansion and complications, which remains amenable to testing in clinical trials.

Conclusions and future directions

Thoracic aortopathies are silent killers of increasing prevalence. Despite this, TAA remains an understudied condition with suboptimal management strategies that rely on an imperfect parameter (aortic size) for decision-making, followed by a watchful waiting until an irreversible abnormality occurs and either culminates in a catastrophic

outcome (acute aortic syndrome) or in prophylactic surgical repair. In the present chapter, we demonstrated the similarities between natural aortic aging and TAA (considered by some as an accelerated, focal aging of the affected segment of aortic wall), the resulting aortic functional and hemodynamic abnormalities associated with thoracic aortopathy, and the role of alterations in aortic stiffness and hemodynamics on aneurysm growth and aortic events.

Although this research field is relatively young, existing evidence highlights a significant role for incorporating measures of function (aortic stiffness, central blood pressure, and pulsatile hemodynamics) into clinical practice to better assess a patient's disease activity and aneurysm-related risk. By affording a window into the evolving fundamental biology of TAA expansion, measures of aortic function may provide an early indication of when adverse events are occurring in the aortic wall, presenting the opportunity to intervene on susceptible patients before experiencing excessive dilation and having to resort to surgery to correct an irreversible abnormality. This is key for development of new therapies for TAA, as there is a potential for these aortic function measures to be used toward identifying patients that would benefit from novel biological therapies directed toward the unstable aortic wall. Further, aortic function measures may be used to personalize a surveillance plan for patients, suggesting closer imaging follow-up and earlier prophylactic surgery for those with faster predicted growth or higher risk of aortic events, and longer imaging intervals and delayed surgical intervention for those with slower predicted growth or lower risk of events. This will optimize utilization of healthcare resources. By moving from standard size cutoffs to a personalized assessment based on a combination of individual characteristics, aortic size, and function, TAA care will be brought into the realm of precision medicine, with significant potential to improve outcomes. To achieve this, additional studies are needed to develop and validate TAA risk prediction algorithms, and to test biological interventions aimed at containing disease activity and preventing progressive aneurysm dilation.

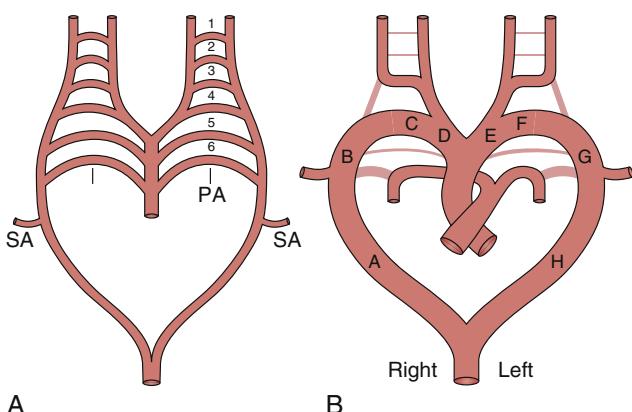
Arterial stiffness and pulsatile hemodynamics in congenital heart disease

Michael A. Quail

Department of Pediatric Cardiology, Great Ormond Street Hospital for Children and University College London, London, United Kingdom

Background

Congenital heart disease (CHD) is any developmental malformation of the heart or great vessels. Involvement of the aorta is common and may occur in isolation (coarctation or interruption of the aortic arch) or in association with more complex abnormalities such as hypoplastic left heart. Aortic involvement (usually dilatation) may also complicate forms of CHD traditionally considered to be limited to the right heart, such as tetralogy of Fallot (TOF).


Normal aortic morphology

The normal aorta is a spiral structure, arising above the aortic valve and ascending in a cranial and rightward direction. At the level of the right pulmonary artery, the *ascending aorta* spirals leftward and posteriorly, adopting a transverse orientation. The *transverse aorta* passes to the left of the trachea and is morphologically divided into proximal and distal portions. The *proximal transverse aorta* gives rise to the innominate and left common carotid arteries (LCCAs), and the *distal transverse aorta* gives rise to the left subclavian artery (LSA). In normal fetal life, the aorta and left pulmonary artery (or pulmonary trunk) are connected by the arterial duct (ductus arteriosum), a vessel which facilitates a physiological bypass of the lungs, redirecting right ventricular cardiac output to the descending aorta. The *aortic isthmus* is the region of insertion of the ductus arteriosus into the aorta and is usually located on the under surface of the aorta in the vicinity of the LSA. Distal to the aortic isthmus, the *proximal descending aorta* spirals caudally toward the diaphragm passing leftward to the vertebral bodies.

Aortic development

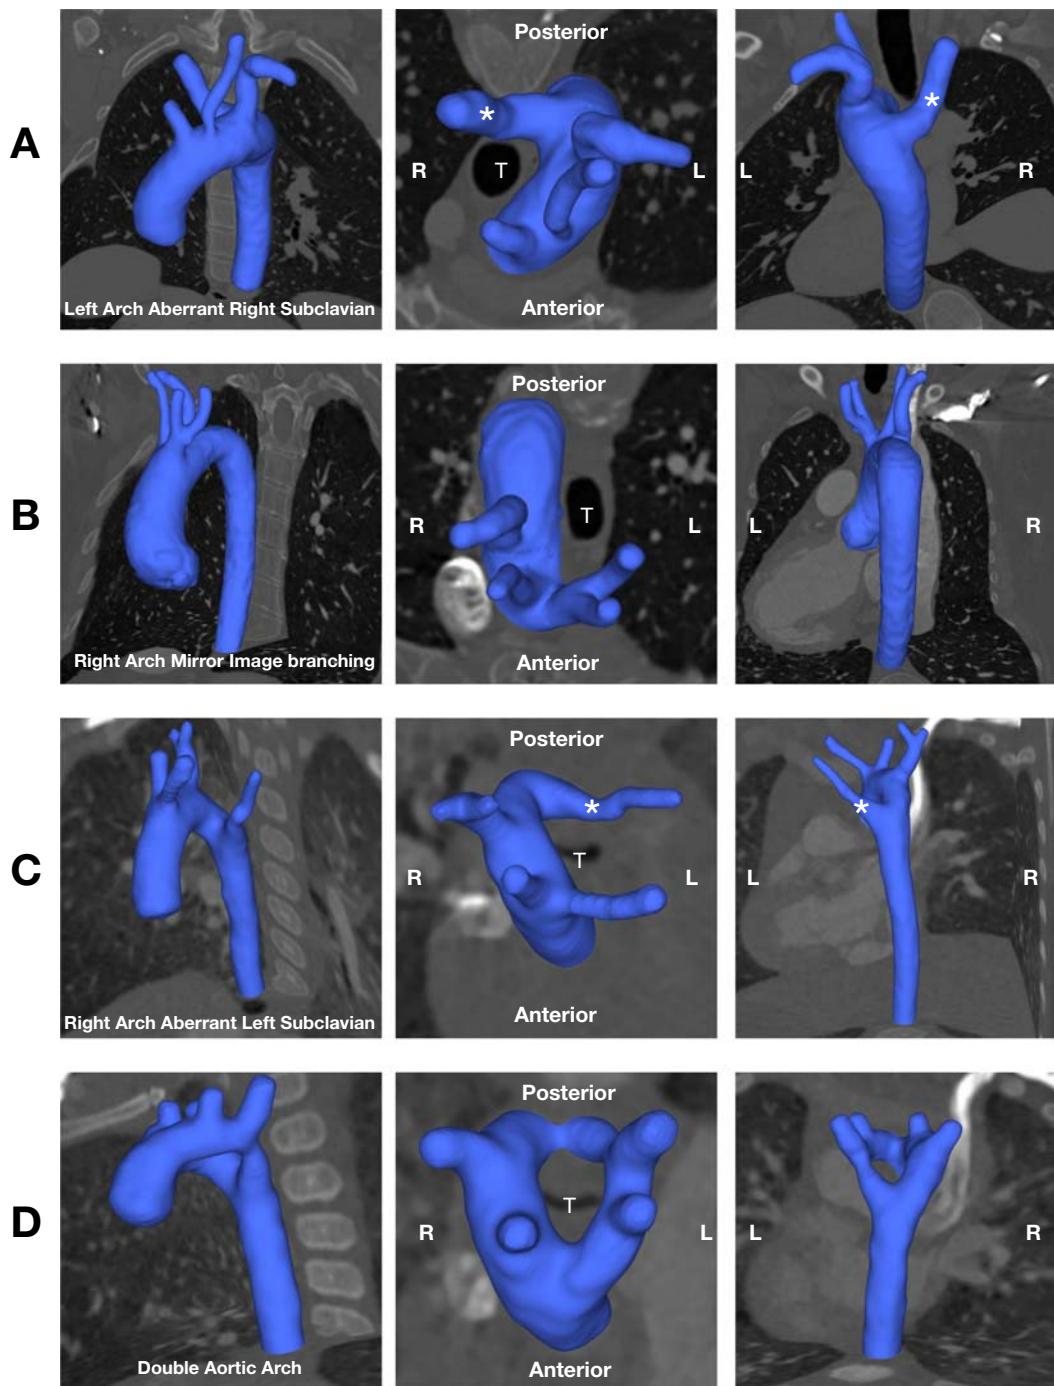
The aortic arch and pulmonary trunk, together with the main branches, are evolutionarily related to six pairs of arterial arches which exist in embryological life. The aortic arches represent the blood supply to the embryological pharyngeal (branchial) arches. Remodeling of these transient symmetrical arch arteries into the definitive adult left-sided aortic arch pattern involves the asymmetrically programmed regression and persistence of specific arch arteries. This process involves signaling between the endothelial cells lining the pharyngeal arch arteries, neural crest cell−derived smooth muscle and mesenchyme, and the endoderm; disruption of this process is believed to contribute to congenital abnormalities of the aortic arch.[1,2]

The embryological aortic arches partially encircle the pharynx to connect the ventral aorta to the paired dorsal aortas, which are joined to the future descending aorta. Edwards originally proposed a simplified embryonic double arch system (Fig. 46.1A and B) which can assist understanding the morphological variations which can occur.[3−5] Once the third paired arches have developed, the first and second paired arches disappear. The cephalic extension of the ventral and dorsal aorta beyond the fourth arch becomes the common carotid (portion of ventral aorta between third and fourth arches), internal carotid (cephalic extension of ventral aorta beyond third arch), and external carotid (third arch and cephalic extension of dorsal aorta) arteries, respectively, on each side. The dorsal aortas between the third and fourth arches regress. The part of the ventral aorta proximal to the fourth arch on the right becomes the brachiocephalic artery (segment D, Fig. 46.1B), and on the left it becomes the future aortic arch between the

FIGURE 46.1 (A) The basic pattern of the six pairs of primitive aortic arches with the position of the primary pulmonary arteries (PA) and subclavian arteries (SA) also indicated. (B) The embryonic double arch system is formed by the fourth arches and the dorsal aortas of both sides. The various lettered segments may persist or disappear in different configurations of the great arteries.

right brachiocephalic and LCCAs (segment E, Fig. 46.1B). The fourth arch on the left side becomes the future aortic arch between the LCCA and the origin of the future LSA (segment F, Fig. 46.B), and on the right it forms the origin of the future right subclavian artery (segment C, Fig. 46.1B). The fifth paired arches usually disappear but may persist. The lateral portion of the left sixth arch forms the ductus arteriosus, and the medial portions of both sixth arches form the origins of the pulmonary arteries. The seventh intersegmental arteries migrate cephalad to form the future subclavian arteries (see Fig. 46.1A). Ultimately, the spiral septation of the ventral aorta, or common arterial trunk, provides for separation of the pulmonary trunk from the ascending aorta.

In normal development, we observe the disappearance of segment A (see Fig. 46.1B) of the dorsal aorta and distal part of the right sixth arch while the distal part of the left sixth arch persists as the arterial duct, thus giving rise to a left aortic arch. Atresia or persistence of various segments can give rise to morphological aortic variations (see Fig. 46.2), some of which may result in vascular rings with compression of the trachea or esophagus.

Coarctation of the aorta and interrupted aortic arch


Coarctation of the aorta is a form of aortic obstruction, characterized by narrowing at the level of the aortic isthmus. The prevalence is 2.9 per 10,000 births and globally it represents 3.6% of all CHD (Table 46.1).[6] The condition is more common in boys, with a 2:1 sex ratio. Morphologically, this lesion is a localized intraluminal projection of a "shelf" from the posterior or lateral wall of the isthmus in the region of the ductus arteriosus.

Coarctation is also often associated with a variable degree of hypoplasia of the transverse arch. As the ductus arteriosus closes, the degree of aortic obstruction becomes progressively more severe, resulting in reduced systemic perfusion, acutely increased afterload, and cardiogenic shock. Initial medical treatment includes resuscitation and initiation of intravenous prostaglandin therapy to maintain or restore ductal patency. Definitive surgical treatment requires resection of the narrowed aortic isthmus, with end-to-end anastomosis or patch angioplasty using the LSA or prosthetic patch material. Rarely a primary percutaneous balloon angioplasty or endovascular stenting is performed. Antenatal diagnosis is difficult but can identify a proportion of infants with features suggestive of coarctation, who can be stabilized prior to clinical deterioration by commencing prostaglandin therapy at birth. Less severe forms of isthmus narrowing, or those with an extensive collateral supply may present later in life, sometimes with resistant arterial hypertension (Fig. 46.3). A collateralized circulation is not developed at the time of birth because the aorta is not obstructed in utero, but may develop in those with less severe obstruction over weeks and months. Coarctation may occur in combination with other forms of CHD, most notably bicuspid aortic valve in approximately 50% of patients (conversely coarctation occurs in approximately 5% of patients with bicuspid valves). Turner syndrome is the most frequent chromosomal abnormality associated with coarctation. This, together with the male preponderance suggests an X-chromosome dosage effect.[7,8]

Interrupted aortic arch (IAA) is characterized by complete luminal discontinuity in the aortic arch; it is morphologically subdivided according to the location of the interruption. Type A is interrupted at the level of the aortic isthmus, after the LSA (20%); Type B is interrupted in the distal transverse arch between the left common carotid and LSA (75%), Fig. 46.4; and Type C is interrupted in the proximal transverse arch, between the innominate artery and left common carotid (5%). IAA is a developmentally different entity to coarctation and is more frequently associated with other complex cardiac lesions and genetic abnormalities. The prevalence of IAA is 0.4 per 10,000 births, and it represents 0.6% of all CHD (Table 46.1).[6] DiGeorge syndrome (22q11 deletion) is the most frequently associated chromosomal abnormality. IAA shares medical and surgical management strategies with coarctation but has a higher rate of reintervention.[9,10]

Hypertension after coarctation repair

Large studies published in the late 1980s and early 1990s identified an emerging problem among patients who had undergone surgical repair of coarctation—a very high prevalence of hypertension, Table 46.2. An increased rate of hypertension also appears likely for IAA, despite limited

FIGURE 46.2 Aortic arch morphological variations. (A) Left aortic arch with aberrant right subclavian artery (0.5% of population). There is persistence of segment A with atresia of segment B and C (see Fig. 46.1B). (B) Right aortic arch with mirror image branching caused by atresia of segment H (see Fig. 46.1B), is seen in 2%−3% of the population. (C) Right aortic arch with aberrant left subclavian artery is due to the absence of the fourth arch on the left side (segments F and G, Fig. 46.1B) with persistence of segments A and H. The aberrant left subclavian artery has a retroesophageal course and forms an incomplete vascular ring if the arterial duct is right sided. However, in the presence of a left-sided arterial duct connecting the origin of the aberrant subclavian artery to the left pulmonary artery, the vascular ring becomes complete. (D) Double aortic arch (DAA) is the most common cause of tracheoesophageal compression. Here, persistence of segment A (see Fig. 46.1B) will result in a DAA completely encircling the trachea and esophagus, sometimes leading to severe obstruction. Each aortic arch gives rise to respective common carotid and subclavian arteries.

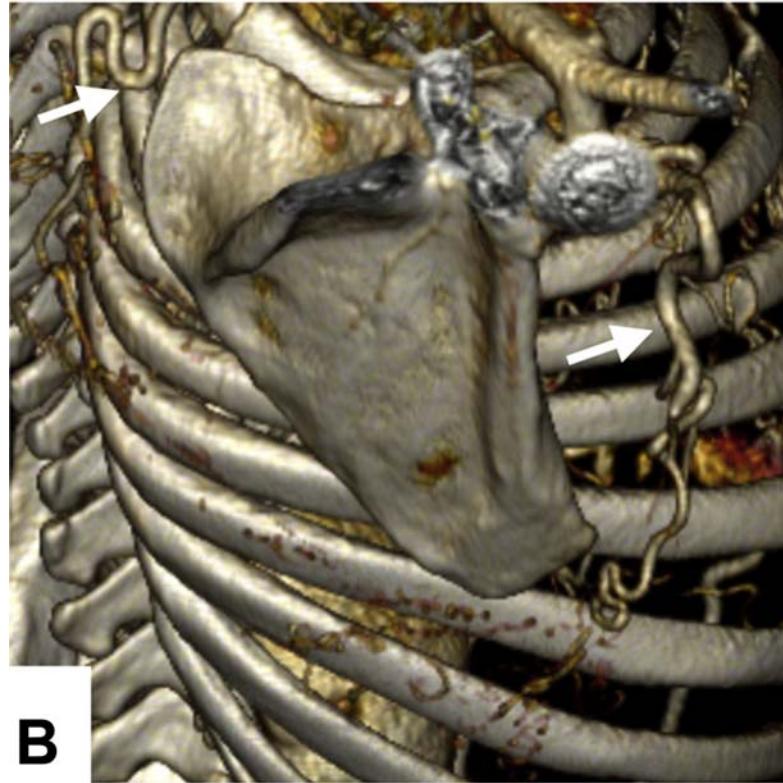
TABLE 46.1 Prevalence and percentages of common forms of congenital heart disease.

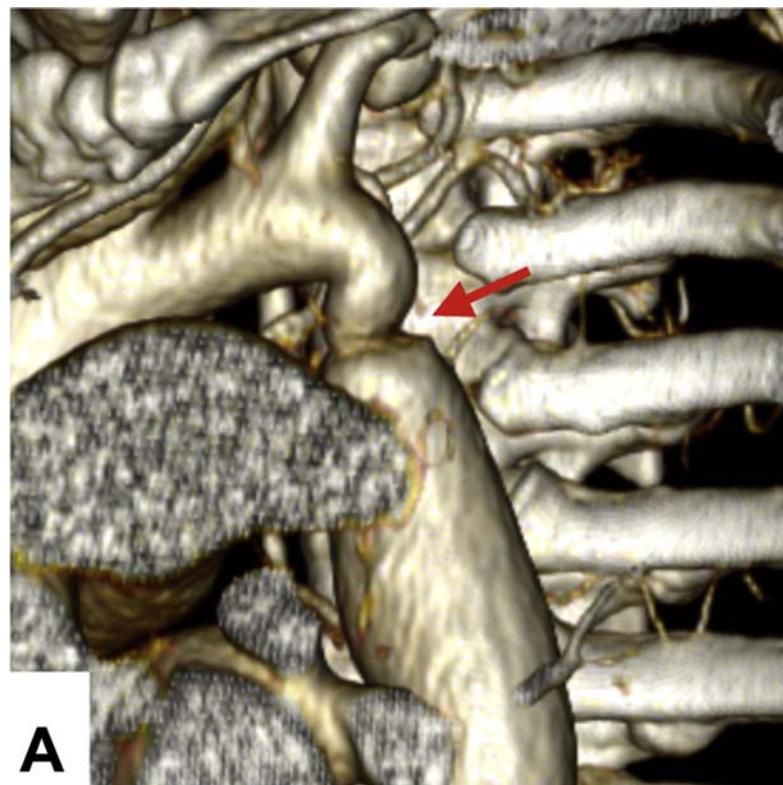
Congenital heart disease subtype	Prevalence of congenital heart disease subtype per 1000 (95% confidence interval)	Percentage of congenital heart disease subtype, % (95% confidence interval)
Ventricular septal defect	3.07 (2.85−3.31)	35.6 (33.9−37.3)
Atrial septal defect	1.44 (1.22−1.69)	15.4 (13.5−17.4)
Patent ductus arteriosus	1.00 (0.80−1.23)	10.2 (8.5−12.0)
Pulmonary stenosis	0.55 (0.49−0.61)	6.2 (5.7−6.8)
Tetralogy of Fallot	0.36 (0.33−0.39)	4.4 (4.1−4.8)
Transposition of the great arteries	0.30 (0.27−0.32)	3.8 (3.4−4.2)
Atrioventricular septal defect	0.29 (0.27−0.32)	3.6 (3.3−3.9)
Coarctation of the aorta	0.29 (0.26−0.31)	3.6 (3.3−3.9)
Interrupted aortic arch	0.04 (0.03−0.05)	0.6 (0.4−0.8)

Adapted from Liu Y, Chen S, Zühlke L, et al. Global birth prevalence of congenital heart defects 1970-2017: updated systematic review and meta-analysis of 260 studies. **Int J Epidemiol** 2019; 48:455−463.

data. A recent systematic review has estimated the prevalence of hypertension in adults following coarctation repair as 32.5% (range 25%−68%),[a] which is significantly higher than expected for equivalent groups of teenagers and young adults without coarctation.[11] By contrast, the estimated UK prevalence of hypertension is: 1% between 16 and 24years; 11% between 15 and 34years; and 18% between 35 and 44 years of age (*BHF statistics compendium 2019*). In the USA, the prevalence of hypertension among 18−39 year olds is 7.5% (*CDC 2015−16*).[12]

A large contemporary study from Sweden using a national registry (n = 653), found hypertension in 53% of adult patients, raising the possibility earlier studies have underestimated the extent of the problem.[13] Similarly high levels were also reported recently by Lee et al.[14] in a large single center study of 834 patients. Systemic hypertension was present in 57% (375/661) and prehypertension in a further 13% (83/661) of patients. Risk factors for elevated blood pressure included age, sex, and age at repair and residual coarctation. Thirty-six percent of patients (289/796) were on at least one antihypertensive medication. Hypertension was found to be difficult to treat; multiple medications were required in 10% (2 mediations), 4% (3 medications), 2% (4 medications), and 0.3% (5 medications) of patients. It is of great concern that only 18% (50/279) of patients on antihypertensive medication were normotensive.

The average age of repair in studies covering the period 1960−1980 was significantly older than current practice. However, a trend toward earlier coarctation repair was already emerging at this time: Koller et al.[15] reported that




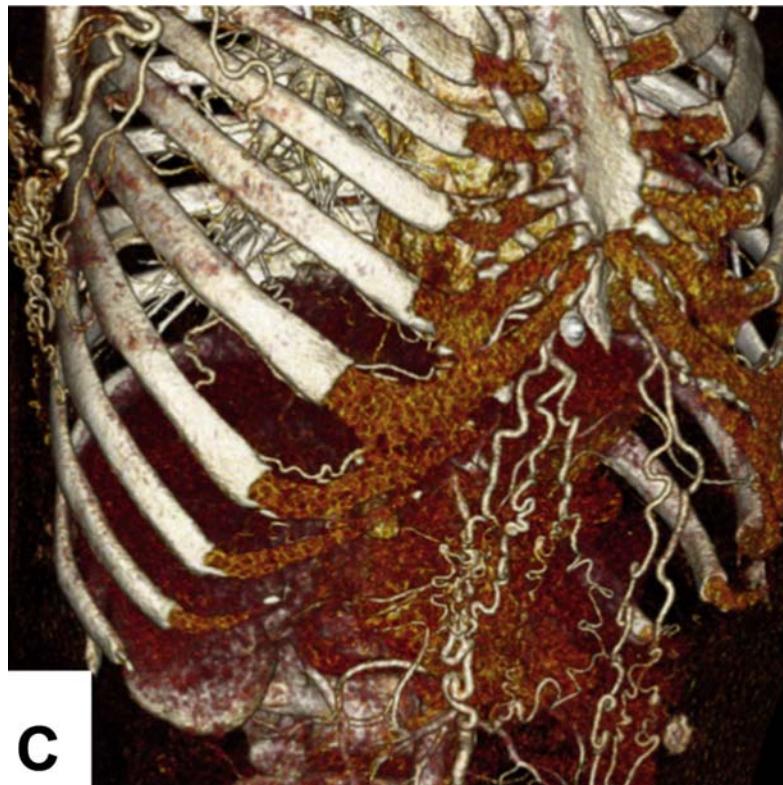
the percentage of patients operated before age two years of age doubled from 12% in the period 1961−70, to 26% in 1971−80. In a contemporary cohort (Great Ormond Street Hospital for Children, 2004−20), the median age of repair was 25 days (IQR eight days−six months), with 83% of infants repaired under two years (unpublished data from author's institution).

The trend to earlier coarctation repair was facilitated by two major developments in CHD practice during the 1970s and 1980s. First, infants with severe coarctation could now be resuscitated and stabilized using prostaglandin infusions to dilate the ductus arteriosus, thus providing the first effective emergency therapy for duct-dependent cardiac lesions.[16−19] The second important development was the ability to more easily diagnose infants with arch obstruction noninvasively by the proliferation of echocardiography.[20]

An understanding of the evolution of clinical practice during the latter part of the 20th century is important because many patients with severe coarctation died in infancy and are underrepresented in early studies. Samples in earlier studies are therefore dominated by groups of patients who survived infancy (due to less severe disease) but had been exposed to a hypertensive ascending aorta (and cerebrovascular circulation) for many years prior to repair. Optimism that early repair may mitigate the high prevalence arose from an observation that younger patients appeared to have a lower prevalence of hypertension.[15,21,22]

Unfortunately, the view that earlier surgery would completely mitigate the increased risk of hypertension has not been realized. A large study of children by O'Sullivan et al.[23] showed that approximately 30% of the cohort operated on in infancy (median age of 2.6 months [IQR 0.5−48 months]) had significantly elevated blood pressure, based on either office or ambulatory readings, when followed up at a mean age of 12 years. Unpublished data from

[a] The age of patients at time of assessment in published studies is variable, but typically less than 40years. There is also considerable variability in the definition of hypertension and inclusion of patients with some degree of residual obstruction.

FIGURE 46.3 Computed tomography (CT) aortogram from adult patient with unrepaired coarctation of the aorta. (A) Narrowed aortic isthmus (*red arrow*). (B) Arterial collaterals on right lateral chest wall and back (*white arrows*). (C) Arterial collaterals on anterior chest wall and abdomen.


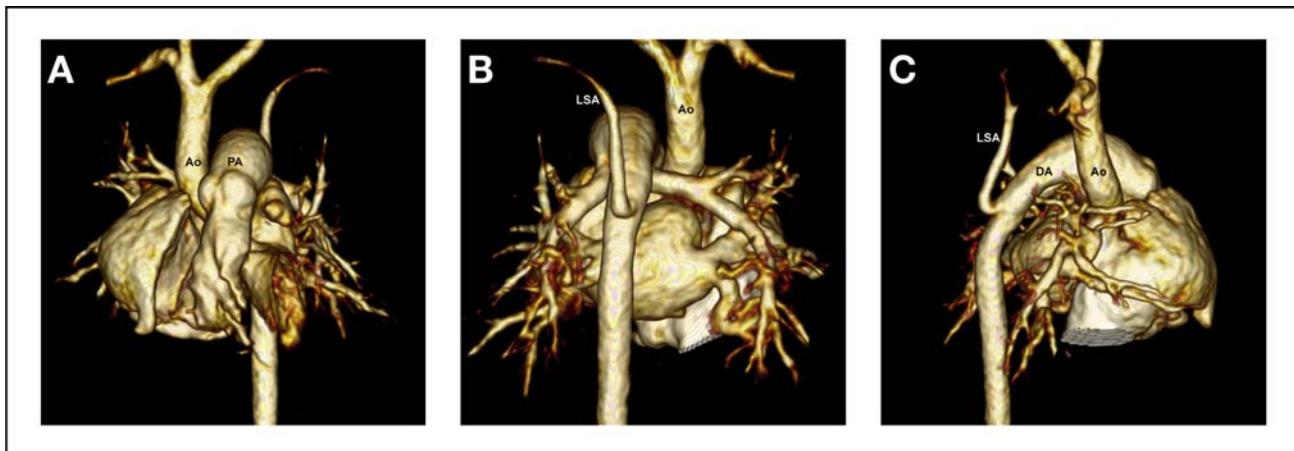


FIGURE 46.3 cont'd.

the author's institution indicate that approximately 20% of children aged 5−7 years after successful neonatal coarctation repair have prehypertension (systolic and diastolic blood pressure >90th centile), Fig. 46.5. These data suggest that even in an era of very early coarctation repair, patients without arch obstruction remain at increased risk for hypertension. Such hemodynamic abnormalities manifest even in early childhood, but unfortunately the underlying mechanisms are unclear.

Cardiovascular morbidity

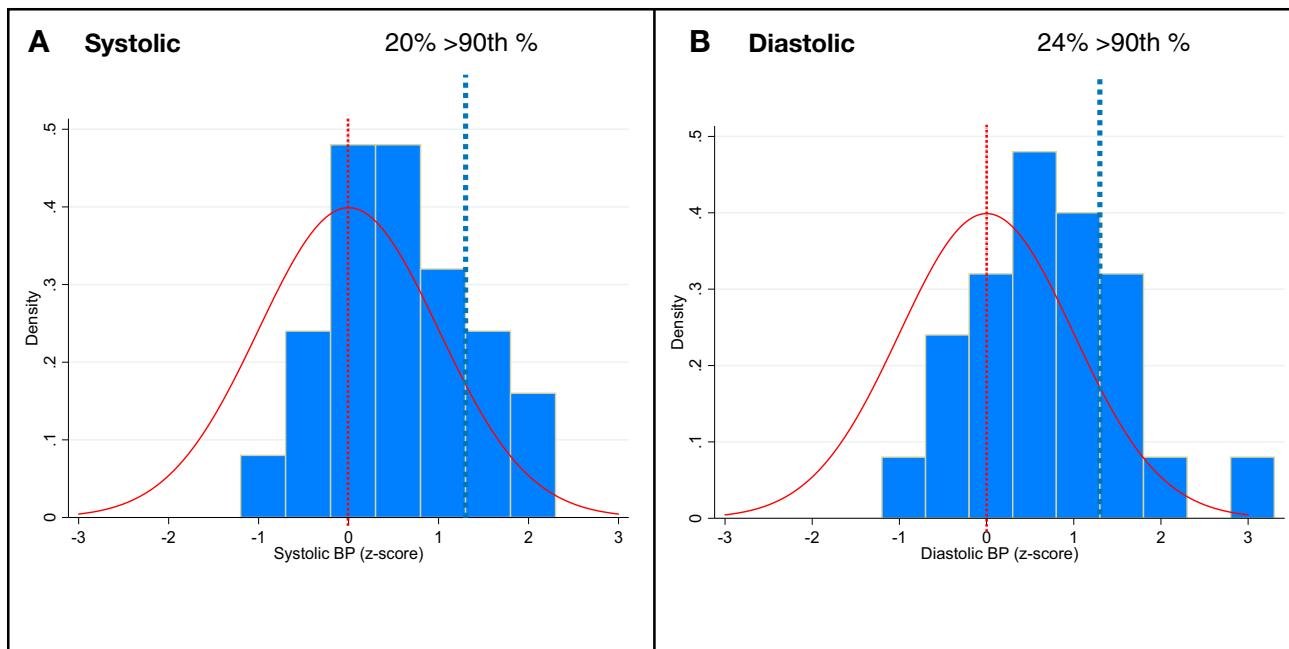
Patients with repaired coarctation of the aorta exhibit higher rates of cardiovascular disease.[21,24−28] A systematic review


FIGURE 46.4 Computed tomography (CT) aortogram from a neonate with unrepaired Type B interruption of the aortic arch, (interruption of the distal transverse arch between the left common carotid and left subclavian artery). (A) Anterior projection showing the relationship between aorta (Ao) and pulmonary artery (PA), note the absence of the distal transverse aorta. (B) Posterior projection showing origin of left subclavian artery (LSA) from the descending aorta. (C) Lateral projection showing ductus arteriosus (DA) connecting pulmonary artery and descending aorta.

TABLE 46.2 Prevalence of Hypertension in large observational studies of coarctation and interrupted aortic arch.

Author	Year of study	Sample size	Definition of HTN (mmHg)	Residual gradient excluded	Age at operation (year)	Mean follow up (year)	HTN (%)

FIGURE 46.5   Childhood blood pressure in 25 children, mean age 5.8 (SD one year) who underwent neonatal coarctation repair in 2012−14. (A) Distribution of casual systolic blood pressure (SBP), compared to normal distribution according to age and height, 20% had SBP >90th centile. (B) Distribution of diastolic blood pressure (DBP), compared to normal distribution of age and height, 24% had DBP >90th centile.

found a disappointing survival rate of 87.4% at a mean age of 40 years in patients with aortic coarctation, with a particularly increased risk of cerebrovascular events and myocardial infarction.[29] Recent data by Lee et al. in a sample of 834 patients report overall survival of 99%, 88%, and 65% at 30, 50, and 70 years of age, respectively. Survival was significantly reduced compared with a matched normal population (standardized mortality ratio: 3.20, log-rank: $P < .001$).[14] A study by Roifman et al.[30] used registry data to compare patients with coarctation to patients with a repaired ventricular septal defect (VSD). Those with coarctation had higher rates of congestive heart failure (14.8% vs. 7.4%; $P < .0001$), stroke (5.6% vs. 2.6%; $P < .0001$), coronary artery disease (4.9% vs. 3.5%; $P = .04$), and peripheral vascular disease (13.1% vs. 2.7%; $P = .0001$). The authors found that the increased risk of cardiovascular morbidity appeared due, at least in part, to a higher burden of "traditional" cardiovascular risk factors, including hypertension and dyslipidaemia which were disproportionately higher in patients with coarctation.

Pickard et al.[31] examined the relationship between coarctation repair and cerebrovascular events in a cross-sectional study utilizing the US National Inpatient Sample database from 2005 to 2014. Among 4,894,582 stroke discharges, 207 had a diagnosis of coarctation. After adjusting for potential confounders, coarctation patients had strokes at significantly younger age compared with others: 18.9 years younger for all-cause stroke ($P < .001$), 15.9 years younger for ischemic stroke ($P < .001$), and 28.5 years younger for hemorrhagic stroke ($P < .001$). The authors found an increased rate of diabetes in patients with coarctation and confirmed the high prevalence of hypertension.

These concerning data highlight the need for close cardiovascular surveillance of coarctation patients, with mitigation of cardiac risk factors to prevent cardiovascular morbidity and mortality.

They also raise an important question: why are patients at risk of hypertension following successful aortic repair? We will explore this question in the following sections.

Abnormalities of pulsatile hemodynamics

Arterial stiffness—regional effects

Several studies, in the 1990s and 2000s, showed an association between abnormal arterial stiffness and hypertension in patients with coarctation.[32−35] These findings have been extensively replicated and strongly support a role for increased arterial stiffness as a key explanatory variable underlying the increased rates of hypertension in coarctation.[36−40]

In 1997, Xu et al.[41] used intravascular ultrasound at the time of cardiac catheterization to measure the aortic stiffness in patients with coarctation. The authors appear to be the first group to suggest regional variation in arterial stiffness in the aorta of patients with coarctation, showing increased stiffness in the aorta proximal to the coarctation. However, data from this study suggest an important role for different segmental loading conditions. Following balloon dilatation of coarctation, there was a reduction in distal compliance and distensibility as a result of increased distal pressure. This finding demonstrates the influence of loading conditions on stiffness metrics, which is especially problematic in patients with residual coarctation.

In 2001, de Divitiis et al.[33] reported muscular artery stiffness metrics in coarctation patients (n = 64, mean age = 19 ± 9.9; median age at repair = 4 months) and controls (n = 45, mean age = 20 ± 8.1). The authors reported abnormal brachial-radial pulse wave velocity (PWV), but normal femoral-dorsalis PWV. This PWV finding was replicated in a slightly larger study by the same group in 2003. Which also showed a relationship between ambulatory BP and increased LV mass.[32]

Asymmetric upper-lower body stiffness has been reported across different ages, levels of blood pressure, and method of ascertainment.[37,42–44] However, the role of different segmental loading conditions has not been sufficiently resolved.

It remains an unanswered question whether the increased proximal stiffness is congenital or acquired. However, data from children suggest that the phenomenon occurs early.[43,45]

Central pressure and total arterial compliance

It is well recognized that brachial systolic blood pressure (SBP) usually overestimates central SBP due to patient specific pressure augmentation, and there is some evidence that central SBP is a better predictor of cardiovascular risk.[46] Limited data exist on the correct assessment of central blood pressure in CHD, especially in the presence of regional variations in stiffness which may affect pulse pressure amplification.

One approach to estimate central aortic blood pressure is to use cardiovascular magnetic resonance (CMR)-derived area-time data in the ascending aorta, calibrated to brachial mean and diastolic pressure using an exponential model of the pressure-area relationship.[47] This method avoids the use of a generalized transfer function, which may not be valid in patients following coarctation repair.[48]

The possibility of CMR-derived central pressure and simultaneous aortic flow makes it feasible to possible to perform a comprehensive, noninvasive, assessment of central arterial hemodynamics. A single breath-hold flow acquisition with simultaneous oscillometric blood pressure provides data to calculate: central aortic pressure, systemic vascular resistance (SVR) (MAP/cardiac index); total arterial compliance (TAC) (2-element Windkessel model using central pulse pressure and aortic flow); PWV/characteristic impedance (Bramwell–Hill equation, using delta area and pulse pressure); and wave intensity analysis (WIA).

Quail et al.[49] used this technique in a study of coarctation patients (median age = 22 years; IQR 20–28) without arch obstruction and representative of those repaired in the 1990s. These patients were slightly older at repair than current cohorts (described above): median age at repair was 4.0 months (IQR 0.5–48.2 months); 68% had their repair <2 years of age. The main findings of this study were that compared to healthy controls, patients with repaired coarctation showed evidence of an aortopathy associated with elevated central SBP, decreased TAC, increased ascending aorta local PWV and increased backwards compression waves (BCWs), without differences in aortic root characteristic impedance (due to an increased aortic root size). Despite similar brachial blood pressure, central SBP was on average 6 mmHg higher in patients.

Conflicting data have arisen in studies using the SphygmoCor device to assess central hemodynamics using radial applanation tonometry. Swan et al.[40] measured central blood pressure in postcoarctation repair patients and normal volunteers, and in contrast to the study by Quail et al.,[49] no difference was observed in c-SBP. However, this may be partly due to their exclusion of any patient with high brachial artery blood pressure. By contrast, Szczepaniak-Chicheł et al.[50] studied 85 patients with repaired coarctation and found higher c-SBP, PWV, and augmentation index. Unfortunately, despite the many advantages of such devices, the validity of a generalized transfer function in patients with CHD remains uncertain. In particular, generalized transfer functions may not adequately control for the abnormal wave reflections that may be present in patients postcoarctation repair.[48,51]

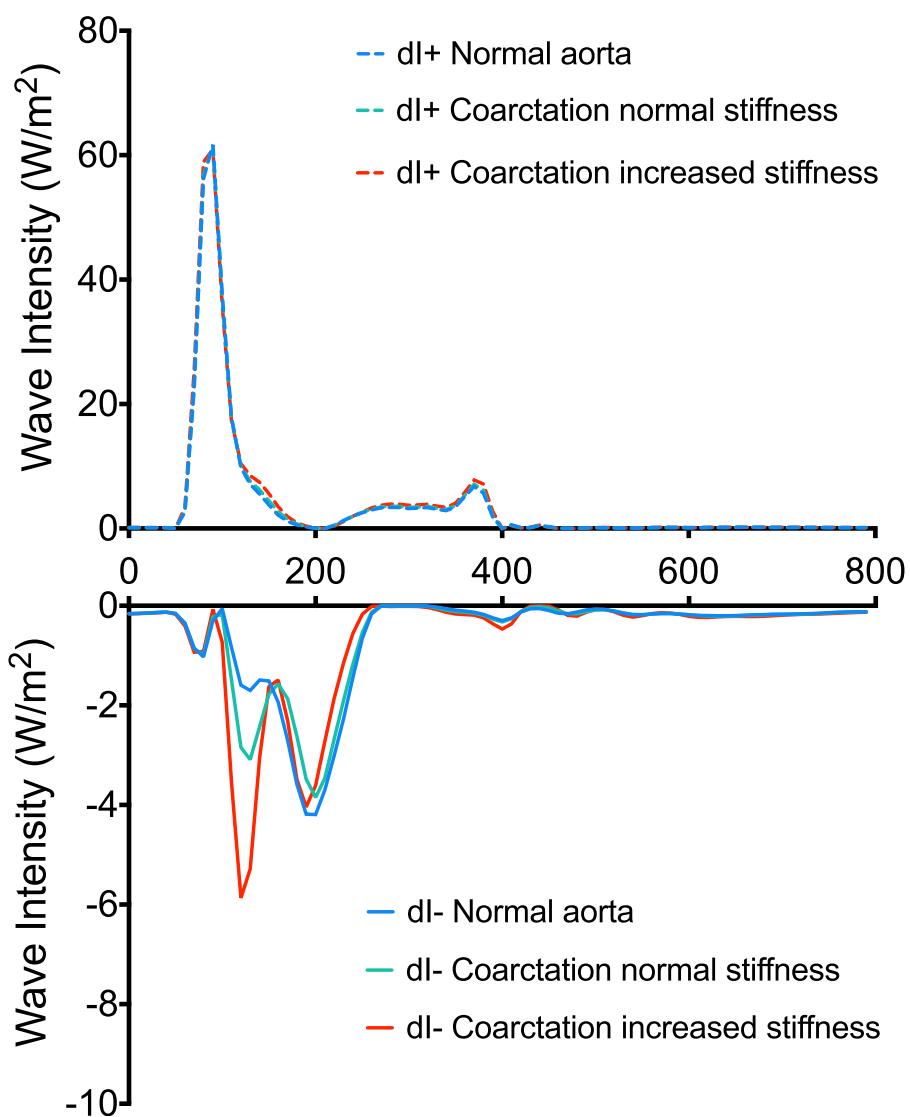
Murakami and Takeda recruited 20 patients following coarctation or IAA repair and age-matched controls who had not undergone aortic surgery. Aortic pressure was measured invasively during cardiac catheterization. Compared to controls, patient with arch repairs had higher SBP (105.2 ± 12.2 vs. 94.7 ± 11.7 mmHg, P = .0018) and pulse pressure (40.4 ± 7.2 vs. 32.7 ± 5.3 mmHg, P = .0004). Patients also had increased augmentation index (27.5 ± 15.4 vs. −3.47 ± 8.8%, P < .0001), suggesting increased wave reflection.

Data from the preceding chapter sections indicate that hypertension manifests prematurely in patients with coarctation as a consequence of early aortic stiffening. However, the hemodynamic abnormalities are not limited to increased pressure and aortic stiffness, but also other elements of aortic input impedance which are less frequently considered, such as aortic wave reflections.

Aortic wave reflections

Experimental occlusion of the thoracic aorta in animals has been shown to result in partial reflection of the early systolic forward compression wave, thereby increasing ventricular afterload.[52–55] Similar findings have also been observed in humans with unrepaired coarctation at the time of cardiac catheterization and surgery.[54]

After surgical repair of coarctation, the presence of increased wave reflection has been inferred based on abnormal augmentation index or semiquantitative assessment of aortic flow curves.[38,40,56,57] However, augmentation index may not be a reliable index of wave reflection, since it

has a major dependence on both aortic wave speed, forward wave amplitude, and left ventricular function. Unfortunately very few studies have investigated simultaneous pressure and flow relationships.[58]


Recently, it has been shown that WIA can be performed noninvasively using image-based measures of arterial distension and blood flow.[49,59−61] The initial implementation by Feng and Khir relied on ultrasound imaging; however, phase contrast magnetic resonance (PCMR) can also provide accurate measures of distension and flow (see Chapters 2 and 4).[62] Unfortunately, high temporal resolution data are necessary to accurately assess wave speed, and this conventionally requires long free breathing acquisitions which may be associated with image blurring due to bulk motion of the aortic root through the imaging plane.[63]

Using high temporal resolution PCMR in the ascending aorta, Quail et al. performed WIA using flow (Q) and area (A) waves.[49] The authors found that patients with coarctation had evidence of higher BCWs compared to controls, and that the magnitude of the BCW was an important explanatory variable of LV mass in the sample. It is speculated that these reflections arise from reflection sites in repaired the aortic arch. To support this thesis, one-dimensional (1D) computer models were used to simulate the repaired aortic arch: First, the diameter of a segment in the descending aorta was reduced by 25% to mimic a mild residual aortic coarctation, while maintaining the normal distensibility. Second, the stiffness of the narrowed section was increased by five orders of magnitude to mimic the effect of a stiffened coarctation repair zone. Using this model, the authors observed an increase in backwards reflections in mild coarctation which was significantly increased in the presence of a stiffened segment (Fig. 46.6). These data are in keeping with the more sophisticated FSI modeling study by Taelman et al.[64]

Mynard et al.[65] have performed detailed experimental and computer modeling studies of wave reflection in

FIGURE 46.6 A validated one-dimensional (1D) model of the systemic vascular tree was used to explore differences in wave reflection between controls and patients following coarctation repair. The model solves the 1D Navier–Stokes equations and provides pressure and flow waveforms along the arterial tree. The model was run using a time-varying elastance model for the heart on its upstream boundary, such that simulated waves originate from the interaction of the pumping heart in the arterial tree. Apart from the baseline condition (Blue) using default parameters for the model (default lengths, inlet and outlet diameters, and arterial distensibility), two additional scenarios were simulated. First, the diameter of a segment in the descending aorta was reduced by 25% to mimic a mild residual aortic coarctation, while maintaining the normal distensibility (Green). Second, the stiffness of the narrowed section was increased by five orders of magnitude to mimic the effect of a stiffened coarctation repair zone (Red). Positive (dI+) and Negative wave intensity (dI−) in 1D simulation. Units of wave intensity are conventional W/m². Note scale of dI− increased relative to dI+ to assist visualization. In the coarctation models, increased backward compression waves are observed, which increase in magnitude in the presence of stiffened segment.

coarctation with particular reference to the effects of wave reflection on the cerebral circulation. Their study investigated the hypothesis that the BCW is not only reflected back toward the heart but also partially transmitted into cerebral circulation. The authors measured simultaneous pressure and flow in the aorta and brachiocephalic trunk (BCT) of eight sheep with surgically induced coarctation of two severities: (A) 10 mmHg and (B) 25 mmHg mean pressure increase in ascending aorta. Using wave power analysis,[66] it was shown that aortic constriction produced not only an aortic BCW, but also a second forward compression wave in the BCT that augmented pressure and flow after the initial forward compression wave, which increased with increasing coarctation severity.

In further mathematical and computational analyses, the authors investigated the effects of altering the stiffness of the head and neck vessels to examine the influence on wave transmission to the cerebrovascular system and on LV load. The authors discovered that stiffer or smaller head and neck vessels (i.e., with lower admittance, which is the inverse of impedance) had two important effects: (1) Greater transmission of FCW from the ascending aorta to aortic isthmus, and also greater reflection of BCW from the aortic isthmus to ascending aorta. Both of these mechanisms would tend to increase the impact of wave reflection on LV load; (2) Increased transmission of waves toward the brain with increased aortic stiffness was reversed or ameliorated when stiffness in the head and neck branches was also increased. Although this reduced peak flow pulsatility in the carotid artery, it increased pulse pressure and flow pulsatility in the middle cerebral artery.

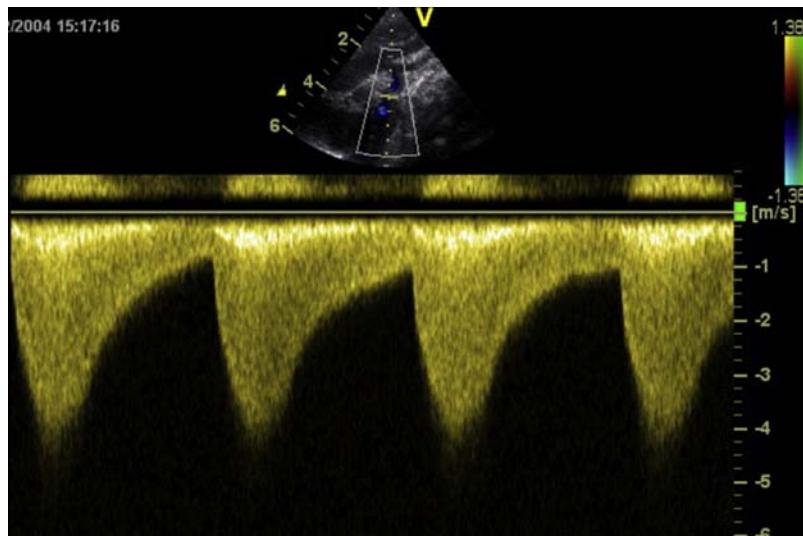
This group complemented this experimental work with an observational study of head and neck wave reflection in patients with coarctation. Kowalski et al.[67] showed that coarctation subjects had higher brachial and central SBP ($P = .04$), with lower aortic compliance and increased characteristic impedance (Z_c). Aortic distensibility was the only independent predictor of central aortic SBP on multivariable analysis. In agreement with their modeling work, carotid forward compression wave power was higher and was negatively correlated with aortic compliance ($r^2 = 0.42$, $P < .001$) and distensibility ($r^2 = 0.37$, $P = .001$) in coarctation subjects. Although carotid intima-media thickness was higher ($P < .001$), carotid biomechanics were no different.

In contrast to Quail et al.,[49] aortic wave power and wave reflection indices were not different in control and coarctation patients. The reasons for this difference could be related to factors such as differing imaging modalities (magnetic resonance imaging vs. ultrasound) and acquisition locations (ascending aorta vs. transverse aortic arch), or more likely—differences in patient characteristics which are typical in the coarctation literature. Another possibility is different carotid stiffness in the samples which could

affect reflection to the ascending aorta according to their modeling study. Increased aorto-carotid transmission of wave energy following surgical repair of aortic coarctation may contribute to the high rates of cerebrovascular disease in this group. This work contributed substantially to our understanding of possible biomechanical mechanisms of cerebrovascular disease in coarctation patients.

Geometric considerations

Aortic arch obstruction

Residual aortic arch obstruction (residual or recurrent stenosis at the repair site) can occur in patients with coarctation and results in increased proximal aortic pressure. A contemporary study found arch obstruction in 15% of patients using a conventional definition of a Doppler-derived peak gradient >25 mmHg.[68] However, studies which have specifically excluded patients with residual obstruction still demonstrate an increased risk of hypertension (Table 46.2).


Arch obstruction can be identified using routine clinical assessments, including clinical imaging (Doppler echocardiography or cross-sectional imaging) or clinical measurements (brachial-ankle BP gradient). An interesting phenomenon in echocardiographic imaging of native or recurrent coarctation is the presence of continuous diastolic flow distal to the coarctation site (Fig. 46.7). The pattern is traditionally ascribed by cardiologists to the severity of the stenosis. However, the phenomenon is better understood in terms of a Windkessel, with consideration given to both the resistance of the coarctation and the proximal aortic compliance.[69] Conceptualized in this way, the presence of diastolic flow is related to the RC time constant. Patients with severe stenosis but significantly reduced proximal compliance may not manifest this echocardiographic finding, due to a lower RC time constant and more rapid diastolic pressure decay.

Abnormal aortic shape without obstruction has also been implicated as a significant mediator of increased load after coarctation repair.[38,39] Quenelle et al. found that persistent, mild aortic arch hypoplasia, even in the absence of an arm-leg SBP difference at rest, is also associated with late systemic hypertension.[70] Acute arch angulation (the gothic arch) has also been proposed as an important determinant of increased load and hypertension.[38,39] In particular, the gothic arch has been associated with exercise hypertension and abnormal flow profiles that are suggestive of increased wave reflections.[38,39] However, other studies have demonstrated no relationship between shape and exercise hemodynamics.[71]

Types of repair

As described briefly in the background section, aortic coarctation may be repaired via a number of surgical techniques, including end-to-end anastomoses (with

FIGURE 46.7 Continuous wave Doppler flow profile in the proximal descending aorta in a patient with unrepaired coarctation of the aorta (closed ductus arteriosus). There is increased velocity and continuous antegrade flow in diastole which is related to the severity of the stenosis and the compliance of the proximal aorta.

variable augmentation of the transverse arch, so-called extended end-to-end anastomosis), subclavian flap aortoplasty (the subclavian artery is used to augment the narrowed isthmus), or prosthetic material patch repairs (e.g., Dacron, GoreTex). Each of these approaches will affect the aortic geometry and regional stiffness. While it is possible that variation in surgical strategy may influence hypertension risk, the evidence for this is currently limited.[72] A recent prospective study compared vascular phenotypes in patients treated by either surgery, balloon dilatation, or endovascular stenting, and found no significant group differences.[73]

Three-dimensional shape and hemodynamics

The analysis of complex three-dimensional (3D) shape is difficult; the aorta is a curved tube with continuous variation in curvature and radius along its length.[74,75] Unfortunately, the coarctation literature suffers from evaluations of aortic shape which are often qualitative (i.e., identification of a gothic arch) or overly simplistic (i.e., simple height/width ratios). This may be why several studies have produced contradictory results regarding the link between shape and hemodynamic parameters.[71] Curvature and "shape" are often conflated with most definitions of abnormal shape actually relating to curvature. Using principal component analysis, Quail et al.[76] recently analyzed the relationship between the two components of 3D shape (curvature and radius) and pulsatile hemodynamics including wave reflections. Using this methodology, the authors found no association between principle components of curvature and abnormal wave reflection, suggesting that the so-called Gothic arch is less important than suggested by other groups. By contrast, principle components of radius were associated with the magnitude of the BCW.

Specifically, a large ascending aorta (associated with bicuspid valves), transverse arch hypoplasia, and a relatively smaller descending aorta were all associated with an increased magnitude of BCW.

The fact that curvature does not significantly influence wave reflections is not surprising from a mechanical point of view. The wave lengths of pressure and flow waves are in the order of meter, much larger than the geometrical dimensions of the aorta and its bends and curves. This explains why arterial wave dynamics are very well described using 1D formulations of the momentum equations.[77]

What causes the arterial abnormalities arise in coarctation?

In the previous sections, we have explored the data which show that patients with repaired coarctation have a very high prevalence of hypertension, and this appears to be due to an underlying vasculopathy characterized by reduced TAC, increased ascending aorta PWV, and pathological wave reflections.

However, it is still unexplained why patients develop this vasculopathy, given successful early repair of coarctation. In order to effectively reduce the excess cardiovascular risk in this population, it is important that this question is answered, although currently there are little explanatory data.

Congenital stiffness or control of systemic vascular resistance?

A commonly held view is that the aorta in coarctation is congenitally noncompliant. While this is a possibility, it is difficult to separate from transient abnormalities of arterial function in the perioperative period.[43,45]

Unpublished data from the author's institution showed a 20% incidence of prehypertension (casual SBP and DBP >90th centile) in 5—7-year-old children. These children had proportional elevations in SBP and DBP (and thus increased mean pressure, rather than pulse pressure), likely due to higher SVR. This pattern contrasts with older patients, in whom the predominant hemodynamic mechanism of hypertension is reduced TAC with normal SVR, characterized by a widened pulse pressure and a stiff aorta.[49]

The presence of elevated SVR is strongly suggestive of abnormal renal and autonomic control mechanisms. Infants with coarctation are at increased risk of renal injury at the time of aortic surgery due to either preoperative cardiogenic shock or renal ischemia due to aortic cross clamp.[78–80] Unfortunately, there are no long-term studies assessing the relationship with incident hypertension.

A role for autonomic dysfunction in coarctation is suggested by the presence of abnormal stress responses in patients with coarctation, in particular during exercise.[34,58,71,81] However, the underlying mechanisms are unclear, and could include the effect of increased stroke volume in a system with markedly reduce TAC. Alternatively, abnormal autonomic control mechanisms may be operating in children following coarctation repair.[28,82–84] Reasons for afferent baroreflex dysfunction in coarctation include abnormal antenatal baroreflex development (developmental programming), vagal nerve injury (aortic arch manipulation), or injury to descending inhibitory pathways due to subclinical spinal ischemia during aortic cross clamp.[65,66]

Evidence for neurohumoral abnormalities is suggested by a study of children by Hauser et al.[85] The cardiovascular response to the sympathomimetic, isoprenaline, is characterized by an increased heart rate and a reduction in blood pressure due to vasodilation. In a study of children with repaired coarctation (mean age 11.3 ± 6 years), 20% experienced a "paradoxical" increase in BP to isoprenaline. These children also had an elevated plasma renin activity response to exercise and high rates of early, transient, postoperative hypertension. These data suggest that abnormal responses to physiological stress in late childhood may be mediated by abnormal activity of the RAS and autonomic nervous system.

Assessment of endothelial function by flow-mediated dilatation has featured heavily in many studies of coarctation and has suggested the presence of endothelial dysfunction in patients,[33,34] as summarized in Table 46.3. However a recent careful study of contemporary patients, including half who had a diagnosis of hypertension, demonstrated no abnormalities of endothelial dysfunction by either reactive hyperemia or circulating endothelial progenitor cells.[86]

Evolution to vasculopathy—inflammation and biomechanics

Although congenital stiffness, renal, autonomic or neurohumoral abnormalities could explain the initiation of hypertension in coarctation, they do not fully explain the increased rate of aortic stiffening with age in coarctation, Fig. 46.8.

Inflammation is emerging as an important risk factor for the development of large artery stiffness and hypertension. In the general adult population and in other specific disease groups, systemic inflammation is associated with increased large artery stiffness.[87–93]

Conventionally, hypertensive vascular remodeling has been ascribed to smooth muscle cell hypertrophy and medial collagen deposition by these cells.[94] However, there is a growing body of knowledge that points to inflammation within the adventitia as a significant and perhaps even the principal contributor to pathological hypertensive remodeling.[95–97] The underlying idea is that adventitial inflammation switches the normal adaptive response to hypertension (increased wall thickness) to an exaggerated and maladaptive process.[98,99]

Variation in a child's systemic inflammatory state may potentiate maladaptive remodeling caused by elevated blood pressure in coarctation. Acute inflammatory stimuli in coarctation may include SIRS due to surgery or cardiogenic shock, or chronic inflammation due to renal dysfunction.[100–102] Additional variability in childhood systemic inflammation has many causes, including infections/vaccinations, obesity, psychological stress, and poverty.[103–106]

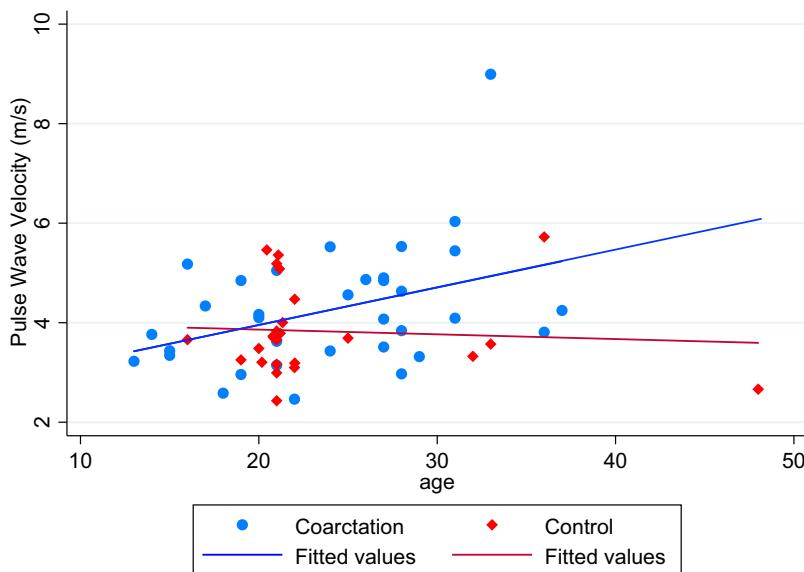
Both systemic and aortic inflammations have also been described in adults after coarctation repair; however, their role in the development of aortic stiffness is unclear.[45,86,107–110] While increased inflammatory biomarkers have been reported, there has not been an unambiguous relationship demonstrated with either hypertension or stiffness, Table 46.1.

Vascular abnormalities in other forms of congenital heart disease

Compared to coarctation of the aorta, the literature related to other forms of CHD is sparse.

Tetralogy of fallot

TOF is the most common form of *cyanotic* CHD, occurring in 36 per 10,000 live births. Morphologically the principal defect of this condition is anterocephalad deviation of the muscular outlet septum resulting in the tetrad of, VSD, pulmonary outflow tract obstruction, overriding aorta, and right ventricular hypertrophy. Complete repair of TOF was devised over 50 years ago and can result in complete intracardiac repair in early infancy. However, despite excellent short- and medium-term survival rates, the 30-year actuarial survival for patients repaired before their fifth birthday is 90% of the expected survival rate and the annualized risk of death triples in the third postoperative decade.[111,112]

TABLE 46.3 Selected studies of inflammatory and vascular function biomarkers in coarctation of the aorta.


Study	Year	Type of study	Biomarkers	Vascular biomarkers	Disease status	Mean age	Cases, N (% males)	Pulse wave velocity	Pressure	Aix	Other vascular	Serum findings	Notes
Brili (atherosclerosis)[109]	2005	Case-control	IL-1b, IL-6, sVCAM-1, sICAM-1, E-Selectin	Flow mediated-dilatation (FMD)	Normotensive coarctation patients, age operation 17.7 years	29.9	15 (30%)				Higher IMT and lower carotid distensibility in coarctation versus control. Lower FMD in coarctation versus control	Coarctation versus control: higher sICAM-1, higher sVCAM-1, higher IL-1b, higher E-selectin. (No difference, CRP, fibrinogen, IL-6)	No explicit linear relationships between serum inflammation and stiffness metrics
Osmancik (Endothelium)[130]	2006	Case-control (pediatric)	IL-6, sE-Selectin, sL-Selectin, sICAM-1		Mean age at operation 7.7 years (3–12.8). Pre- and postoperative samples		17 (82%)					sICAM-1 higher in coarctation than controls at 10 months. No differences pre- or postoperative in adhesion molecules or IL-6.	Postoperative samples 10 months after surgery
Brili (JACC)[108]	2008	Randomized cross-over trial: Ramipril 5 mg/day four weeks	IL-1b, IL-6, sCD40L, sVCAM-1, CRP	Flow mediated-dilatation (FMD)	Normotensive coarctation patients, age operation 13.4 years	27.3	20 (65%)		Reduced systolic pressure with ramipril versus control: 110 versus 121 mmHg		Improved flow-mediated dilatation with ramipril	Reduced: IL-6, IL-1b, sVCAM and sCD40L with ramipril	
Brili (Heart)[131]	2012	Open-label: atorvastatin 10 mg/day four weeks	IL-1b, IL-6, sVCAM-1	Flow mediated-dilatation (FMD)	24% hypertensive in atrovastatin arm, age repair 10 years	31.4	17 (60%)	—	—	—	Improved flow-mediated dilatation with atorvastatin		Reduction in IL-1b and sVCAM-1 in atorvastatin

Study	Year	Design	Biomarkers	Vascular method	Population							
Mizia-Stec (IJC)[110]	2012	Case-control	Asymmetric dimethylarginine (ADMA), hsCRP	Flow-mediated dilatation (FMD), intima-media thickness, PWV	47% hypertensive, age operation 11.1 years.	34.1	62 (60%)	Higher pulse wave velocity (PWV) in patients than controls (higher PWV in hypertensive cases)		Lower FMD in patients versus controls, higher IMT in hypertensive coarctation	ADMA and CRP higher in hypertensive patients than not-hypertensive (also higher than controls)	Inverse linear relationship between ADMA and FMD. No relationship with CRP (personal communication with author)
Moutafi (IJC)[132]	2012	Case-control	IL-1b, IL-6, sVCAM-1, sICAM-1, E-Selectin, IL-10, Endothelin-1, TNF-alpha	Flow mediated dilatation (FMD), Sphygmocor: PWV, Aix	Mean systolic blood pressure (SBP) 130 ± 19 mmHg, age operation 7.4 years	25.3	19 (47%)		Higher AIx in patients versus controls	Lower FMD in patients versus controls, lower aortic distensibility and higher stiffness index in patients versus controls	Higher inflammatory markers in patient than controls (except IL-6, sFAS, ET1 and TNF-alpa)	No explicit linear relationships between serum inflammation and stiffness metrics
Moutafi (IJC)[133]	2014	Case-control (pediatric)	IL-10, IL-6, TNF-alpha, sFAS, Endothelin-1, sICAM-1, sVCAM-1, E-Selectin			9.1	10 (60%)			No differences in aortic distensibility or stiffness between cases and controls	Elevated IL-10, IL-6, TNF-alpha and sFas in patients. No differences in endothelin-1 or soluble adhesion markers	
Radke (Heart)[86]	2014	Case-control	IL-6, IL-8, ICAM-1, VCAM1, MCP1, VEGF. Circulating endothelial progenitor cells	Peripheral arterial tonometry	50% hypertensive. Mean age at operation seven years	35	20 (80%)			No differences in peripheral tonometry or EPCs between hypertensive and normotensive patients	Only MCP-1 higher in patients compared to controls

TABLE 46.3 Selected studies of inflammatory and vascular function biomarkers in coarctation of the aorta.—cont'd

Study	Year	Type of study	Biomarkers	Vascular biomarkers	Disease status	Mean age	Cases, N (% males)	Pulse wave velocity	Pressure	Aix	Other vascular	Serum findings	Notes
Wybraniec (JASH)[134]	2014	Case-control	Renalase, CRP	Sphygmocor: PWV, AIx. Intima-media thickness	Dacron patch repair. 42% hypertensive. Median age at operation 10 years.	33	50 (62%)	Higher PWV in hypertensive cases	Inverse correlation between renalase and pulse pressure			Higher CRP in cases than controls. Significant association between CRP and diagnosis of hypertension: OR 1.13 (1.03—1.23) [per 1 mg/L increase in CRP]	
Brili (IJC)[42]	2016	Case-control	TGF-beta, IL-6	Sphygmocor: PWV, AIx			17	Higher carotid-radial, but not carotid-femoral PWV in coarctation				Elevated TGF-beta and IL-6 in coarctation	No explicit linear relationships between serum inflammation and stiffness metrics
Brili (Circ Imaging)[107]	2018	Case-control	18-FDG PET-CT, Spyhgmocor	Sphygmocor: PWV, AIx	Normotensive coarctation patients	—	15	No relationship with PWV and TBR	Higher target to background ratio (TBR) associated with higher mean pressure	No relationship between Aix and TBR	Higher TBR in coarctation patients (particularly bicuspid valve) than controls. Descending aorta highest TBR	Correlation between IL-6 and TBR	Control group treated for lymphoma
Rog (Acta Cardiologica)[135]	2018	Case-control	Fibrinogen, hsCRP	Sphygmocor: PWV, AIx	Mean SBP 137 ± 16 mmHg. Median age at operation 8.7 years	27.5	58 (62%)	Higher PWV in hypertensive coarctation. Correlation between PWV and fibrinogen ($r = 0.31$, $P = .039$)	Higher central SBP in patients than controls	Higher AIx in patients versus controls		CRP and fibrinogen higher in coarctation than controls	No association of PWV with hsCRP

FIGURE 46.8 Relationship between pulse wave velocity and age in patients with coarctation repaired in infancy <1 year (Blue), compared with healthy controls (Red). Significant linear relationship between covariates for coarctation group ($P = .02$). Nonsignificant association for control group ($P = .7$). *Unpublished data from Quail MA, Short R, Pandya B, et al. Abnormal wave reflections and left ventricular hypertrophy late after coarctation of the aorta repair.* **Hypertension** *2017; 69:501−509.*

In addition to the right ventricular lesions of TOF, it is also increasingly recognized that these patients have an increased risk of progressive aortic root dilatation.[113] Risk factors for progressive aortic dilation include the presence of pulmonary atresia, right aortic arch, history of an aortopulmonary shunt, male sex, and the presence of a 22q11 deletion[114]; pregnancy does not appear to be associated with a significantly increased risk of progression or aortic events.[115] Current data indicate that the risk of aortic dissection is less than for other forms of connective tissue disease.[116] However, aortic root and valve surgery may be required when accompanied by significant aortic regurgitation.

Histological studies of the aortic wall in TOF have highlighted degeneration of the tunica media of the aorta (including fibrosis, fragmentation of elastic fibers, and loss of smooth muscle cells) as an important cause of aortic root dilatation.[117,118] Abnormal aortic distensibility has also been described in children and adults with both repaired and unrepaired TOF (Table 46.4).[119,120]

Senzaki et al. has performed the most detailed assessment of aortic pulsatile hemodynamics in TOF.[58] In this study, simultaneous aortic pressure and flow data were acquired using a high-fidelity pressure transducer and a catheter-mounted flow velocity probe at the time of cardiac catheterization to calculate aortic impedance in patients and controls. Flow velocity was converted to flow volume using echocardiographic measurements of the sinutubular junction.

TOF patients had larger aortic diameters than controls: 18.8 mm (SD 4.8) versus 15.8 mm (SD 3.6). Patients had similar systolic, but lower diastolic and mean blood pressures. In patients compared to controls, there was higher impedance modulus at heart frequency (Z_1; 204 vs. 151 dyn s/cm^5.m^2; $P < .05$) and higher Z_c (average impedance moduli at 3−10 Hz; 158 vs. 105 dyn s.cm^{-5}.m^2; $P < .05$). Patients had an overall stiffer vasculature as assessed by TAC (0.93 vs. 1.24 mL/mmHg/m^2; $P < .05$) and PWV (5.6 vs. 4.2 m/s; $P < .05$). Interestingly, patients also had evidence of increased wave reflection as measured as the ratio between the peak amplitudes of forward and backward pressure waves (0.21 vs. 0.16; $P < .05$). There was a nonsignificant trend to higher SVR in TOF. The authors reported a significant inverse correlation between cardiac index and measures of pulsatile load.

These data are interesting as they show abnormalities of pulsatile hemodynamics in the absence of hypertension in TOF. Left ventricular dysfunction is common in TOF. In retrospective unpublished data from the author's institution, 13% of patients (53/408) have at least mild LV systolic dysfunction on CMR imaging (LVEF <55%). However, while indices of LV systolic function are frequently abnormal, they are infrequently severe (<3%). The reasons for impaired LV function in TOF are poorly understood but are likely multifactorial. One possible explanation, at least in part, could be abnormal pulsatile hemodynamics arising as a consequence of abnormal aortic biomechanics.

Other forms of congenital heart disease

Abnormalities of arterial biomechanics have been described in several other forms of CHD (including transposition of the great arteries [Table 46.4] and in single ventricle CHD), but their clinical significance remains uncertain.[121−125]

TABLE 46.4 Selected studies of arterial stiffness in patients with tetralogy of fallot and transposition of the great arteries.

Author	Year	CHD	Sample size	Age at study (years)	Finding
Grotenhuis (Heart)[136]	2009	Tetralogy of Fallot (TOF)	16	31	Reduced aortic elasticity (pulse wave velocity [PWV] and aortic root distensibility)
Cheung (Heart)[137]	2006	TOF	31	15.3	Increased heart-femoral PWV in patients
Senzaki (Heart)[58]	2012	TOF	36		Invasive haemodynamcis: Increased aortic characteristic impedance and PWV; Reduced total arterial compliance; higher aortic wave reflection;
Seki (EJCTS)[120]	2012	TOF	37	1	Prior to corrective surgery. Invasive hemodynamics: Increased PWV
Murakami (ATS)[122]	2000	TGA—arterial switch	15	4.5	Reduced distensibility in "neo-aortic root" (Sinus and STJ). Normal distensibility ascending and descending aorta
Mersich (Hypertension)[123]	2006	TGA—atrial and arterial switch	34 atrial; 14 arterial	13.2 (atrial); 8.1 (arterial)	Increased carotid beta stiffness index in both atrial switch and arterial switch patients
Grotenhuis (Radiology)[121]	2000	TGA—arterial switch	15	16	Reduced distensibility in "neo-aortic root" (STJ). Increased PWV (transit time)

Conclusions

In this chapter, we have discussed the abnormalities of arterial stiffness and pulsatile hemodynamics in patients with CHD, with a particular focus on coarctation of the aorta. There is an extensive body of evidence showing that coarctation is associated with excessive cardiovascular morbidity and mortality compared to the normal population or other forms of CHD. Abnormalities in vascular function appear in early life and are associated with the development of a vasculopathy characterized by elevated blood pressure, reduced arterial compliance, increased stiffness (particularly the proximal aorta), and pathological wave reflections. This latter phenomenon increases LV afterload with resultant hypertrophy and emerging evidence suggests a role in the pathogenesis of cerebrovascular events. There are important knowledge gaps: Why does this vasculopathy develop?; Is the increased risk of cardiovascular mortality associated with hypertension only, or are more complex hemodynamic abnormalities such as wave reflections involved?; Can medical therapies be used to attenuate wave reflections and reduce afterload? Finally, it is vital that we begin to better understand the hemodynamic abnormalities in order to develop rational treatments to prevent their development and associated complications.

Introduction

Acute infections can perturb the cardiovascular system acutely and are also associated with increased cardiovascular risk in the long-term. Patients with chronic infections are also at increased risk of cardiovascular disease. In this chapter, using sepsis as model for acute infection, and infection with the human immunodeficiency virus (HIV) as model for chronic infection, we discuss the association between infections and the cardiovascular system and explore the potential role of arterial stiffness in these relationships.

Arterial stiffness and sepsis

Sepsis is a life-threatening multiorgan dysfunction caused by a dysregulated host response to infection.[1] The pathophysiological cascade of sepsis starts when an invading pathogen (bacteria, virus, or fungus) is recognized by the innate immune system and triggers the generation and release of inflammatory mediators that while promoting an immune response against the infecting agent, can also have detrimental effects on several body organs. A detailed discussion of the molecular, cellular, and regulatory pathways of sepsis, as well as the range of organ involvement and treatment strategies in this condition are beyond the scope of this Chapter, and the reader can refer to published reviews on this topic.[2] The circulatory system is preeminently affected in sepsis, and cardiovascular abnormalities are a hallmark of this syndrome. In this section, we will discuss our current understanding of the circulatory responses to sepsis, how arterial stiffness could influence this paradigm, the current experimental and clinical evidence of a relationship between sepsis and arterial stiffness, and the potential mechanisms underlying this association.

Effect of sepsis on the circulatory system

Short term

In the prevailing model of the effect of sepsis on the circulatory system, the acute septic inflammatory response leads to the synthesis and release of inflammatory mediators (tumor necrosis factor, interleukin [IL]-1, IL-6, IL-8, IL-12, IL-18, interferon γ, prostaglandins [PGs], and matrix-metalloproteases [MMPs], among others) and toxic oxidative and nitrosative intermediates into the blood, and the adhesion of platelets and leukocytes to the endothelium.[3,4] The net result is vascular smooth muscle dilation and disruption of the supportive structures of the vascular endothelium, including the cell cytoskeleton (actin), intercellular adhesion molecules (tight junctions), and an array of supportive proteins. These effects produce dilation of the "resistance" vessels (i.e., vessels with predominant vascular smooth muscle wall architecture like small arteries and arterioles) and capillary "leakage" (with outflow of intravascular proteins and plasma fluid) into the extravascular space, both leading to a drop in the peripheral vascular resistance and effective preload, progressively challenging the conservation of adequate blood pressures.[3,5] Compounding these effects is the development of a form of nonischemic sepsis-induced cardiomyopathy characterized by ventricular dilatation, reduced ventricular contractility, and both right and left systolic and diastolic dysfunction.[6,7] In its most advanced stages, sepsis results in a form of shock that is poorly responsive to plasma volume expansion and the administration of vasopressor and inotropic agents, and that shows poor tolerance to fluid challenges. Increased serum markers of myocardial injury (i.e., cardiac troponin) are present in a majority of patients with sepsis and they are associated with increased sepsis mortality.[8]

The mechanisms underlying this sepsis-induced cardiomyopathy are not well understood but appear to involve excessive formation of nitric oxide (NO), reactive oxygen species and nitrogen radicals, mitochondrial dysfunction, transcriptional and metabolic changes, direct cardiotoxicity from bacterial products and inflammatory molecules, and ischemic damage due to mismatches between the metabolic demands of the myocardium and the coronary blood supply (i.e., "supply/demand mismatch").[6,7,9,10] Sepsis-associated myocardial dysfunction can affect both systolic and diastolic function, and it is present in a majority of patients with sepsis.[11] Given the circulatory and metabolic demands of sepsis and the effect of sepsis on myocardial function, it is not surprising that sepsis is one of the most common precipitants of new-onset or acutely decompensated heart failure,[12,13] and that sepsis carries a particularly poor prognosis in patients with preexisting diagnosis of heart failure.[14,15] However, the relationship between sepsis and new onset heart failure is confounded by the need for aggressive fluid resuscitation, which often leads to a markedly positive sodium and water balance over short periods of time, particularly in critically ill patients.

The incidence of acute myocardial infarction during sepsis is difficult to ascertain due to the difficulty of distinguishing between true myocardial infarction and nonischemic sepsis-induced myocardial injury, and the changing criteria for defining myocardial infarction in clinical research.[16] Contemporary reports suggest that myocardial infarction complicates the course of about 4% to 8% of patients with severe sepsis.[17,18] A similar incidence of myocardial infarction has been reported in patients with pneumonia.[19–21] The mechanisms contributing to the increased risk of myocardial infarction during sepsis and associated states (i.e., pneumonia) are largely unknown, but infection driven increased systemic and coronary inflammatory activity, and dominant prothrombotic conditions, among others, have been proposed as potential contributors.[22–24]

Intermediate and long term

In the last decade, a growing body of literature suggests that the effects of sepsis and other sepsis-related conditions such as pneumonia on the circulatory system are not limited to the short-term but can extend for months and years after an index septic/infectious episode. Epidemiologic studies show that new-onset heart failure can occur in as many as 13% of sepsis survivors by year 2 after their index sepsis episode.[25] Compared to nonhospitalized and hospitalized controls without sepsis, the risk of heart failure in sepsis survivors over 7 years after their index sepsis episode is increased by 43% and 48%, respectively.[26] Likewise, among elderly survivors of pneumonia requiring hospitalization, about 10% develop new-onset heart failure in the first year after the index pneumonia episode.[27] Compared to elderly controls without pneumonia, the risk of new-onset heart failure in pneumonia survivors is increased by about sevenfold between 30 and 90 days after the index infection, about threefold between 90 days and 1 year, and almost twofold between 1 and 5 years post-pneumonia.[27] An increased long-term risk of new-onset heart failure after pneumonia has also been observed in other age-groups.[28]

Both sepsis and pneumonia survivors also remain at high risk of myocardial infarction and stroke.[29] Epidemiologic studies of sepsis survivors suggest a one-year post-sepsis incidence of stroke and myocardial infarction of 18% and 9%, respectively.[30] Similar to the risk of HF, the risk of myocardial infarction in sepsis survivors over 7 years of follow-up after their index episode of sepsis and relative to nonhospitalized and hospitalized controls was increased by 22% and 14%, respectively. Among elderly survivors of pneumonia, the cumulative incidence of (composite) myocardial infarction or stroke is 12% at 30 days after pneumonia, 13% at 90 days and 18% at 1 year.[31] Compared to controls without pneumonia, the risk of myocardial infarction or stroke in elderly survivors of pneumonia with severe sepsis is increased by about fivefold in the first 30 days postinfection, two- to threefold between 1 month and 1 year postpneumonia, and about onefold afterward and up to 10 years.[31] An increased long-term risk of myocardial infarction and stroke after pneumonia has also been observed in other age-groups.[30,31]

Sepsis and arterial stiffness

Mostly neglected in the pathophysiologic model of the acute circulatory effects of sepsis discussed above, is the role of the larger elastic conduit arterial vessels and the ventricle-arterial pulsatile interactions in the septic state. In the current model, the circulatory system is conceived as a pump-driven, one-way system of blood flow in which the hemodynamic effects of the pulsatile nature of the cardiac cycle and the mechanical properties of the arteries that accommodate the blood ejected by the heart in each heartbeat are largely overlooked. However, as discussed throughout this textbook, the arterial tree imparts afterload to the left ventricle, and arterial structure and function directly impact both steady and pulsatile left ventricular afterload. Microvascular and muscular artery dysfunction in sepsis could interact with large artery stiffness to produce adverse patterns of left ventricular afterload that may contribute to cardiac complications both during sepsis and after recovery from the acute septic episode.

Animal studies on sepsis and arterial stiffness

In rabbits, injection of lipopolysaccharide (LPS, the major component of the outer membrane of gram-negative bacteria) induces reduction of endothelium-mediated relaxation of the aorta in the context of a severe-sepsis type of response.[32] In another swine LPS-induced sepsis model, LPS infusion produces, within an overall hypotensive hyperdynamic septic-shock type of response, acute reversal of the usual pulse pressure (PP) amplification (from aortic to radial or femoral arteries), and reduced total arterial compliance increased aortic characteristic impedance (Zc) (Table 47.1).[33] Interestingly, these adverse large artery changes occurred despite a reduction in blood pressure. There are no animal studies examining long-term effects of sepsis on arterial stiffness.

Human studies on sepsis and arterial stiffness

Concordant with the animal models above, a challenge with the *Salmonella typhi* capsular polysaccharide vaccine in healthy volunteers resulted in acute increase of the carotid-femoral PVW by 0.43 m/s, but a reduction in the augmentation index (by 5%) at 8 h postchallenge. The latter effect was thought to result from a reduction in the magnitude of wave reflection at peripheral sites secondary to peripheral vasodilation.[34] In a study of 45 septic patients (median age 67 years; interquartile range 54−75), the median carotid-femoral pulse wave velocity (PWV) was 14.6 (8.1−24.7) m/s when measured within 24h of admission compared to 12 m/s, the reference value for hypertensive individuals ≥70 years old (with or without history of dyslipidemia and/or smoking). In this study, however, carotid-femoral PWV did not correlate with the progression of multiple organ failure, (before or after adjustment for vasopressor use), or with improvement in the subgroup of patients who had cardiovascular instability at baseline. Nonetheless, Cox regression and survival analyses (including age, APACHE II, and baseline SOFA score) showed shorter hospital survival time for patients with

carotid-femoral pulse wave velocity >24.7 m/s (HR = 9.45, 95% CI 1.24−72.2; P = .03).[35,36] This cutoff corresponds to a very high value of carotid-femoral PWV, indicating marked large artery stiffening. Another study of 21 patients with sepsis found a significant increase in their cardio-ankle vascular index (CAVI) after 1 week of treatment, with no significant change in blood pressure, relative to the measurements at their presentation to the emergency department before initiation of guideline-directed therapy for sepsis (7.9 ± 2.4 at presentation vs. 9.6 ± 1.8 at 1 week, P < .001). The magnitude of CAVI increase posttreatment correlated with initial serum levels of procalcitonin, a biomarker associated with inflammation, bacterial infections, and infection severity. In this study, there was no association between CAVI and a systemic inflammatory response syndrome score, prevalence of hypertension and diabetes, type of infection or treatment.[37] There are no human studies examining long-term effects of sepsis on arterial stiffness. Interestingly however, the long-term incidence of new-onset heart failure after recovery from sepsis is not significantly different between survivors that exhibit left ventricular dysfunction during sepsis and survivors whose left ventricular function remained preserved, thus suggesting that factors other than myocardial injury during the acute septic state can contribute to the elevated long-term risk of cardiovascular morbidity postsepsis.[25]

Potential mechanisms for an effect of sepsis on arterial stiffness

Infections can produce acute inflammatory changes in human aortic cells. In an in-vitro model, *Staphylococcus aureus* induced several inflammatory responses in human aortic endothelial cells including cyclooxygenase-2 expression, PGE_2 secretion, and PGE_2/ IL-6/matrix metallopeptidase-9 (MMP-9)-dependent cell migration.[38] Infection with influenza virus in Apo-E deficient mice induced the expression of MMP-13 in aortic atherosclerotic plaques.[39] Administration of the Streptococcus pyogenes Phospholipase A_2 to mice acutely upregulates the

TABLE 47.1 Derived aortic hemodynamic parameters in a porcine model of endotoxemia.

Parameter	Baseline	Endotoxemia	ANOVA
	Mean ± SD	Mean ± SD	Baseline to endotoxemia

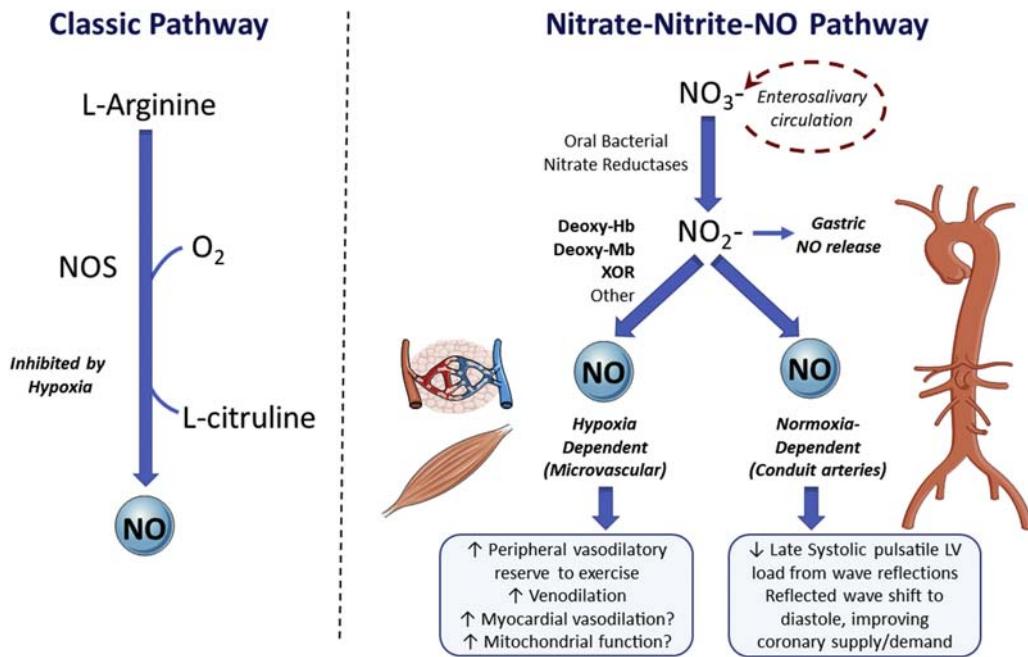
transcription of the cell adhesion molecules ICAM1 and VCAM1 and their aortas.[40] In humans, white blood cell count, a marker of systemic inflammatory activity that is very sensitive to acute infections, correlates with increased brachial-ankle PWV.[41] The increase in carotid-femoral PWV after vaccination with *Salmonella typhi* capsular polysaccharide described in the previous sections correlated with increases in inflammatory markers such as C-reactive protein, IL-6, and MMP-9, and interestingly, pretreatment with aspirin blunted these effects.[34] In animal models, a septic insult results in an inflammatory infiltration of the aortic wall that continues well after the septic episode has resolved and into the long-term.[42] Therefore, it seems likely that sepsis can affect the function and structure of conduit arterial vessels and that inflammation is the main driver of this effect. However, the putative specific mechanisms by which the inflammatory response in sepsis would affect arterial stiffness (i.e., elastin degradation, smooth muscle dysfunction, endothelial dysfunction, extracellular tissue matrix remodeling, cellular inflammatory infiltration, etc.) remain to be studied in detail.

Can alterations of the human microbiome by antibiotics used to treat acute infections affect the associations between sepsis and cardiovascular phenotypes?


The historical view of the interaction between microbes (bacteria, viruses, and/or fungi) and humans is of a constant battle in which microbes try to establish infection in our bodies and we try to eliminate them from our system. However, over the last two decades, we have come to realize that because of human/microbe coevolution, a large variety (in the trillions) of microbial communities reside in our bodies in a symbiotic manner, primarily in the gastro-intestinal tract. This large collection of resident microbes (and their genes) is referred to as the "human microbiome" and has the human gastrointestinal tract as its primary anatomical residence.[43] Rather than a mere co-existence, the relationship between the human body and the microbiome is dynamic and bidirectional where internal (i.e., age, hormonal changes, inherited genes, among others) and external factors (diet and antibiotics, among others) can affect the composition of the microbiome, and the make-up of the microbiome is also capable of affecting body physiological functions such as immune, metabolic, and vascular functions, among others.[43] Relative to arterial stiffness, for example, Menni et al.[44] demonstrated, in adult middle-aged female twins, that arterial stiffness (measured by carotid-femoral PWV) is inversely correlated with gut microbiome diversity and with the abundance of specific bacterial taxa (mainly from the Ruminococcaceae family). Because (*a*) these bacteria have been linked to lower levels of gut derived endotoxemia in mice; (*b*) experimentally

induced endotoxemia is known to increase inflammatory cytokines in humans; and (*c*) persistent low-grade systemic inflammatory activity is associated with increased arterial stiffness; it has been hypothesized that an association between the composition of the gut microbiome and arterial stiffness could be mediated, at least in part, by the effect of the microbiome make-up on the background systemic inflammatory activity of humans.[45]

The make-up of the oral microbiome could also affect arterial stiffness via the increased or decreased bacterial metabolism of nitrates. In humans, NO formation occurs via two pathways: (1) The L-arginine-NO pathway (where NO synthases [NOS] catalyze the formation of NO from L-arginine and O2), and (2) the nitrate-nitrite-NO pathway (NOS-independent; Fig. 47.1).[46]

In the nitrate-nitrite-NO pathway, inorganic nitrate reaches the oral cavity from (*a*) dietary nitrate (from vegetables such as leafy greens, beets, among others); and (*b*) salivary nitrate (actively taken off the circulation and concentrated in the saliva by the salivary glands).[46] In the oral cavity, bacteria of the oral resident microbiome reduce nitrate to nitrite. Nitrite and remaining nitrate are then swallowed and almost fully absorbed in the intestine (>90% bioavailability). Nitrite in blood is then directly reduced to NO in reactions catalyzed by several molecules, particularly deoxygenated myoglobin[47] and hemoglobin.[48] Meanwhile, ~75% of circulating nitrate (coming from intestinal absorption and from being the stable end-metabolite of NO) is excreted in urine and the rest is taken-up by the salivary glands to continue the cycle just described.[46] Mammalian cells are thought to be incapable of reducing nitrate to nitrite; therefore, reduction of nitrate to nitrite by the oral microbiome is the limiting step in this pathway. NO is known to decrease the vascular tone of resistance vessels and coronary and brachial conduit arteries, and more recent evidence suggests that higher NO blood levels from oral nitrate supplementation can also functionally reduce the hemodynamic effects of stiffened larger vessels, probably via modulation of smooth muscle tone.[49,50]

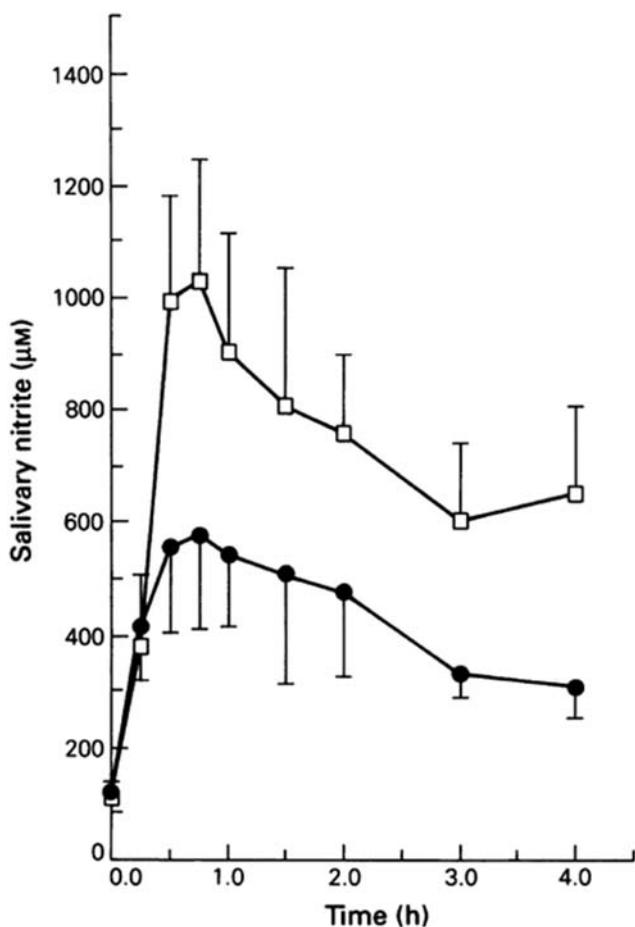
Antibiotics are the mainstay treatment for acute infections including sepsis. Since antibiotics, depending on their class, have important effects on the composition of the intestinal microbiome,[51] it is possible that they could also affect putative associations between the human microbiome and arterial stiffness. For example, Dougall et al.[52] demonstrated that pretreatment with amoxicillin (a beta-lactam antibiotic with high activity against *Veillonella sp.*, the most important nitrate-reducing bacterial taxa of the mouth) reduces the concentration of salivary nitrite by 40% after a loading dose of potassium nitrate (Fig. 47.2). Thus, if an association existed between oral nitrite production levels and arterial stiffness, it could be affected significantly by the administration of antibiotics. These considerations

FIGURE 47.1   The classic NOS-dependent NO pathway (left), and the nitrate-nitrite-NO pathway (right). *Deoxy-Hb*, deoxy-hemoglobin; *Deoxy-Mb*, deoxy-myoglobin; *NOS*, nitric oxide synthase; *XOR*, xanthine oxidoreductase. *Reproduced from Chirinos JA, 2018,* **J Card Fail***, 24(4); 74−77.*

are even more relevant when current evidence suggests that alterations of the intestinal microbiome induced by antibiotics can be lasting and long-term.[51]

Finally, it is important to acknowledge that any association between the composition of the intestinal microbiome and arterial stiffness is likely complex, and that the effect of antibiotics on this relationship, given the differences among them in terms of antibacterial spectrum, intestinal absorption, and other factors, need not to be consistent in only one direction. For example, treatment of older mice (20− 24 months of age) with a cocktail of very broad spectrum nonabsorbable antibiotics including ampicillin, neomycin, metronidazole, and vancomycin produced a decrease in their aortic PWV to levels that were no longer different from those of control young mice (8−10 weeks of age).[53]

Arterial stiffness and human immunodeficiency virus infection

Once invariably fatal, infection with HIV has evolved into a more chronic condition in which combination antiretroviral therapy (CART) can effectively suppress viral replication and extend the life expectancy of people living with HIV (PLHIV) to levels that approach the general population.[54,55] As a consequence, age-related noncommunicable conditions like cardiovascular diseases are becoming an increasing burden for PLHIV.[56] Indeed, while death rates associated with cardiovascular diseases in the general population and some high risk groups (like people with inflammatory polyarthropaties) are decreasing, these rates


continue to rise in PLHIV (Fig. 47.3).[57] It is estimated that by the year 2030, 73% of PLHIV will be ≥50 years of age, and 78% of them will have cardiovascular disease.[58] In this section, we discuss the burden of cardiovascular disease, including coronary artery disease and heart failure in PLHIV, review the evidence suggesting increased risk of arterial stiffening in this population and the potential mechanisms in this relationship.

Myocardial infarction in people living with human immunodeficiency virus

Although myocardial infarction is not directly related to arterial stiffness, since it is a consequence of atherosclerotic disease of the coronary vessels, it is useful to review its epidemiology in PLHIV, to better understand the burden of cardiovascular disease in this population. Moreover, some mechanisms of arterial disease may be common to conduit muscular arteries and proximal elastic large arteries.

Epidemiological studies have consistently demonstrated a 0.5- to one-fold increased risk of myocardial infarction in PLHIV compared to uninfected individuals, even after adjustment for other known cardiovascular risk factors (including smoking, which is particularly prevalent in this population).[59−62] The magnitude of this excess risk of MI associated with HIV infection is comparable to other major traditional risk factors (Fig. 47.4).[59,60,63]

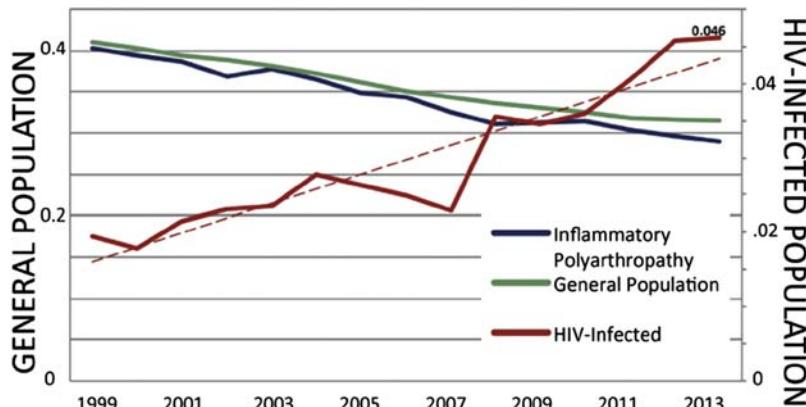
The excess MI-risk attributable to HIV is higher in patients whose infection is suboptimally controlled (as measured by lower CD4 cell counts and higher detectable


FIGURE 47.2 Mean salivary nitrate concentration (±s.e. mean) after ingestion of potassium nitrate (200 mg) showing the significantly lower levels attained after a two-day course of amoxycillin (●) when compared with control (□) in healthy male volunteers. *Reproduced from Dougall HT, Smith L, Duncan C, Benjamin N. The effect of amoxycillin on salivary nitrite concentrations: an important mechanism of adverse reactions? Br J Clin Pharmacol. 1995; 39(4):460–462.*

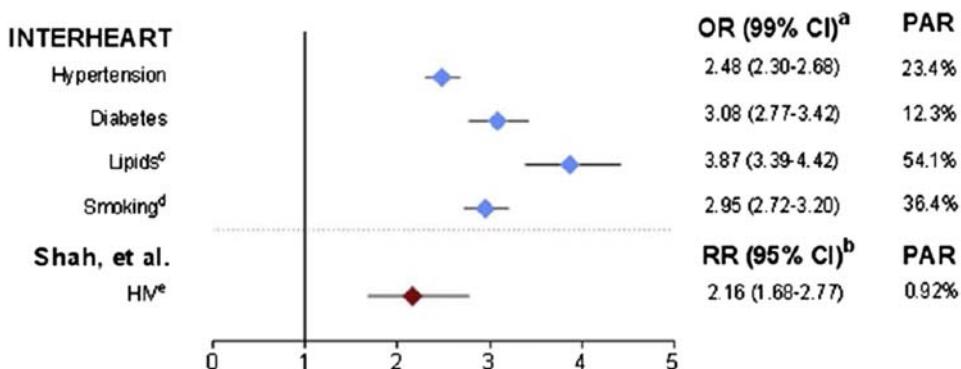
levels of viral copies of HIV in blood) and in those that interrupt CART.[64,65] Nonetheless, excess risk of MI is still present (at around 0.5-fold higher) even among PLHIV that achieve undetectable viral levels (<500 viral copies/ml) in blood with treatment.[59] Data suggest that MI risk is also increased in "elite controllers," a unique population of PLHIV (<1% of them) able to suppress HIV replication below detectable levels in blood without CART, but the magnitude of this excess risk is not well defined.[66] A primary mechanism for the increased risk of MI attributable to HIV infection is thought to be persistent immune dysregulation. PLHIV with lower nadir CD4 cell counts before initiation of CART are at higher risk of MI.[67] PLHIV exhibit higher levels of CRP compared to uninfected individuals, and increasing levels of HIV viral load correlate positively with IL-6 levels in this population.[68,69] Higher CRP and IL-6 are both independently associated with


greater MI-risk in PLHIV.[70,71] In addition to smoking being highly prevalent among PLHIV,[61,62] some studies suggest a magnified effect of smoking on MI-risk in the setting of HIV infection with approximately three of four MIs among PLHIV being associated with ever smoking compared to only one of four MIs among uninfected controls.[72] Dyslipidemia, hypertension, and diabetes are also more prevalent in PLHIV, and this observation has been linked to CART use.[73–75] Some specific antiretrovirals have also been associated with increased MI-risk in PLHIV, independent of traditional cardiovascular risk factors. Antiretrovirals belonging to the protease-inhibitors class, especially those approved before the early 2000s, have been associated with about 10% increase in the risk of myocardial infarction per year of use.[76–78] The newer protease-inhibitors atazanavir and darunavir appear to carry significantly less cardiovascular risk than their older counterparts with atazanavir appearing to have the safest cardiovascular risk profile.[77] Abacavir, another antiretroviral belonging to the nucleoside reverse transcriptase inhibitors class has also been linked, although inconsistently, to a higher risk of myocardial infarction.[79,80] However, both early protease inhibitors and abacavir are no longer preferred agents in contemporary CART regimens.[81] Integrase inhibitors, a newer class of antiretroviral agents are associated with favorable lipid profiles but also increased risk of obesity and their overall effect on MI-risk and in the context of CART regimens with other antiretroviral classes is to be characterized.[82–84]

Heart failure in people living with human immunodeficiency virus

In the pre-CART era, AIDS-related dilated cardiomyopathy, often accompanied by pericardial involvement, affected as many as one-third of AIDS patients.[85,86] This disorder appeared to be secondary to direct myocardial invasion by HIV, opportunistic infections of the myocardium by other pathogens, and also inflammation and autoimmunity.[85,87] However, with the wide adoption and ever earlier initiation of CART, AIDS-related dilated cardiomyopathy has become rare in developed countries.[88] Nevertheless, PLHIV appear to still remain at higher risk of developing HF even when CART is widely available.[89–94] Over the last decade, several large studies have consistently documented a HF-risk increase in PLHIV compared to uninfected controls (Table 47.2).[89–95] The magnitude of this HIV-associated HF-risk increase has varied between 0.3- and 1.5-fold among studies, it has been demonstrated in both predominantly male[89,91–95] and female populations,[90] and it has shown independence from coronary heart disease (prevalent or incident),[89–95] traditional cardiovascular risk factors,[89–95] and makers of socioeconomic status and access to health care.[92,93,95,96] Importantly, while

most of these studies used administrative data codes for the ascertainment of HF diagnosis,[89−92,94] one study used a centralized adjudication protocol involving objective clinical, laboratory, radiographic, and pharmacy criteria.[93] Compared to uninfected controls with HF, PLHIV with HF also have higher risk of hospitalization, rehospitalization (after an index HF hospital admission), sudden cardiac death, and cardiovascular and overall mortality, and lower CD4 counts, higher viral loads and lower LV ejection fraction are associated with worse outcomes.[94,97−101] Depression appears to have a synergistic effect with HIV infection in increasing HF risk.[91]

The contribution of the different phenotypes of HF (i.e., HF with reduced ejection fraction [HFrEF] and HF with preserved ejection fraction [HFpEF]) to the burden of PLHIV is still not well characterized. A large study (31,523 subjects) of predominantly (97%) male PLHIV without prior history of

cardiac disease found 941 cases of newly diagnosed HF (defined by the new documentation of one or more inpatient or two or more outpatient ICD.9 codes consistent with HF) over a mean follow-up of seven years. After extracting EF values from clinical notes using an automated extraction application, of these 941 cases, 284 (30%) were classified as HFpEF (EF ≥50%), 142 (15%) as borderline HFpEF (EF ≥40% and <50%), and 380 (41%) as HFrEF (EF <40%); another 135 (14%) did not EF ascertained. Relative to uninfected controls, the adjusted risks of HFpEF, borderline HFpEF and HFrEF were increased by 21%, 37%, and 61%, respectively (Table 47.2). The risk of HFrEF was particularly elevated (by 2.6-fold) among PLHIV younger than 40 years at baseline.[94] In another study of only women with prevalent HF of mean age of 59 years, HFpEF comprised 71% and 63% of cases among PLHIV (n = 1388) and controls (n = 13,781), respectively

Feinstein et al., 2018[93]	USA	4640 PLHIV and 4250 uninfected controls ~80% male in both groups Mean age 40 years old in both groups No prior diagnosis of heart failure Baseline prevalence of coronary heart disease 5% in both groups	New diagnosis of heart failure, centrally adjudicated by physicians based on clinical and laboratorial criteria	Mean of 5.6 years	HR 2.1 (95% CI 1.4–3.2)
Yen et al., 2019[95]	Taiwan	24,153 PLHIV (72% on CART) and 96,612 uninfected controls 94% male in both groups Mean age 32 years old in both groups No prior diagnosis of heart failure	New diagnosis of heart failure defined as new documentation of one or more inpatient or three or more outpatient ICD-9 codes 428.xx	Mean of 5.8 years	HR 1.5 (95% CI 1.3–1.8)
Prasada et al., 2020[96]	USA	2715 PLHIV and 19,358 uninfected controls 85% males in PLHIV and 43% in controls Mean age 43 years old in PLHIV and 49 years old in controls No prior diagnosis of heart failure	New diagnosis of heart failure defined as new documentation of an unspecified set of ICD.9 codes associated with heart failure	Median of 3.6 years	HR 1.3 (95% CI 1.0–1.7)

ICD-9 denotes International Classification of Diseases, Ninth Revision. HR denotes hazard ratio. IRR denotes incidence rate ratio. RR denotes relative risk. HFpEF denotes heart failure with preserved ejection fraction, EF ≥50%. Borderline HFpEF, ≥40%–49%. HFrEF denotes heart failure with reduced ejection fraction, EF <40%.

($P = .44$). Although left ventricular ejection fractions were similar between groups, HIV-infected women had wider QRS (113.19 vs. 97.20 ms; $P < .0001$) and higher pulmonary artery systolic pressure (49.12 vs. 39.10 mm Hg; $P < .0001$). HIV + women also had higher rates of HF hospitalization, longer HF hospitalizations, lowers rates of optimal pharmacological therapy for HFrEF, and higher rates of all-cause and cardiovascular mortality.[101] A meta-analysis of studies of cardiac function in PLHIV observed a shift toward lower prevalence of systolic dysfunction in more recent reports and in settings of wide availability of CART.[102] In another meta-analysis of 11 studies of paucisymptomatic PLHIV without clinical cardiovascular disease, the pooled incidence of diastolic dysfunction among 2242 participants (mean age, 42 years) was 43.4% (95% CI: 31.7%−55.0%) compared to only 8.3% (95% CI: 2.2−14.3) for systolic dysfunction.[103] For reference, the prevalence of diastolic dysfunction in the general population aged 45−55 years is estimated at ∼6%.[104,105] In studies where LV mass is assessed, PLHIV without clinical HF consistently show larger masses than uninfected controls.[106−110] However, differentiation between eccentric versus concentric LV hypertrophy was not clear. All in all, current data appear to signal to HFrEF being more prominent among male PLHIV and HFpEF more prominent in female PLHIV. However, given the high prevalence of subclinical diastolic dysfunction in PLHIV, and as this population continues to age, it is likely that HFpEF will continue to take a more prominent role overall.

An association between persistent immune dysregulation and increased risk of HF in PLHIV, similar to the case of MI risk in this population, has also been proposed though its supportive evidence is less robust. Among 5098 PLHIV participating in a trial of intermittent versus continuous use of CART, serum levels of IL-6, high sensitivity CRP, and D-dimer were associated with an increased risk of a composite endpoint of cardiovascular disease that included cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, congestive heart failure, coronary revascularization, coronary artery disease requiring drug treatment, and peripheral arterial disease.[71] Otherwise, we could not find reports documenting associations between inflammatory markers and specific HF risk in PLHIV. Several studies also suggest that PLHIV, even when well controlled with CART and without clinical heart failure, have increased myocardial inflammation, interstitial fibrosis and steatosis as measured by cardiac magnetic resonance.[111−114] However, the exact contribution of these abnormalities to the excess HF risk of PLHIV is not well defined. There is a relative paucity of data about the influence of CART on HF risk. One study suggested that the excess risk of HF associated with HIV decreases over time as the duration of CART increases.[95] The use of tenofovir, an antiretroviral of the nucleotide reverse transcriptase

inhibitor class, has been associated with lower incidence of HF whereas the use of antiretrovirals of the protease inhibitor class has been linked to lower left ventricular ejection fraction, higher pulmonary artery systolic pressure, and increased mortality and readmission rates after a hospitalization for acute decompensated HF in PLHIV.[115] Overall the effect of CART on HF risk is still unclear.

Human immunodeficiency virus infection and arterial stiffness

In two small studies from 2005 to 2008, Schillaci et al.[116,117] found that PLHIV that were either CART-naive or already receiving CART, had higher carotid-femoral PWV than uninfected controls. Since then, several subsequent reports, also mostly with small sample sizes, have delivered inconsistent results on this topic, with some studies finding increased aortic stiffness in PLHIV compared uninfected controls,[116−128] while others did not.[129−139] Reports have also been conflicting regarding the impact of CART on arterial stiffness as some studies found a negative impact of CART on PWV,[118,119,125,132,139] whereas others did not.[120,126,131,134] This divergence in findings could well be explained by the small sample sizes of these studies and also the remarkable heterogeneity among them including, but not limited to, the sex and age composition of their groups, their geographic setting, the time since HIV diagnosis in their PLHIV cohorts, the techniques used to account for the central blood pressure, the arterial segments used for the measurement of PWV (some including muscular arterial segments), the exposure to CART among PLHIV participants, the duration and composition of the CART regimens, the degree of immunodeficiency reached before CART was initiated, the degree of immune recovery with CART, and the techniques and equipment used to measure PWV (Table 47.3). Several studies also claimed the assessment of PWV in PLHIV but did not specify the arterial paths for their measurements and thus, they are difficult to interpret.[140−143]

Studies that investigated other specific determinants of PWV in PLHIV showed that factors that have been associated with arterial stiffness in the general population, such as age, blood pressure, smoking, body mass index, dyslipidemia and metabolic syndrome, are also primary determinants of arterial stiffness in PLHIV.[116−120,122−125,129−131,133,136−139] The magnitude of the effect of the metabolic syndrome on arterial stiffness seems especially magnified in PLHIV.[123,139] Among factors specific to HIV infection, lower nadir T-CD4+ cell counts (i.e., before initiation of CART), ongoing immune dysregulation, and duration of exposure to CART also seem to be associated with PWV in PLHIV.[118−120,123,126,127,132,136,139] Overall, however, the preponderance of data suggests that the burden of

TABLE 47.3 Studies of arterial stiffness in people living with HIV (PLHIV).

Study, country, year (ref)	Population	Measurement instrument	Findings	Significance	Factors associated with PWV in PLHIV
Schillaci et al., Italy, 2005[116]	**32 PLHIV** (78% men, mean age 41 ± 8, mean BMI 25 ± 4, all on CART) 32 uninfected controls (78% men, mean age 41 ± 8, mean BMI 25 ± 3)	SphygmoCor Vx (AtCor Medical, West Ryde, NSW, Australia)	Mean cfPWV in PLHIV, 7.6 ± 1.1 m/s Mean cfPWV in uninfected controls, 6.8 ± 1.2 m/s	$P = .015$	Age, duration of CART
Schillaci et al., Italy, 2008[117]	**39 PLHIV, CART naive** (67% men, mean age 37 ± 8, mean BMI 23 ± 3) 28 uninfected controls (67% men, mean age 37 ± 7, mean BMI 25 ± 3)	SphygmoCor Vx (AtCor Medical, West Ryde, NSW, Australia)	Mean cfPWV in PLHIV, CART naive, 7.5 ± 1.4 m/s Mean cfPWV in uninfected controls, 6.7 ± 1.1 m/s	$P = .001$	Age, mean arterial pressure, serum gamma-glutamyl transpeptidase, HIV infection
Vlachopoulos et al., Greece, 2009[129]	**51 PLHIV, CART naive** (92% men, mean age 33 ± 8, mean BMI 24 ± 3) 35 uninfected controls (89% men, mean age 33 ± 8, mean BMI 27 ± 5)	Complior SP (Artech Medical, Pantin, France)	Mean cfPWV in PLHIV, CART naive, 6.4 ± 0.8 m/s Mean cfPWV in uninfected controls, 6.3 ± 1.0 m/s	0.74	Age, BMI, aortic systolic and diastolic blood pressure, brachial systolic and diastolic blood pressure, hs-CRP, and LDL-cholesterol
Lekakis et al., Greece, 2009[118]	**22 PLHIV, CART naive** (all men, mean age 40 ± 13, mean BMI 23 ± 3) **34 PLHIV, CART exposed** (96% men, mean age 40 ± 14, mean BMI 23 ± 2) 28 uninfected hypertensive controls (96% men, mean age 41 ± 13, mean BMI 24 ± 3) 28 uninfected normotensive controls (96% men, mean age 40 ± 12, mean BMI 24 ± 3)	Complior SP (Artech Medical, Pantin, France)	Mean cfPWV in PLHIV, CART naive and CART exposed, 8.1 ± 1.4 m/s Mean cfPWV in uninfected normotensive controls, 6.7 ± 1.1 m/s Mean cfPWV in PLHIV, CART naive and CART exposed, 8.1 ± 1.4 m/s Mean cfPWV in uninfected hypertensive controls, 9.0 ± 1.0 m/s Mean cfPWV in PLHIV, CART naive, 7.5 ± 1.3 m/s Mean cfPWV in PLHIV, CART exposed, 8.4 ± 1.4 m/s Mean cfPWV in PLHIV, CART exposed, 8.4 ± 1.4 m/s Mean cfPWV in uninfected hypertensive controls, 9.0 ± 1.0 m/s Mean cfPWV in PLHIV, CART naive, 7.5 ± 1.3 m/s Mean cfPWV in uninfected normotensive controls, 6.7 ± 1.1 m/s	$P = .03$ $P = .01$ $P = .03$ $P = .25$ $P = .03$	Mean or diastolic blood pressure, serum cholesterol, serum triglycerides, CART duration, protease-inhibitor use, and nucleoside reverse transcript inhibitor use

TABLE 47.3 Studies of arterial stiffness in people living with HIV (PLHIV).—cont'd

Study, country, year (ref)	Population	Measurement instrument	Findings	Significance	Factors associated with PWV in PLHIV
Kelly et al., Malawi, 2019[126]	**279 PLHIV**, (56% men, median age 37 [IQR 31−43], median BMI 20 [IQR 18−22], CART naive at enrollment) 110 uninfected controls (40% men, median age 35 [IQR 31−41], median BMI 22 [IQR 20−25])	Vicorder device (Skidmore Medical, London, UK)	Mean cfPWV in PLHIV at baseline 7.54 m/s (95% CI, 7.36−7.72 m/s) Mean cfPWV in control at baseline 7.19 m/s (95% CI, 6.92−7.45 m/s) Mean cfPWV in PLHIV at 10 weeks of CART 7.41 m/s (95% CI, 7.21−7.61 m/s) Median cfPWV in controls, 7.15 m/s (95% CI, 6.89−7.41 m/s) Mean cfPWV in PLHIV at 22 weeks of CART 7.20 m/s (95% CI, 7.02−7.39 m/s) Median cfPWV in controls, 7.32 m/s (95% CI, 7.05−7.58 m/s) Mean cfPWV in PLHIV at 44 weeks of CART 7.24 m/s (95% CI, 7.04−7.45 m/s) Median cfPWV in controls, 7.21 m/s (95% CI, 6.93−7.50 m/s)	$P = .07$ $P = .02$ $P = .46$ $P = .59$	Persistence of initially high proportion of PD-1+ CD8+ T cells
Toribio et al., US, 2020[127]	**34 PLHIV** (all women, mean age 52 ± 4; mean BMI 32 ± 7; 59% on CART) 34 uninfected controls (all women; mean age 52 ± 4; mean BMI 32 ± 7)	MRI	Mean taPWV in PLHIV: 8.6 ± 1.3 m/s Mean taPWV in controls: 6.5 ± 1.3 m/s	$P < .0001$	sCD163 levels
Martínez-Ayala et al., Mexico, 2020	**51 PLHIV** (90% men, mean age 33 ± 10, mean BMI 23 ± 4, CART naive) 51 uninfected controls (86% men, mean age 32 ± 10, mean BMI 25 ± 3)	PulsePen (Diatechne, Milan, Italy)	Median cfPWV in PLHIV 7.4 m/s (IQR, 0.12 m/s) Median cfPWV in controls 6.8 m/s IQR, 0.12 m/s	$P < .01$	Not reported

BMI, body mass index; *CART*, combination antiretroviral therapy; *cdPWV*, carotid-dorsalis pedis PWV; *cfPWV*, carotid-femoral PWV; *cPWV*, carotid (local, one-point) PWV; *crPWV*, carotid-radial PWV; *haPWV*, heart-ankle PWV; *PLHIV*, people living with HIV; *PWV*, pulse wave velocity; *taPWV*, thoracic aorta PWV. Several studies that did not specify the arterial paths for the measurement of PWV were not included.[140−143]

traditional risk factors for vascular aging are the major determinants of arterial stiffness in PLHIV, and that immune alterations more specific to HIV infection play a less important role.

Chronic inflammatory activity in the vascular walls of conduit arteries has been proposed as a mechanism for accelerated "aging" of these vessels and resultant increased arterial stiffness.[144,145] Few studies have assessed aortic inflammation in PLHIV using positron emission tomography. Four studies by Subramanian et al.[146] (27 PLHIV recruited prospectively and 27 historic uninfected controls), Taglieri et al.[147] (20 PLHIV recruited prospectively and 20 prospective uninfected controls), Lawal et al.[148] (121 PLHIV and121 uninfected controls, both historical), and Longenecker et al. (55 PLHIV and 19 uninfected controls, both groups prospectively recruited) found that compared to uninfected controls, PLHIV had a significant increase (though marginal) in aortic inflammation even when their infection was well controlled on CART and differences in traditional cardiovascular risks factors were accounted for. However, another study by Knudsen et al.[149] did not corroborate this finding. In 12 PLHIV naive to antiretroviral therapy, commencement of CART did not translate in meaningful changes in aortic inflammation at six months post-CART initiation despite effective HIV viral suppression.[150]

Hence, a putative association between HIV infection and increased arterial stiffness and its mechanisms, let alone its clinical implications, remain poorly defined and they should be the focus of future research.

Conclusion

A robust body of epidemiological evidence demonstrates that cardiovascular disease is a significant contributor to the morbidity and mortality associated with acute and chronic infections. For the case of acute infections, cardiovascular disease not only complicates the course of infected patients in the short term but also in the long term, after the infection has clinically resolved. The biological pathways driving these associations are poorly understood. Furthermore, regarding the association between acute infections and cardiovascular disease, the mechanistic framework under which this relationship has been approached has mostly neglected any putative role of arterial stiffness and pulsatile hemodynamics. For the association between chronic infections like infection by HIV and cardiovascular disease, studies on the role of arterial stiffness and pulsatile hemodynamics are limited by small sample sizes, methodological shortfalls, and lack of standardization. A higher awareness of the importance of arterial stiffness and pulsatile hemodynamics in cardiovascular disease among clinicians and researches, the simplification of their surrogate measures, and the standardization of measuring instruments

should greatly facilitate the characterization of the role of arterial stiffness and pulsatile hemodynamics in the relationship between infections and cardiovascular disease in future studies.

Chapter 48

Arterial stiffness, hemodynamics, and microvascular complications in conditions characterized by low arterial pulsatility

Barry J. McDonnell[1], William K. Cornwell, III[2] and Eric J. Stöhr[1,3]

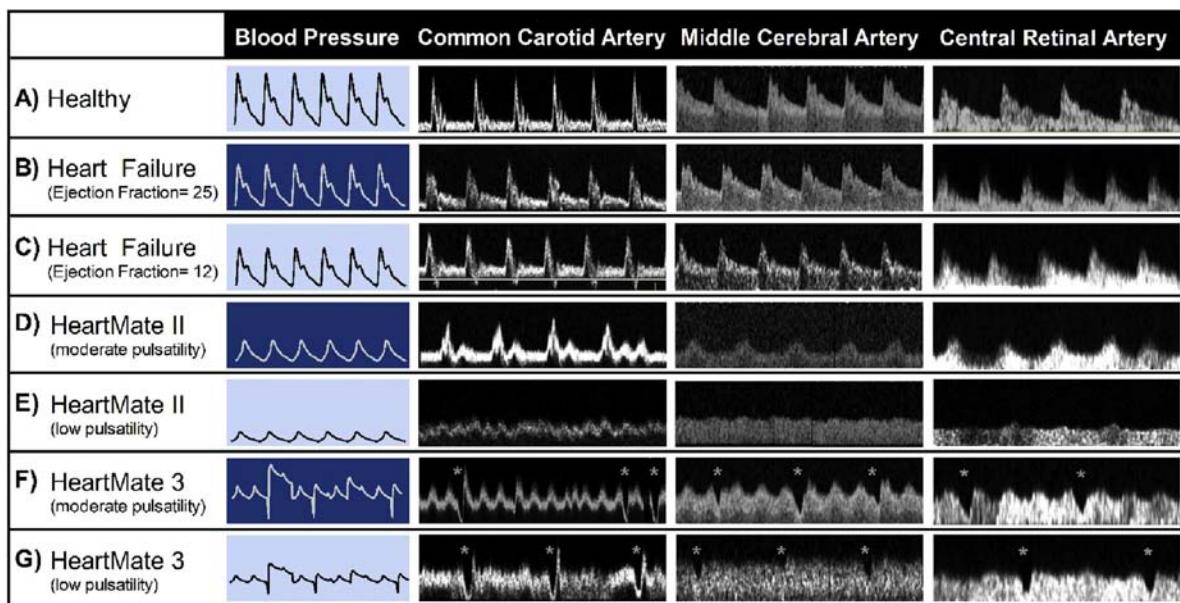
Introduction

In the mammalian cardiovascular system, pressure and flow oscillations across a single cardiac cycle are generally referred to as "pulsatility." To distinguish between different types of pulsatility, several different terms exist. Pulsatility related to oscillations in blood *pressure* is often quantified as pulse pressure (PP). PP is calculated as the difference between systolic and diastolic pressure of the arterial pressure waveform and can be influenced by variations in stroke volume and compliance of the large arteries. Conversely, pulsatility related to oscillations in blood *flow* is commonly quantified as the pulsatility index (PI). The PI describes the relationship between the peak systolic flow velocity and the end-diastolic velocity, normalized to the prevailing mean flow velocity. It should be noted that although PP and PI have similar biological origins, there are many instances when these are not interchangeable and specificity of terminology when describing pulsatility is always advised.


A large body of literature has shown that both high PP and high PI are associated with large artery stiffness, altered hemodynamics (e.g., turbulent flow patterns), and microvascular complications. Specifically, increased PP and PI have been shown to relate to microvascular complications and end-organ damage in healthy aging and disease, including diabetes and end-stage renal disease.[1–3]

Unfortunately, literature describing how the arterial network and cardiovascular system interact and react to continuous, *low* PP and PI is limited. Yet, the in vivo investigation of the effects of low PP and PI is possible in patients implanted with a continuous-flow left ventricular assist device (LVAD). Studying LVAD patients can therefore expand our understanding of the effects of altered PP and PI by identifying the impact of low PP and PI on the macro- and microcirculation.

Over the course of the last 25 years, different pulsatile and continuous-flow LVAD systems have been developed.[4]

The main role of such implantable devices is to support the failing heart and improve the peripheral circulation while patients wait for a donor heart for transplantation (termed bridge-to-transplant therapy), or as a permanent therapy in patients who do not meet the criteria for heart transplantation (termed destination therapy).

There are different models of mechanical pumps used. The majority of LVAD systems used today are considered continuous-flow pumps (continuous output of blood volume, characterized with predominantly low oscillations between systolic and diastolic flow and pressures). However, these different LVAD models have drastically different mechanical interactions with the blood, they output blood volume using different pump settings (e.g., at different pump speeds) and produce different hemodynamic profiles in the macro- and microcirculation. See Fig. 48.1 below.

FIGURE 48.1   **Hemodynamic profiles.** (A) In healthy individuals, the PP and PI are clearly present across the whole body, from the macrocirculation (here, carotid artery) to the microcirculation (here, central retinal artery). (B, C) In heart failure, PP is slightly reduced as reflected by the lower oscillations in blood pressure. However, PI in the macro- and microcirculation is maintained. (D, E) LVAD patients implanted with the continuous-flow HeartMate II have a much lower PP and PI. (F, G) Although HeartMate 3 patients also have a reduced PP and PI, the "artificial pulse" can interrupt the continuous flow. Because the "artificial pulse" is not synchronized with the native heartbeat, sometimes it creates marked oscillations in the macro- and microcirculation (represented by *), while at other times it has much less of an affect. This makes the PP and PI waveforms of HeartMate 3 patients unpredictable, and hence increases the difficulty in measuring blood pressure and interpreting the biological impact of the "artificial pulse."

Low pulsatile hemodynamics in continuous-flow left ventricular assist device therapy

In the sections below, the physiological and clinical consequences of living with continuous-flow LVADs will be described and evaluated.

Clinically, the implantation of an LVAD significantly improves survival for appropriate candidates with advanced heart failure.[5,6] Although LVADs are successful at achieving their aims of unloading the left ventricle (LV) of a failing heart and restoring the cardiac output to normal levels at rest, patients implanted with such devices often present with increased rates of microvascular complications (e.g., stroke, gastrointestinal (GI) bleeding, and cerebral microbleeds). These complications are likely caused by the combined effects of a chronically failing heart with a powerful, continuous-flow LVAD that transmits low pulsatile pressure and flow to the microcirculation. The cardiac output generated by both the native heart and the LVAD is characterized by a low pulsatile pressure and flow profile in the ascending aorta. These low pulsatile pressure and flow hemodynamics dramatically impact on how the cardiovascular system regulates itself and interacts with such low oscillations, in a bid to maintain systemic homeostasis.

Acute and chronic consequences of these low pulsatile oscillations may determine the degree of large artery stiffening and the hemodynamic energy transmitted to the microcirculation.

Because of their different LVAD settings and the altered hemodynamic profile of the cardiac output, important differences in PP and PI can be observed between commonly implanted LVADs. Fig. 48.1 highlights some of the variability in hemodynamics that may have a role in determining the magnitude and severity of both macro- and microvascular complications in LVAD patients.

Importantly, recent clinical trials have revealed significant differences in device therapy—associated outcomes, with the newest generation of LVADs, the HeartMate 3 devices, achieving a significantly better clinical outcome than the HeartMate II.[5,6] Potential reasons for this clinical benefit have been proposed, including the reduction of the mechanical shear between the metal bearings and blood (achieved by the combination of a lower pump speed, wider bore size, and the introduction of an "artificial pulse" that washes out the mechanical components of the pump), and a consequently lower von Willebrand factor degradation.[7] Automated modulations in pump speed, which occur at a frequency of 0.5Hz (every 2 seconds), create what is known as the "artificial pulse". These pump modulations

may provide some pulsatility to the periphery, but further study is warranted to determine the degree to which this "artificial pulse" simulates normal physiology. Because the occurrence of the artificial pulse is not synchronized with the native heart rate, the resultant pressure and flow dynamics are not entirely predictable (see Fig. 48.1F and G). However, to date, superiority of HeartMate 3 over the HeartMate II devices in lowering specific microvascular complications (e.g., rates of GI bleeding and hemorrhagic stroke) has not been shown.

Before discussing the impact of low pulsatile pressure and flow on microvascular complications, the next section will address the consequences of low PP and PI on the macrocirculation which plays an important role in dampening or transmitting the central hemodynamics to the peripheral microcirculation.

Effects of low pressure and flow pulsatility on the macrocirculation

In conditions like the LVAD therapy described in the previous section, the low pulsatile pressure and flow are already present at the level of the ascending aorta. Consequently, the entre circulation, from the central elastic arteries to the microvessels, is affected. Sections Sympathetic nerve activity, vascular remodeling, and aortic stiffness, Endothelial dysfunction, and Blood pressure below describe the different effects of low pressure and flow pulsatility of LVAD patients on the macrocirculation.

Sympathetic nerve activity, vascular remodeling, and aortic stiffness

Because of a reduced systolic blood pressure in advanced heart failure patients, the baroreflex is often chronically activated via the baroreceptors located in the central macrocirculation. In accordance, the increased sympathetic activity has been shown to maintain arterial perfusion pressures via increasing vascular resistance as heart failure with reduced ejection fraction progresses. Similarly, data in LVAD patients reveal a markedly elevated muscle sympathetic nerve activity attributed to the missing pulsatile stretch of the baroreceptors (because the low arterial oscillations caused by the weak native heart and the continuous flow of the LVAD create an extremely low PP and PI). Importantly, it has been shown that acute restoration of rhythmical distension of the baroreceptors through alterations of LVAD speed settings (i.e., increasing the pulsatile nature of the flow and pressure output) can lower SNA in LVAD patients.[8] These data suggest that the low PP and/or PI play an important role in the overall cardiovascular regulation, and that restoring PP and/or PI to optimal levels

may reduce future bleeding complications in LVAD patients.[9,10] It should be noted that while previous pulsatile LVAD systems did not present with high levels of GI bleeding when compared to continuous-flow LVADs, they did present with increased risk of stroke. Therefore, creating optimal pulsatile pressure and flow for these LVAD patients may be essential for reducing overall risk. Since increased SNA induces vascular remodeling of large and small arteries in non-LVAD patients, it can be postulated that the high SNA reported in LVAD patients may have long-term consequences on subsequent macro- and microvascular complications.[11]

Unfortunately, due to the inability to accurately measure pressure oscillations within many LVAD patients, measuring arterial stiffness independent of blood pressure during LVAD therapy is very challenging, if not impossible. Therefore, several studies have used the methodological approach to compare heart failure patients before LVAD surgery and shortly after orthotopic heart transplant (OHT).

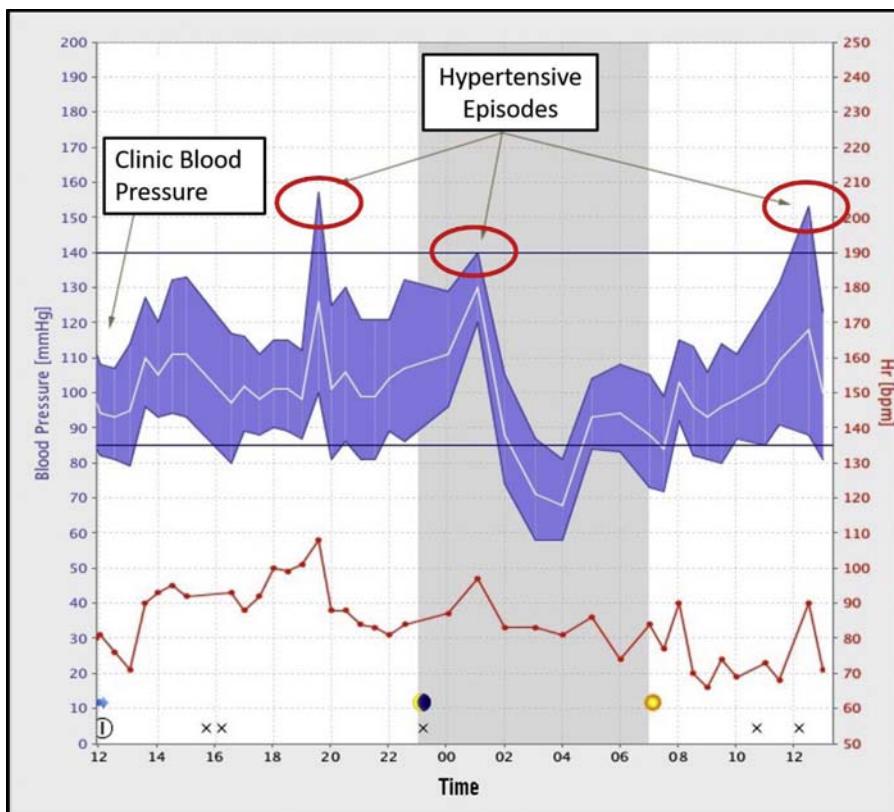
Indeed, it has been shown that patients on LVAD therapy have higher aortic stiffness compared to heart failure patients not on LVAD support.[12] These findings were further described by a reduced smooth muscle content and an increased collagen content of ascending aorta tissue samples, harvested during transplant after only 7 months on LVAD therapy. LVAD patients may thus experience dramatic aortic stiffening as a result of major structural remodeling compared to heart failure patients not on LVAD therapy. In addition, more recent evidence suggests that aortic stiffness index [aSI: ln(systolic/diastolic pressures) to (relative change in diameter)] does not increase in all LVAD patients, highlighting a differential macrovascular response to continuous-flow therapy.[13,14] The reasons for such disparate responses may be attributed to the duration of LVAD support, differential pharmacological therapy, and the individual LVAD settings (mostly pump speed). Moreover, the same data highlighted that composite outcome (reported as GI bleeding, pump thrombosis, and stroke) was highest in those patients where aSI increased while on LVAD therapy, compared to those patients where aSI did not increase or even decreased. As such, this study emphasizes the potentially important link between increased arterial stiffness and microvascular complications.

One point that must not be ignored is the probable impact of the severity of heart failure and duration prior to LVAD implantation, as well as the potential effects of the duration of LVAD therapy, which may influence how and to what extent continuous flow interacts with an already diseased cardiovascular system, and thus impacts on the macro- and microcirculation.

Endothelial dysfunction

In addition to increased sympathetic nerve activity, accelerated vascular remodeling, and arterial stiffness, patients with continuous-flow LVADs have been shown to have greater levels of endothelial dysfunction compared to heart failure patients with reduced ejection fraction.[15] Since endothelial dysfunction is associated with high cardiovascular risk, understanding the extent and reasons behind this endothelial dysfunction in LVAD patients is critical.[16] In a non-LVAD population, the cyclical changes in blood flow and pressures create an optimal shear stress on the endothelial layer of the arteries, stimulating the release of endothelial-derived nitric oxide (NO), which is necessary for smooth muscle relaxation, dilatation, and regulation of arterial stiffness.[17] In continuous-flow LVAD patients, it has been proposed that the low PI results in a decreased stimulation of the endothelium and thus a lower NO, with a subsequent reduction in dynamic endothelial responsiveness and increased arterial stiffness.[18]

One approach used to determine endothelial function is a standardized test termed flow-mediated dilatation (FMD). Typically, the degree of endothelial dysfunction and therefore FMD is predominantly associated with NO release, or to a lesser extent, the release of prostacyclin and endothelial-derived hyperpolarizing factor.[19,20] Unsurprisingly, FMD is lower in continuous-flow LVAD patients compared to patients implanted with pulsatile LVAD systems that are no longer in use.[15] These findings highlight the critical cyclical role that pressure and flow oscillations play in regulating NO release and maintaining endothelial function in LVAD patients. Moreover, the interconnections between the native heart, LVAD speed settings, and device differences may produce different magnitudes of pulsatility (see Fig. 48.1) and subsequent degree of endothelial dysfunction. Since endothelial dysfunction and NO production are associated with increasing arterial stiffness, it is acceptable to suggest that these links may play a role in determining the degree of arterial stiffness observed in LVAD patients and the associated risk of GI bleeding and stroke.

With the introduction of the third generation of LVAD devices (HM3), more studies are needed to investigate the impact of the "artificial pulse" of this system on the development and progression of endothelial dysfunction and arterial stiffness. These much-needed data will elucidate if the "artificial pulse" is even present across the macro- and microcirculation of LVAD patients, and whether it creates enough of an oscillatory swing to stimulate an increased NO release from the endothelial layer and maintain endothelial function.


Given the impact of LVADs on the macrocirculation, it is reasonable to expect that the observed impact of continuous flow and low pulsatility on large artery endothelial dysfunction may also be apparent within the microcirculation. Investigating microcirculatory endothelial dysfunction in specific peripheral organs (e.g., the brain and GI tract) may provide future mechanisms linked to clinical microcirculatory outcome in LVAD patients.

Blood pressure

As already stated, a baroreceptor-mediated rise in SNA increases peripheral vascular tone and contributes to the maintenance of mean arterial pressure (in the face of a reduced systolic BP) observed in LVAD patients. However, due to the absence of detectable pressure oscillations in the majority of LVAD patients, the ability to accurately measure blood pressure is often lacking. The inability to accurately measure systolic and diastolic blood pressure and therefore PP in LVAD patients means that decision-making in relation to optimizing treatment may often be suboptimal. When oscillometric devices fail to capture a blood pressure in the clinic, an alternative of using Doppler to attempt to record a measurement of pressure is often used. Importantly, there has been debate as to what pressure the Doppler method measures (mean arterial pressure vs. systolic pressure). Thus, its interpretation in clinical practice is uncertain. The aforementioned lack of oscillations makes it a critical issue in providing informed treatment for hypertension in patients on continuous-flow LVAD therapy. Importantly, LVAD patients have been shown to have a lower threshold of blood pressure−associated CV risk and outcome compared to that of other populations. For example, the risk of stroke is increased above a relatively low systolic blood pressure ∼101 mmHg, compared to >140 mmHg in typical hypertensive populations.[21−24] Therefore, continuous-flow LVAD patients may be at high risk of stroke due to the inability of their macrovasculature to regulate and maintain a blood pressure below 101mmHg. Moreover, risk of stroke could also be influenced by levels of anticoagulation and levels of v-WF deficiency in these patients. In addition, higher levels of blood pressure may also lead to higher risk of thrombus formation in the LVAD device due to increased stasis from a lowered driving pressure from the system.

The current inability to record and accurately measure blood pressure−related clinical issues in the majority of LVAD patients poses a serious challenge for our understanding. Importantly, these issues are exacerbated in HM3 patients who have a chaotic blood flow and pressure profile due to the artificial pulse (see Fig. 48.1F and G). The chaotic waveform further complicates an accurate blood pressure measurements. At present, there are no commercially available, noninvasive, oscillometric systems that can accurately measure and record blood pressure in HM3 patients. This causes significant challenges during clinical

FIGURE 48.2 The 24-hour blood pressure profile and variability (inclusive of highlighted hypertensive episodes) of a HMII LVAD patient. The figure above describes the blood pressure profile of the HMII LVAD patient over 24 h, with hypertensive episodes circled in red.

follow-up when attempting to measure and treat high blood pressure and reduce microvascular complications.

Importantly, 24-h recordings of ambulatory blood pressure of HMII patients have revealed several blood pressure surges throughout the 24-hour period (see Fig. 48.2). Due to the fact that LVAD patients are already at high risk of stroke at systolic blood pressure levels above 101 mmHg, evidence to show an inability to buffer systolic blood pressure surges >140 mmHg over a 24-h period, could mean that the LVAD patient is potentially at higher risk of microvascular insults during such hypertensive episodes.

Consequences of low pressure and flow pulsatility on the microcirculation

The previous sections have highlighted the impact of low pulsatility hemodynamics from the implanted device on the large arteries. Moreover, the clinical data indicate that the third-generation LVAD, the HM3, is associated with overall improved clinical outcomes. However, there are some remaining clinical challenges that seem to be as problematic with the HM3 as with the HM II. This indicates that the technological advances of the HM3, including the intermittent "artificial pulse," have not sufficiently resolved the circulatory complications in LVAD patients. Several

major complications mentioned above persist even in the third-generation LVAD patients, including right heart failure (27%−32% of patients), GI bleeding (27%), stroke (10%−19%), respiratory failure (22%−24%), and a reduced exercise capacity that is minimally improved from the pre-LVAD heart failure state. In the following paragraphs, we discuss the potential role of microcirculatory disruption in relation to these complications and the possible pharmacological management, before summarizing the potential mechanisms involved.

At present, it seems conceivable that the low pulsatile hemodynamics are a systemic phenomenon, as evidenced by the lower pulsatility across the whole circulation. Recent studies have revealed that the reduced arterial pulsatility of LVAD patients implanted with both the second- and third-generation devices can be seen in the large, intermediate-sized conduit arteries as well as the microcirculation.[25] Of great importance is the observation that the reduction in pulsatility from the aorta and carotid arteries to the middle cerebral and central retinal artery of healthy individuals is halved again in LVAD patients.[25] These findings demonstrate the extent to which the microcirculation of LVAD patients may be impacted. Yet, our current knowledge also suggests that these hemodynamics may have a differential impact on the microcirculation of different end organs, given the varied complications mentioned above.

Right heart failure and respiratory complications

Right heart function is important for the circulatory function of patients with LVADs and may itself produce some microcirculatory complications in the lungs. Studies that acutely changed the LVAD pump speed highlighted the relationship between an unloading of the LV and an overloading of the right ventricle (RV).[26] Unloading the LV to an end-diastolic volume less than 260 mL will increase the volumetric load on the RV and vice versa. This may indicate why a significant portion of LVAD patients experience severe right heart complications, in particular in the postoperative period. Ultrasound of the right heart has revealed some important hemodynamic shifts in LVAD patients and has the potential to inform the clinician about early changes in pulmonary artery pulsatility index as well as of right ventricular dysfunction.[26,27] Whether the altered RV hemodynamics are directly linked to the respiratory complications remains to be elucidated. Phenomena like the exercise-induced arterial hypoxemia in LVAD patients (see below for more details) do suggest that there is a circulatory problem in the lungs, which could either relate to an increased transit time of blood (caused by a volume overload) or to direct respiratory issues.[28]

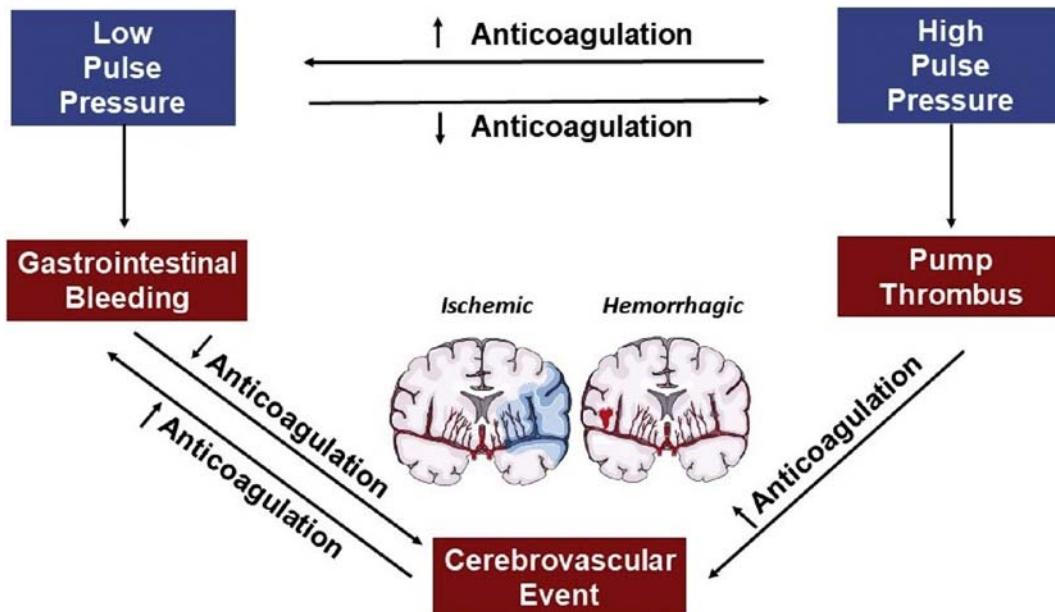
Cerebrovascular complications

In the brain, microcirculatory complications are alarmingly high, with a reported prevalence of 97% of LVAD patients with cortical microbleeds.[29] It is likely that the LVAD itself, and the continuous-flow more precisely, causes such widespread pathophysiologic changes that predispose to microvascular complications. Yet, the kidneys, which are known to be particularly sensitive to altered hemodynamics, are less affected than other organs (in particular when considering the confounding influence of declining muscle mass in the estimation of glomerular filtration rate).[5,30] Despite a concerted effort of the LVAD research community, the mechanisms associated with microcirculatory complications in the brain remain elusive. This is in part the case because of the technical challenges of measuring the microcirculatory hemodynamics in the different target organs. MRI assessments are not possible during LVAD support, and other imaging techniques have their own limitations. Equally, ultrasound has been used successfully to determine hemodynamics in the cerebral circulation, namely the middle cerebral artery.[25] The typical investigation of the middle cerebral artery is, however, not representative of the cerebral *micro*circulation. MRI investigations immediately before LVAD implantation and after OHT have revealed important insights into the cerebral microcirculation as discussed above. But the lack of data on the cerebral microcirculation *during* LVAD support presents a major

gap of knowledge in the LVAD community. Given the close anatomic relationship between the eye and the cerebral circulation, the use of ultrasound to detect flow dynamics and pulsatility in the central retinal artery (diameter range of ∼140–180 μm) of LVAD patients may significantly advance our current knowledge in this area. At present, it is not known whether the HeartMate 3 creates a similar transmission of hemodynamics from the macro- to the microcirculation. Furthermore, the impact of the "artificial pulse" on the macrocirculation and its transmission into the microcirculation remains unknown, and more research is required to assess cerebrovascular, macro- and microcirculatory dynamics in patients with contemporary LVADs.

Gastrointestinal bleeding

For the GI tract, the noninvasive hemodynamic assessment is particularly problematic, since the clinical interventions in response to suspected or overt GI bleeding may worsen the patients' prognosis.[31,32] Studies have shown that the high prevalence of GI bleeding in LVAD patients is associated with angiodysplasia and arterio-venous (AV) malformations.[31,32] Because of the similar prevalence of GI bleeding in HeartMate II and HeartMate 3 patients, the "artificial pulse" of the HM3 does not seem to have had a positive impact. Consequently, the exact mechanisms associated with GI bleeding in LVAD patients remain unknown. However, uncontrolled hypervolemia, increased sympathetic state (known to affect the GI tract), a neurohormonal axis related to AV malformations, and/or the reduced pressure and flow pulsatility could influence the integrity of the GI microcirculation and clinical presentation of GI bleeding. Equally, it is possible that the right heart failure discussed above may cause a backflow into the GI tract that could manifest as microcirculatory complications and ultimately angiodysplasia and GI bleeding.[33,34]

Interestingly, GI bleeding is also prevalent in severe aortic stenosis, suggesting a more general link between altered cardiac output dynamics and GI bleeding across different patient groups. Furthermore, a common complication in LVAD patients is aortic insufficiency, which can lead to aortic regurgitation similar to severe aortic stenosis.[35] However, it is important to acknowledge that the arterial hemodynamics of aortic stenosis are more pulsatile than those of LVAD patients, and that the angiodysplasia of LVAD patients has its own distinct phenotype.[36–38] Instead, the hemodynamics of patients with severe aortic stenosis may actually be more similar to those of advanced heart failure patients *prior* to LVAD implantation. Consequently, the microcirculatory complications experienced during chronic heart failure have the potential to prime the microcirculation and predispose the patients to the above-mentioned complications when the hemodynamics are suddenly altered to a hypervolemic, low-pulsatile state during LVAD support.


Pharmacological decision-making in relation to PP and PI in LVAD patients

Historically, stroke has been the primary cause of death among heart failure patients supported by LVAD from 6 to 24 months of support.[39] The reasons for this are multifactorial and related to comorbidities, medication effects, a prothrombotic state, and other LVAD-related complications that result from chronic exposure to a nonphysiologic pulse.[8,40,41] These factors work together in an almost synergistic fashion to increase the risk of cerebrovascular events.[40] As demonstrated in Fig. 48.3 below, reductions in PP increase the risk of GI bleeding,[42] and reductions in strength of anticoagulation subsequent to a bleeding event substantially increase the risk of pump thrombus formation or an ischemic stroke. Hypertension may increase the risk of pump thrombus formation by nearly threefold, which increases the risk of subsequent stroke. Therefore, careful and personalized medication considerations are required when treating such patients. Potential application of measuring localized flow PI may help inform pharmacological decision-making in the future.

Finally, it is noteworthy that more than one-fourth of LVAD patients experience a device-related infection over time,[43] which independently increases the risk of stroke, possibly as a result of formation of mycotic aneurysms from bacterial seeding.[44]

Left ventricular assist device therapy and exercise capacity

Despite normalization of a resting cardiac output following implantation of an LVAD, patients suffer from severe and persistent reductions in functional exercise capacity. However, the mechanisms related to the reduced exercise capacity and the consequences for the microcirculation are not clear. It has been shown that subjective assessments of quality-of-life and the severity of heart failure improve following LVAD implantation.[45] However, objective metrics such as the maximal oxygen uptake (VO_2max) obtained during cardiopulmonary exercise testing fail to improve and typically remain in the range of 12–15 mL/kg/min, even up to 1 year after device implantation.[46–48] The ability of current-generation LVADs to augment flow during exercise is limited and as such, delivery of oxygenated blood to exercising muscle largely depends on the intrinsic contractility of the native LV.[47,49,50] Considering that the absolute workload and 6-min walk distance mildly improve during LVAD therapy, the lack of a clear increase in VO_2max may be attributable to longstanding skeletal muscle microcirculatory issues. Severe deconditioning of the skeletal musculature because of a long history of chronic heart failure may be one reason, thereby possibly affecting mitochondrial density, mitochondrial respiration, and the energetic efficiency of different muscle fiber types. Equally, the dramatically low PP

FIGURE 48.3 The complex and sensitive interactions between low pulse pressure, high pulse pressure, anticoagulation treatment, and microvascular complications of LVAD patients. Lines show the interconnections between blood pressures, GI bleeding or Pump thrombus and cerebrovascular events when anticoagulation therapy is increased or decreased. *Figure modified and changed from source Cornwell III WK, Ambardekar AV, Tran T, et al. Stroke incidence and impact of continuous-flow left ventricular assist devices on cerebrovascular physiology. Stroke. 2019; 50:542–548.*

and PI in the microcirculation may affect capillary recruitment and O_2 kinetics in the capillaries, which is supported by the observation that LVAD patients experience exercise-induced arterial hypoxemia at low cardiac outputs.[28] Furthermore, exercise among patients with heart failure may be limited by pulmonary, peripheral vascular, autonomic or musculoskeletal abnormalities, and it is not clear by any means that LVAD implantation improves these organ systems.[46] Finally, the pump itself is a denervated machine with no biofeedback mechanisms in place and, as such, does not participate in autonomic/exercise presser reflexes that otherwise facilitate the body's response to exercise, including the regulation of arteriolar and capillary diameter and tone.

Conclusions

It is clear that low pulsatility has detrimental consequences on the macro- and microcirculation that is as serious a problem as excessive pulsatility. However, the role of low pulsatility in LVAD patients must be interpreted and discussed in relation to many interconnecting factors. Such factors include pharmacological treatment regimens, pump speed settings, hypervolemia, O_2 uptake, and the severity of underlying cardiac and vascular disease states pre-implantation. Further studies are needed to understand the direct role of low pressure and flow pulsatility in affecting macro- and microcirculatory health, which will likely substantially advance our general understanding of arterial physiology and circulatory regulation.

Chapter 49

Effects of common antihypertensive treatments on pulsatile arterial hemodynamics

Yi-Bang Cheng and Ji-Guang Wang

National Research Centre for Translational Medicine, Centre for Epidemiological Studies and Clinical Trials, Shanghai Key Laboratory of Hypertension, The Shanghai Institute of Hypertension, Department of Hypertension, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China

Introduction

When the blood flows from the central large elastic aorta to peripheral smaller muscular arteries, systolic blood pressure (BP) increases, without significant changes in diastolic BP and mean arterial pressure, resulting in widened pulse pressure. Although brachial BP highly correlates with central BP, substantial individual discrepancies between central and peripheral BP exist. Some studies have shown that the strength of the associations between target organ damage and systolic BP and pulse pressure was stronger for the central than brachial arteries. In a meta-analysis of 11 studies that included 5648 subjects followed up for 3.8 years, central pulse pressure showed borderline superiority to brachial pulse pressure in the prediction of cardiovascular events.[1]

Several previous studies have shown that various classes of antihypertensive drugs may have different treatment effects. The Conduit Artery Function Evaluation study,[2] a substudy of the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT), showed that amlodipine/perindopril was more efficacious than atenolol/thiazide in reducing central systolic BP and pulse pressure by 4.3 mm Hg (95% confidence interval [CI], 3.3 to 5.4) and 3 mm Hg (95% CI, 2.1 to 3.9), respectively, despite similar brachial BP reductions in the two groups. In addition, central pulse pressure was significantly associated with the risk of the composite outcome of total cardiovascular events and procedures and development of renal impairment.[2] The cardiovascular benefits of amlodipine and perindopril based regimen observed in ASCOT[3] might have resulted at least in part

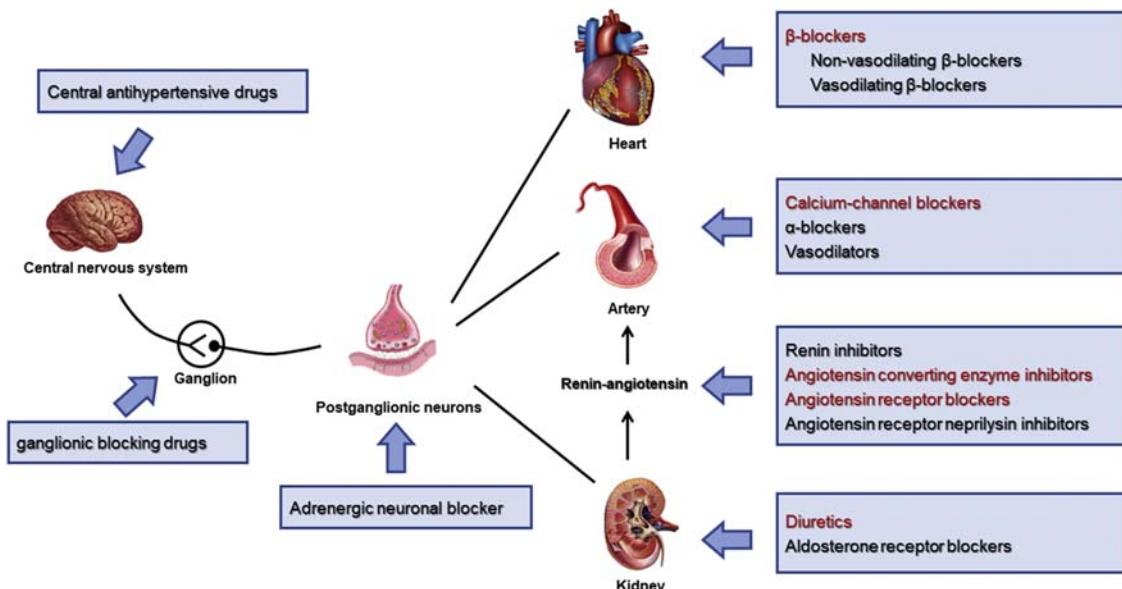
from their effect on central BP, although other hemodynamic effects (such as reduced BP variability) might have been involved as well.[4] There is therefore a growing interest in central BP as a target of treatment in hypertension.

In this review article, we summarize the evidence on the effect of pharmaceutical- or device-based cardiovascular therapeutics on pulsatile arterial hemodynamics. We discuss (1) whether antihypertensive drug treatment reduced arterial wave reflections; (2) whether the newer agents, such as renin-angiotensin-aldosterone (RAS) inhibitors and calcium-channel blockers (CCBs), were more efficacious than the older ones, such as diuretics, β-blockers, and α-blockers; (3) whether the even newer agents, such as vasodilating β-blockers and angiotensin receptor neprilysin inhibitors (ARNIs), were more efficacious than their respective comparators, i.e., non-vasodilating β-blockers and angiotensin receptor blockers (ARBs), respectively. In addition, we also studied device-based antihypertensive therapy for its effects on central hemodynamics.

Antihypertensive drug classes and their mechanisms of action

Current hypertension guidelines recommend several classes of antihypertensive agents for the treatment of hypertension, such as angiotensin-converting enzyme (ACE) inhibitors, ARBs, β-blockers, dihydropyridine CCBs, and thiazide diuretics. These agents reduce BP via different modes of action. ACE inhibitors and ARBs block the RAS

system by inhibiting ACE and blocking the angiotensin II type 1 receptor, respectively. β-blockers reduce BP by inhibiting activation of the sympathetic nervous system, and reducing heart rate and myocardial contractility. Newer β-blockers show ancillary vasodilatory properties, which may play a part in BP lowering. Dihydropyridine CCBs dilate arteries, especially arterioles, and reduce BP by constricting calcium channels on vascular smooth muscle cells. Diuretics exert antihypertensive effects on the kidneys via enhancing electrolytes and water excretion and regulating body fluid volume. Several other classes of antihypertensive agents are also recommended on special conditions or for patients with resistant hypertension, such as α_1-blockers, central sympatholytic agents, loop diuretics, nondihydropyridine CCBs, potassium sparing diuretics (aldosterone receptor antagonists and others), direct vasodilators, and so on. Direct renin inhibitors and ARNIs still have limited availability but can also be used in the treatment of hypertension on various clinical conditions (Fig. 49.1).

Data acquisition, extraction, and analysis


We searched the PubMed, Embase, and Cochrane Central Register of Controlled Trials for randomized controlled trials that tested antihypertensive treatment with central arterial hemodynamics as an outcome measure. The search key terms included "central pressure," "aortic pressure," "carotid pressure," "pulse amplification," "central-to-peripheral pulse pressure ratio," "augmentation index (AI)," "antihypertensive drug," "antihypertensive treatment," and "antihypertensive agent." We limited our search to studies published in English in peer-reviewed journals up to

September 2020. We checked the reference lists of review articles and original studies identified by the electronic search to find other potentially eligible studies.

We identified 140 published studies meeting the above criteria. We excluded 70 studies because of less than four weeks of follow-up time (n = 9), uncontrolled or self-controlled design (n = 4), nonrandomized subgroup analyses (n = 7), dose-dependent study (n = 2) or crossover design (n = 45), or ambulatory central BP as outcome (n = 3). We further excluded 29 studies because of combination antihypertensive therapy (n = 6), within class drug comparison (n = 13), actively controlled trials between RAS inhibitors, ARNI, CCBs, and vasodilating β-blockers comparison (n = 7), or without central BP mean values (n = 1) or 95% confidence intervals (n = 2). Thus, a total of 41 studies were eventually included in the present overview.

These 41 trials[5−45] included 13 trials that compared antihypertensive drugs with placebo[6−10,12,13,15,17] or "usual care,"[4,10,13,15] and 20 trials that compared RAS inhibitors[8,18−23,26−34] (n = 16) or CCBs[20,24,25,35,36] (n = 5) with diuretics,[8,18−20,24,25,33−35] β-blockers[20−22,26−32,36] or an α-blocker,[23] or compared vasodilating with non-vasodilating β-blockers[22,37−43] (n = 8), or ARNI with ARB[44,45] (n = 2). We additionally identified four device-based therapy trials[46−49] for the treatment effect of either renal sympathetic denervation (RDN)[46] or continuous positive airway pressure (CPAP)[47−49] on central pressure and AI.

We based our analysis on summary statistics reported in the literature. For central arterial hemodynamics, we extracted the means and standard deviations for the experimental and control groups separately, at baseline and during follow-up, and if available in the published report,

FIGURE 49.1 Main classes of antihypertensive agents and mechanism of action. Drug classes in red color are those recommended by the current hypertension guidelines.

also changes over time. We extracted measurement information on the techniques used to assess arterial hemodynamics. We searched for specifications about the BP measuring device and other methods for BP measurement, arterial sites, and the algorithm for AI estimation.

For each comparison within each trial, we calculated the absolute difference in the mean changes over time in central systolic BP (mm Hg), central pulse pressure (mm Hg), augmentation pressure (mm Hg) and AI (%) between the experimental and control groups. The pooled effect for each grouping of trials was derived from the point estimate for each separate trial weighted by the inverse of the variance $(1/SE^2)$. Heterogeneity of effect sizes was tested across trials using the χ^2 test. If trials were homogeneous $(P < .10)$, a fixed-effects model was used to calculate pooled effect sizes. Otherwise, a random-effects model was applied to calculate overall differences. Net treatment effects on central pressure and AI were determined by subtracting the mean change in the experimental group from the corresponding mean change in the control group. We ran all aforementioned computations and statistical analyses in Stata version 15 (Stata Corp LP, College Station, Texas, USA).

Antihypertensive drugs versus placebo or no-treatment

This part of our analysis included 13 studies with 635 participants, of whom 415 (65.4%) had been randomized in nine double-blind trials and 220 (34.6%) in four studies with an open design (Table 49.1). Active antihypertensive treatment consisted of an ACEI in three trials (n = 165),[5−7] an ARB in three trials (n = 186),[8−10] an aldosterone receptor antagonist in two trials (n = 102),[11,12] a renin inhibitor in two trials (n = 49),[12,13] a diuretic in one trial (n = 40),[8] and a vasodilating β-blocker in three trials (n = 129).[15−17] Klingbeil's study[8] contributed two groups to the present overview, valsartan or hydrochlorothiazide versus placebo. The weighted mean changes in central systolic and diastolic BP across the nine trials[5,7,8,10−16] were −6.9 mm Hg (95% CI, −9.9 to −3.7, $P < .001$) and −4.1 mm Hg (95% CI, −5.7 to −2.5, $P < .001$), respectively. The weighted mean changes were −2.0 mm Hg (95% CI, −3.5 to −0.6, $P = .007$) in augmentation pressure across five trials,[5,7,8,13,15] and −5.2% (−9.1 to −1.3, $P < .001$) in AI across 10 trials.[5−11,14,15,17]

Renin-angiotensin-aldosterone inhibitors and calcium-channel blockers versus diuretics, β-blockers, and α-blockers

London and colleagues conducted a controlled, blinded study to compare perindopril and nitrendipine on their effects on arterial hemodynamics in patients on chronic hemodialysis.[50] The results showed that 12 months of treatment with ACEI and CCB had similar effects on AI and carotid BP. A series of subsequent studies investigated the central hemodynamic effects of vasoactive antihypertensive agents.[2,8,18−45,51]

The following REASON study[51] revealed that in 471 hypertensive participants followed for 12 months, the indapamide and perindopril combination decreased brachial systolic BP and pulse pressure significantly more than atenolol, with an adjusted between-group difference of −6.02 mm Hg (95% CI, −8.90 to −3.14) and −5.57 mm Hg (95% CI, −7.70 to −3.44), respectively. Similar adjusted between-group differences were observed for central systolic BP [−12.52 mm Hg (95% CI, −17.97 to −7.08)] and pulse pressure [−10.34 mm Hg (95% CI, −14.12 to −6.56)], and for carotid [−5.57% (95% CI, −10.77 to −0.36)] and aortic AI [−5.17% (95% CI, −7.74 to −2.61)].

Taking all the 20 trials together (Table 49.2),[8,18−36] newer antihypertensive agents consisted of an ACEI in seven trials (n = 854),[18−23] an ARB in eight trials (n = 1123),[8,26−32] a renin inhibitor in three trials (n = 197),[22,33,34] and a CCB in five trials (n = 490).[20,24,25,35,36] Compared with diuretics, β-blockers or α-blockers, the differences in the changes in central systolic BP were statistically significant for ACEIs by −3.4 mm Hg (95% CI, −5.9 to −0.9, $P = .008$), for ARBs by −4.1 mm Hg (95% CI, −6.0 to −2.2, $P < .001$), for renin inhibitors by −6.7 mm Hg (95% CI, −7.8 to −5.5, $P < .001$), and for CCBs by −5.6 mm Hg (95% CI, −8.2 to −3.0, $P < .001$). No significant heterogeneity was noticed within the four comparisons ($P \geq .24$). The weighted mean changes were −5.6 mm Hg (95% CI, −6.5 to −4.8, $P < .001$) in central systolic BP across the 20 trials[8,18−36] and −3.3 mm Hg (95% CI, −5.0 to −1.6, $P < .001$) in pulse pressure across 12 studies.[8,18−20,22,24,26,28,30−32,35] The weighted mean changes were −3.4 mm Hg (−5.3 to −1.4, $P < .001$) in augmentation pressure across five trials[8,20,24,27,35] and −6.1% (−7.9 to −4.3, $P < .001$) in AI across 18 trials.[8,19−25,27−36]

Vasodilating versus nonvasodilating β-blockers

β-blockers have been shown to increase central systolic BP or decrease central-to-peripheral BP amplification through slowing heart rate and increasing peripheral vasoconstriction. However, β-blockers are usually classified into three generations: the first-generation nonselective β-blockers, the second-generation cardioselective (selective β1-blockade) agents, and the third-generation agents with ancillary vasodilating action, via the release of nitric oxide and antioxidative, β2-agonistic, and calcium entry blocking effects (Table 49.3).[52] The

[a]Augmentation index was calculated either by the ratio of the second peak (P2) to the first peak (P1) of the central blood pressure wave, or by augmentation pressure (P2−P1) divided by pulse pressure (PP), expressed in percent. @HR75 indicated that augmentation index was adjusted by heart rate at 75 bpm.

TABLE 49.3 Pharmacological effects of various vasodilating β-blockers.

Drugs	Selective β1-blockade (vs. β2)	α-Blockade	Vasodilating actions
Celiprolol	√	√	Activate β2-adrenoceptors, and release nitric oxide and ANP
Nebivolol	√	−	Release nitric oxide
Nipradilol	−	√	Contain the nitric dioxide radicals in chemical structure
Carvedilol	−	√	Release nitric oxide, and antioxidative action
Carteolol	−	−	Activate β2-adrenoceptors, and release nitric oxide
Bucindolol	−	√	Activate β2-adrenoceptors, and release AMP
Betaxolol	√	−	Block Ca^{2+} entry
Bopindolol	−	−	Activate β2-adrenoceptors, and release nitric oxide
Bevantolol	√	√	Block Ca^{2+} entry
Dilevalol	−	−	Activate β2-adrenoceptors
Tilisolol	−	−	Activate ATP-sensitive K^+ channel

ANP, atrial natriuretic peptide; *AMP*, adenosine 5′-monophosphate.

third-generation β-blockers may behave differently from nonvasodilating β-blockers. A total of eight trials[22,37–43] compared vasodilating with nonvasodilating β-blockers on central hemodynamics (Table 49.4). Vasodilating compared to nonvasodilating β-blockers reduced central systolic BP and AI significantly with a weighted mean difference of −2.3 mm Hg (95% CI, −4.6 to 0.03, $P = .053$) and −2.1% (95% CI, −3.9 to −0.3, $P = .02$), respectively. The effect seemed less pronounced than RAS inhibitors and CCBs, probably because of the stroke volume enhancement of β-blockers.[53,54]

Angiotensin receptor neprilysin inhibitor versus angiotensin receptor blocker

Neprilysin is a neutral endopeptidase that degrades several potentially beneficial vasoactive peptides, including natriuretic peptides, bradykinin, and adrenomedullin. Two parallelly conducted randomized, double-blind studies compared ARNI with olmesartan on central pulsatile waves in hypertensive patients with arterial stiffness represented by high pulse pressure. The PARAMETER study[44] revealed that sacubitril/valsartan reduced central aortic systolic BP (primary outcome) greater than olmesartan [between-treatment difference: −3.7 mm Hg (95% CI, −6.4 to −0.9), $P = .01$] after 12-week treatment. Similar results were observed at 12-week treatment in the secondary outcomes, including central aortic pulse pressure (−2.4 mm Hg, $P < .012$) and mean 24-hour ambulatory central aortic systolic BP (−3.6 mm Hg, $P < .001$). However, these pressures were similar between the two groups after 52-week treatment, probably because in the olmesartan group more subjects required add-on antihypertensive therapy than the

sacubitril/valsartan group (47% vs. 32%, $P < .002$). Indeed, Schmieder found that sacubitril/valsartan reduced central aortic pulse pressure to a greater extent than olmesartan (−3.5 mm Hg, $P = .01$) after 52-week treatment, with similar add-on treatment of amlodipine (17.5% *vs.* 29.8%, $P = .12$).[45] Of note, left ventricular mass index was reduced more in the sacubitril/valsartan group, and the between-group difference was marginally significant after adjustment for systolic BP ($P = .0529$).[45]

Organic and inorganic nitrates, soluble guanylyl cyclase stimulators and cyclic guanosine monophosphate (cGMP)-binding phosphodiesterase (PDE5) inhibitors

The production of nitric oxide is important to the vasodilation in muscular arteries through cGMP-mediated processes. Organic and inorganic nitrates cause vasodilation, presumably by enzymatic degradation or conversion to nitric oxide. Soluble guanylyl cyclase (sGC) was the primary receptor for nitric oxide. PDE5 was a cGMP-specific hydrolase. Both sGC stimulators and PDE5 inhibitors regulate vasodilation by increasing the intracellular cGMP concentration. The hemodynamic effects of these agents are discussed in detail in Chapter 52.

Device-based antihypertensive therapy

RDN has proven renal safety in trials and might be efficacious in treating resistant hypertension. In a prospective study,[46] arterial stiffness was assessed by the fingertip tonometry-derived AI at baseline and three-month

TABLE 49.4 Vasodilating versus nonvasodilating β-blockers.

AI, augmentation index; *cBP*, central blood pressure; *HT*, hypertension; *m*, months; *w*, weeks.
[a]Augmentation index was calculated either by the ratio of the second peak (P2) to the first peak (P1) of the central blood pressure wave, or by augmentation pressure (P2−P1) divided by pulse pressure (PP), expressed in percent. @HR75 indicated that augmentation index was adjusted by heart rate at 75 bpm.

follow-up in 40 patients treated with RDN and 10 controls. RDN significantly reduced AI (30.6 ± 23.8 *vs.* $22.7 \pm 22.4\%$, $P = .002$), and the heart rate adjusted AI (22.4 ± 21.6 *vs.* $14.4 \pm 20.7\%$, $P = .002$). Changes in heart rate-adjusted AI were not correlated with BP components, indicating that RDN may function, beyond antihypertensive effect, via the regulation of smooth muscle tone or arterial wall composition.[55]

CPAP is a standard therapy for symptomatic obstructive sleep apnea (OSA), and has been reported to reduce brachial BP. In a randomized crossover trial, 44 patients with resistant hypertension and severe OSA were treated with CPAP or sham CPAP for 3 weeks and crossed over afterwards to the alternative ventilation regimen.[47] In comparison with the sham CPAP, CPAP showed a decrease in central and peripheral systolic/diastolic BP by $-4.4/-4.0$ mm Hg and $-4.6/-3.4$ mm Hg, respectively. In a longer intervention period of 8 weeks, similar reductions in central and peripheral BP were observed. Time to reflection on the pulse wave was improved with CPAP compared to the sham CPAP (3.7 ms, $P = .01$), without any between-group difference in AI.[48] In a three parallel groups trial, 139 adults with obesity and moderate and severe OSA were randomized to CPAP and weight loss alone or both for 24 weeks.[49] Only patients in the CPAP and weight loss combination group showed significant reductions in central systolic BP by 7.4 mm Hg ($P = .004$). None of these treatments significantly changed central pulse pressure, pulse pressure amplification, AI, or carotid-femoral pulse wave velocity. The effect of CPAP on central pressure seemed to be mediated by changes in mean arterial pressure rather than central pulse pressure or arterial stiffness.

Conclusions and perspectives

This review showed some efficacy of pharmaceutical- or device-based cardiovascular therapeutics on arterial hemodynamics, and confirmed divergent effects of various classes of antihypertensive drugs on central BP and AI. Nonetheless, none of the currently available antihypertensive treatments selectively or preferentially reduced central BP over and above their brachial BP lowering effect.

The mechanisms for these treatment effects remained under investigation. Because of the less central BP lowering effect of nonvasodilating β-blockers, heart rate and vasodilation or vasoconstriction must play a major role in the modulation of central hemodynamics. Indeed, in a meta-regression analysis,[56] we previously found that slowing heart rate may to a large extent explain the less efficacy of β-blockers versus the other classes of antihypertensive drugs. However, because of the divergent effects of vasodilating versus nonvasodilating β-blockers, vasoactive property must also play an important part of the central hemodynamic regulation. Studies on the I_f inhibitor ivabradine provided

further evidence. In a randomized, placebo-controlled, crossover, double-blind study in 12 normotensive patients with stable coronary artery disease, sinus heart rate ≥ 70 beats per minute and background β-blocker therapy, ivabradine treatment for 3 weeks reduced heart rate (-15.8 ± 7.7 *vs.* 0.3 ± 5.8 beats per minute, $P = .001$) and increased left ventricular ejection time (18.5 ± 17.8 *vs.* 2.8 ± 19.3 ms, $P = .074$) and diastolic perfusion time (215.6 ± 105.3 *vs.* -3.0 ± 55.8 ms, $P = .0005$), but did not significantly increase central systolic BP (-4.0 ± 9.6 *vs.* 2.4 ± 12.0 mm Hg, $P = .13$) or AI ($-0.8 \pm 10.0\%$ *vs.* $0.3 \pm 7.6\%$, $P = .87$).[57] Taken these evidence together, it is probably the interaction between heart rate and vasoactive property that determine the extent of central pressure augmentation from wave reflections. This hypothesis may be tested in future animal experiments as well as human research.

At present, there is no direct evidence regarding the clinical relevance of central hemodynamics for decision-making in the management of hypertension and cardiovascular prevention. It is therefore imperative to run adequately powered outcome trials to investigate whether central pressure and wave reflection are clinically useful in guiding antihypertensive treatment and other cardiovascular therapeutic approaches for the prevention of cardiovascular events.

Chapter 50

Pharmacologic approaches to reduce arterial stiffness

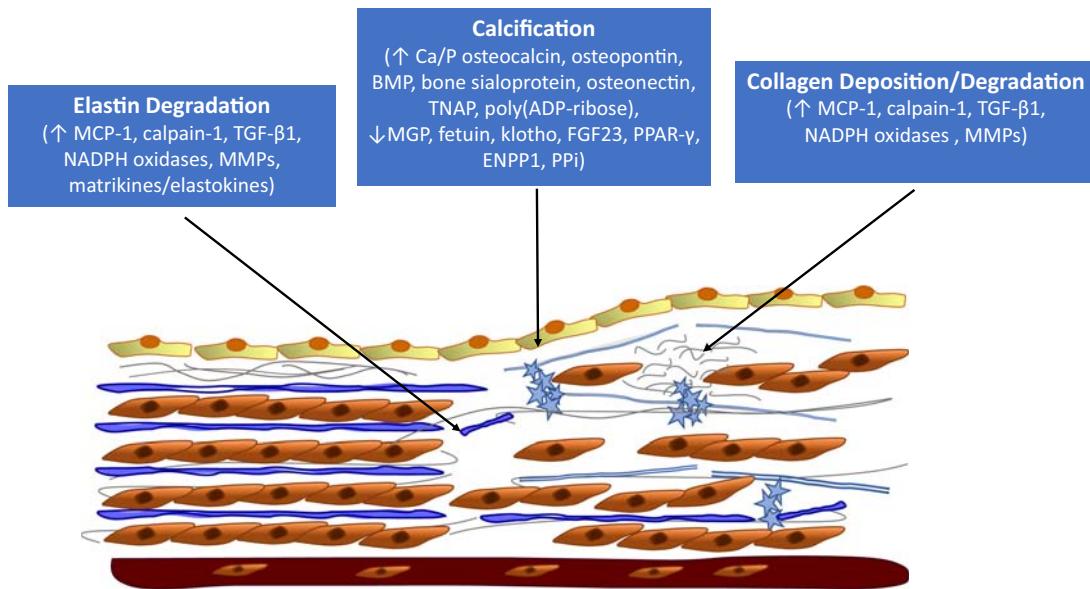
Marina Cecelja and Phil Chowienczyk

British Heart Foundation Centre, King's College London, Department of Clinical Pharmacology, St Thomas' Hospital, London, United Kingdom

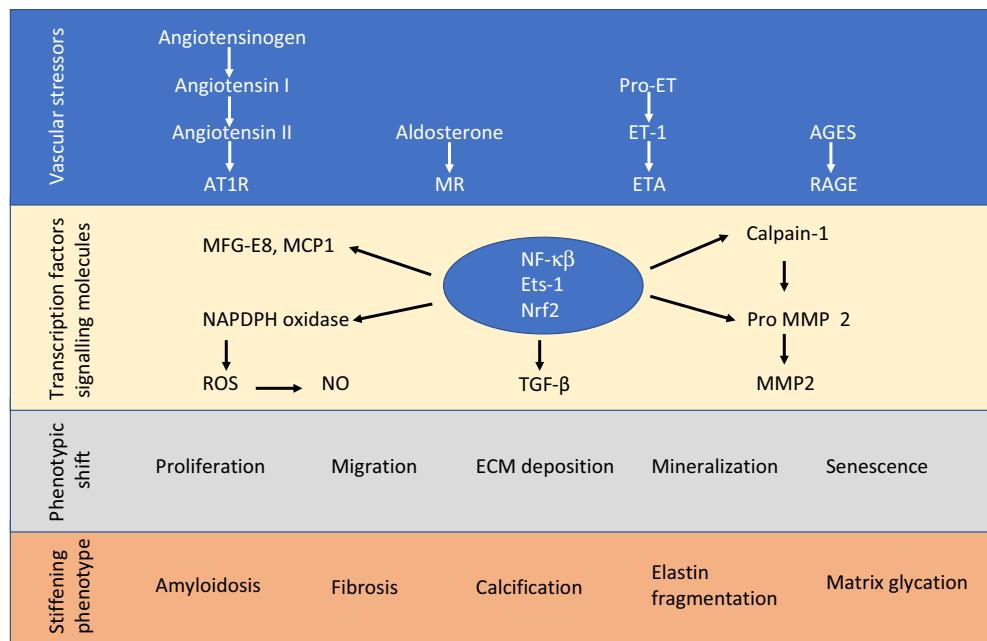
Introduction

Given the physiological importance of aortic stiffening and its association with clinical events and mortality, there has been intense interest as to whether it can be prevented or reversed. Reduction of blood pressure leads to an immediate reduction in arterial stiffness as measured by carotid-femoral PWV, but this is probably mediated in large part by an indirect effect to reduce the distension of the arterial wall and/or an alteration of tone in the vascular smooth muscle of the aorta and large arteries. The various biologic pathways that lead or contribute to large artery stiffening are discussed in detail in Chapters 19−25. The effects of common vasoactive drugs on arterial stiffness and pulsatile hemodynamics are discussed in Chapter 49. This chapter will focus on pharmacological therapies that have a specific effect to reduce large artery stiffness via an action on the structure of the arterial wall. These mostly target the extracellular matrix in the media layer of large arteries (Fig. 50.1).

We first discuss potential therapeutic targets for arterial destiffening and preclinical studies of destiffening, to then focus on clinical studies.

Potential therapeutic targets for arterial destiffening: preclinical studies


Inflammation and oxidative stress

Various mechanisms may underlie the association between inflammation and oxidative stress and arterial stiffening, including elastin degradation (Chapter 19), collagen accumulation, and medial calcification (Chapter 21).[1,2] Inflammation (Chapter 20) is thought to be induced by vascular and other stressors which initiate inflammatory processes through transcription factors and other downstream signaling molecules. A phenotypic shift in vascular


smooth muscles cells is involved (Chapter 22) which leads to their proliferation, migration, deposition of collagen within the extracellular matrix, and calcification of this matrix. This leads to the final vascular stiffening phenotype that may involve elastin fragmentation, deposition of collagen and amyloid, fibrosis, glycation and cross-linking of matrix components, and calcification (Fig. 50.2).

In young rats, chronic infusion of angiotensin II increases the activation of inflammatory transcription factors within the arterial wall[3] inducing a proinflammatory signaling profile characterized by an increase in monocyte chemoattractant protein-1, calpain-1, transforming growth factor-β1 (TGF-β1), and also increased expression of matrix metalloproteinase-2 (MMP-2) and oxidative stress[4] which collectively increase arterial stiffness. Increased TGF-β1 signaling leads to increased synthesis of collagen by vascular smooth muscle cells (VSMCs)[5] and increased expression of MMP-2, which degrades elastin within the arterial wall further contributing to arterial stiffness.[6] In normotensive male rats, inhibition of angiotensin-converting enzyme inhibits proinflammatory molecules and age-associated arterial stiffening.[7]

A further consequence of the proinflammatory state is increased oxidative stress as characterized by increased NADPH oxidases that interact synergistically with inflammation.[8] Excess NADPH oxidase activity leads to increased arterial superoxide levels and inactivation of nitric oxide (NO),[9] alongside inadequate upregulation of cellular antioxidant defenses.[10] In mice, resveratrol, a polyphenol that activates the deacetylase sirtuin-1 (and also inhibits mTOR pathways as described below[11]), prevented an increase in vascular inflammation and oxidative stress induced by a high fat high sucrose diet as well as preventing an increase in aortic stiffness.[12] Administration of SRT1720, a sirtuin-1-specific activator, effectively reversed diet-induced aortic stiffness alongside stimulation of

FIGURE 50.2 Vascular and other stressors including angiotensin II, aldosterone, endothelin, and advanced glycosylation end products generate inflammation through transcription factors and downstream signaling molecules. These include calpain-1, MMPs, MCP-1, and TGF-β1 and NADPH oxidase. Activation of calpain-1, MMPs, TGF-β1, and NADPH oxidase increases oxidative stress and NO bioavailability decreases. There is a phenotypic shift in vascular smooth muscle cell that leads to proliferation, migration, deposition of collagen in the extracellular matrix, mineralization, and senescence. This leads to the final phenotype of stiffening in which there is deposition of amyloid, collagen, elastin fragmentation, fibrosis, calcification, and matrix glycation. *ETA*, endothelin-1 receptor A; *ET-1*, endothelin-1; *Ets-1*, v-ets erythroblastosis virus E26 oncogene homolog 1; *MCP-1*, monocyte chemoattractant protein-1; *MFG-E8*, milk fat globule epidermal growth factor-8; *MMPs*, matrix metalloproteinases; *MR*, aldosterone/mineralocorticoid receptor; *NADPH oxidase*, nicotinamide adenine dinucleotide phosphate oxidase; *NF-κB*, nuclear factor kappa-light-chain enhancer of activated B cells; *Nrf-2*, NF-E2-related factor 2; *NO*, nitric oxide; *TGF-β*, transforming growth factor beta.

antiinflammatory and antioxidant pathways.[12] These findings have also been replicated in nonhuman primates on high caloric diets.[13] Sirtuin activity can also be increased by nicotinamide mononucleotide. In old mice with increased arterial stiffness, supplementation with nicotinamide mononucleotide reduces arterial stiffness alongside a reduction in markers of oxidative stress and increase in elastin and inhibition of collagen.[14]

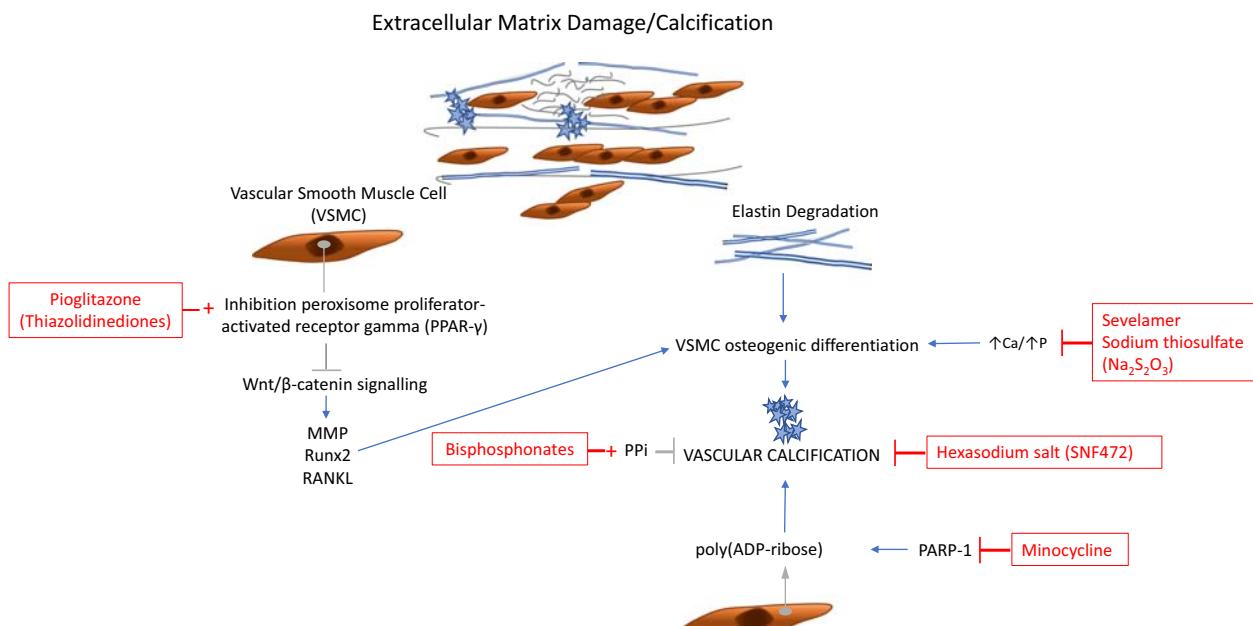
Vascular mitochondrial oxidative stress, another source of vascular oxidative stress, is associated with excessive production of mitochondria-derived reactive oxygen species (mtROS) produced as a result of cellular metabolism. Mice deficient in mitochondrial antioxidant protein manganese superoxide dismutase (SOD2) exhibit arterial stiffening.[1] mtROS may promote stiffening through several pathways including redox-related alterations in matrix protein turnover altering the breakdown of collagen and elastin.[15–17] A consequence of increased mtROS is mitochondrial DNA damage, which in turn drives maturation of proinflammatory cytokines.[15,18,19] In male mice, the mitochondria-targeted antioxidant MitoQ, which lowers mitochondrial oxidative stress, prevented age-associated increases in aortic pulse wave velocity in old (27 month) but not in young (6 months) mice. MitoQ did not affect collagen expression or cytokine expression but did partially preserve elastin expression.[20] Curcumin, a naturally occurring polyphenol found in the spice turmeric, has been associated with reduced oxidative stress. In old (26–28 month) C57BL6/N mice supplementation with curcumin restored large artery stiffness to levels similar to that seen in young (4–6 month) mice, ameliorating age-associated oxidative stress and collagen deposition.[21]

Conditions of low cellular energy which can be induced by selective nutrient deprivation, exercise or hypoxia, are associated with increased oxidative stress. They activate adenosine monophosphate (AMP)-activated protein kinase (AMPK) which then phosphorylates a diverse number of targets to direct cell metabolism toward adenosine triphosphate (ATP) generating catabolic pathways such as fatty acid oxidation, autophagy, and glucose utilization and away from ATP-consuming anabolic pathways (e.g., fatty acid, lipid and protein synthesis, and cell growth and proliferation).[22] mTOR kinase, part of two multiprotein complexes, mTORC1 and mTORC2, is a kinase which when activated (for example, by insulin and growth factors) regulates ATP-consuming anabolic pathways and suppresses ATP-generating catabolic pathways.[22] In mice, aging is associated with increased mTOR activation,[23] whereas downregulation of mTORC1 in genetically modified murine models[24] and via pharmaceutical interventions has been associated with an increased lifespan.[25] Rapamycin may inhibit mTOR and in mice fed a rapamycin supplemented or control diet for 6–8 weeks, age-related increases in mTOR activation were inhibited by

rapamycin. In old mice (30 months), rapamycin inhibited NADPH oxidase expression and superoxide production which were comparable to that of young (4 months) mice. Importantly, an age-associated increase in aortic stiffness evidenced by higher pulse wave velocity in old compared to young mice was inhibited and collagen content reduced by treatment with rapamycin.[23] These potential antiaging properties of rapamycin have led to interest in developing less toxic analogues of rapamycin that could be used in clinical studies.[26] The findings that drugs which act to reduce oxidative stress and increase lifespan also reduce arterial stiffness are consistent with calorie restriction successfully prolonging lifespan and reducing arterial stiffness in animal models.[27]

Vascular calcification

Calcification of the vessel wall contributes to increased arterial stiffness.[28] Mechanisms that lead to vascular calcification are discussed in detail in Chapter 21. Briefly, vascular calcification is now known to be an active process resembling osteogenesis in which VSMCs undergo osteogenic differentiation, losing their contractility markers (αSM0actin and α-SM22) and expressing many of the proteins associated with bone formation including osteocalcin, osteopontin, bone morphogenic protein (BMP), bone sialoprotein, osteonectin, and collagen.[29] These proteins often accumulate in areas of metabolically active calcification and have a high binding affinity for calcium salts. The phenotypic shift of VSMC seems to be induced by various conditions which include a proinflammatory environment[30,31] and oxidative stress.[32,33] Osteogenically differentiated VSMCs also release apoptotic bodies and matrix vesicles into the extracellular matrix which serves as nucleation sites for accumulation of hydroxyapatite crystals.[34,35] In healthy individuals, precipitation of calcium in tissue is inhibited by regulatory factors including matrix gla protein (MGP), fetuin, klotho, and fibroblast growth factor 23 (FGF23). It is likely that initiation and progression of calcification is dependent on complex cellular interactions between promoters and inhibitors of calcification and the exact mechanism of mineral nucleation is not fully elucidated. Collagen is the predominant extracellular matrix component around which mineralization occurs.[36] However, as discussed in detail in Chapter 19, elastin degradation also promotes calcification through elastin-derived soluble peptides (matrikines or elastokines) which can also activate VSMC osteogenic differentiation,[37] and increase matrix affinity for nucleating mineral deposition.[38]

Rat and mouse animal models of vascular calcification fall into two predominant categories: naturally occurring age-dependent calcification (e.g., DBA2 mice and polycystic kidney disease) or calcification induced by various interventions.[39] Treatment with large doses of vitamin D


and nicotine, for example, leads to a proinflammatory state, medial calcification, and increased wall stiffness. The potential interplay between inflammation and calcification in this model is illustrated by a study in which pioglitazone, which is thought to have antiinflammatory actions via activation of peroxisome proliferator–activated receptor gamma (PPAR-γ), reduced medial calcification alongside a reduction in inflammatory markers, elastin fragmentation, and arterial stiffness.[40] Several genetically modified mouse models are characterized by calcification and include those leading to alterations in matrix gla protein, osteopontin, and ectonucleotide pyrophosphatase/phosphodiesterase-1 (ENPP1). ENPP1 converts ATP into adenosine 5′-monophosphate (AMP) and pyrophosphate (PPi), an endogenous inhibitor of hydroxyapatite formation. PPi is hydrolyzed by tissue-nonspecific alkaline phosphatase (TNAP) and overexpression of TNAP is associated with vascular calcification. Mutations in ATP-binding cassette C6 (ABCC6) mouse models lead to vascular calcification through incompletely understood mechanisms but which are likely to include regulation of PPi. Findings by Ziegler et al.[41] suggest that ABCC6 acts in concert with ENPP1 to regulate PPi.

Actions of PPAR-γ inhibitors and other drugs that may have more specific effects to prevent calcification are summarized in Fig. 50.3.

Bisphosphonates probably have multiple actions to inhibit arterial calcification: acting as a nonhydrolyzable analogue of PPi and a TNAP inhibitor (in $Abcc6^{-/-}$ mice they attenuate the development and progression of vascular calcification[42]), blocking apatite crystal formation,[43] inhibiting metalloproteinases,[44] and inhibiting expression of tumor necrosis factor-α, which promotes osteoblastic differentiation of vascular cells.[45] They can be metabolized by phagocytes into nonhydrolyzable adenine-containing analogues of ATP,[46] which inhibit adenine nucleotide translocase, promoting the activation of caspase-3 and leading to apoptosis of macrophages and osteoclasts.[47]

In chronic kidney disease, hyperphosphatemia and a raised serum calcium–phosphate product is associated with vascular calcification. The potential importance of the calcium–phosphate product is illustrated by a study in uremic rats fed on a high phosphorus diet for 6 months, treated with a calcium-containing phosphate blocker and sevelamer, a noncalcium containing phosphate blocker. Even though both treatment regiments effectively reduced phosphate levels, only sevelamer-treated rats reduced vascular calcification.[48] Sodium thiosulfate ($Na_2S_2O_3$) has antioxidant properties[49] and chelates calcium to form soluble calcium thiosulfate complexes.[50] Pasch et al.[51] found that uremic rats treated with thiosulfate did not develop aortic calcification compared to untreated control rats; this was associated with increased urinary calcium excretion and reduced bone strength. Preclinical studies of a hexasodium salt (SNF472) with the active ingredient myo-inositol hexaphosphate (IP6) which binds to sites of hydroxyapatite crystals have demonstrated reduced development of calcification[52] and reduced progression of established calcification in uremic and nonuremic rodent models of calcification.[53]

FIGURE 50.3 Pathways of extracellular matrix damage and calcification. *Ca*, calcium; *MMP*, matrix metalloproteinase; *PARP-1*, poly (ADP-ribose)-1; *P*, phosphate; *PPi*, pyrophosphatase inhibitor; *RANKL*, Receptor activator of nuclear factor kappa-b ligand; *Runx2*, Runt-related transcription factor 2.

Another potentially exciting therapeutic target for vascular calcification and stiffening is poly(ADP-ribose) (PAR) which is a posttranslational polymer of two or more ADP-ribose units added to proteins by the enzymes PAR polymerases (PARPs) in a process called PARylation. PAR is found in developing fetal bone and the dominant PARPs are expressed in response to oxidative stress.[54,55] Muller et al.[56] showed that PAR can generate calcified spherical particles and bone-like calcification of collagen fibrils. Importantly, in a uraemic rat model, treatment with minocycline (a widely used antibiotic, 5–50 mg/hg), which directly inhibits PARP-1, reduced calcification in the aorta, femoral and carotid arteries. This is a potentially exciting area that could be directly translated into human clinical pharmacology since minocycline is widely used as an antibiotic in humans and has low toxicity. However, it can cause gastrointestinal disturbances, photosensitivity reactions, and rarely more serious side effects that may limit long-term use. Other related tetracycline antibiotics which may also inhibit PARP-1 are also in human use.

Elastase inhibitors and extracellular matrix metalloproteases

Extracellular matrix components, particularly elastin and collagen, are fundamental structural components of large arteries. Pathological processes relating to these structural proteins, such as elastin fragmentation/degradation, collagen accumulation, and cross-linking, are thought to be key mechanisms underlying age-related arterial stiffening.[1] As discussed above, elastin degradation may also promote calcification by activating VSMC osteogenic differentiation.[37] As discussed in more detail in Chapter 19, elastin can be degraded by proteolytic enzymes with "elastase-like" activity including serine and cysteine (cathepsins) proteases and MMPs.[57] MMPs are proteins which are involved in the breakdown of the extracellular matrix and their activity is increased in aged vascular cells.[58,59] Tissue inhibitors of MMPs (TIMPs) are likely to play a role in regulating extracellular matrix components. In a rat aneurysm model, local application of TIMP-1 preserved elastin in the media and prevented aneurysm rupture.[28] MMPs also activate TGF-β1[31] further contributing to a proinflammatory vascular state. In 16-month-old rats, administration of a broad-spectrum MMP inhibitor, PD166739, reduced age-associated arterial proinflammatory signaling, reduced elastic fiber degeneration and collagen deposition, and prevented the age-associated increase in blood pressure (consistent with a reduction in stiffening).[31] Other inhibitors of MMP include zinc chelators, marimastat, and the antibiotic doxycycline.[60] In hypertensive rats, doxycycline favorably altered the ratio of MMP-2 to TIMP-2, preventing hypertension and arterial wall thickening.[61] In a "two-kidney one clip" hypertensive rat model, doxycycline

reduced MMP-2 and prevented a rise in blood pressure.[62] In male Wistar rats, where calcification was induced with warfarin and vitamin D, doxycycline prevented calcification,[63] but may also have had actions through PARP-1 inhibition as discussed above. Not all studies with doxycycline have been positive: in a spontaneously hypertensive rat model, even though doxycycline improved structural alterations, blood pressure and PWV were not affected.[64]

Micro-RNAs

Micro-RNAs (miRNAs) are small (19–25 nucleotide long) noncoding posttranscriptional regulators of gene expression that have been implicated in the regulation of most biological processes including arterial stiffness.[65] miR-765, miR-1185, miR-181b, and miR-21, in particular, have been implicated in arterial stiffness.[66,67] Although the exact mechanisms by which miRNA signaling pathways modulate arterial stiffness are unclear, reduction of miR-181b expression is associated with activation of the TGF-β pathway, inflammation, accumulation of collagen, and arterial stiffening.[68] Deletion of the microRNA-degrading complex that degrades miR-181b prevented arterial stiffening associated with chronic high salt intake in mice.[65] miRNA may also play a central role in VSMC phenotype modulation and/or vascular relaxation. Experimental data investigating whether pharmacological intervention of miRNA signaling pathways could lead to a reduction of arterial stiffness are limited. In uremic dilute-brown agouti 2 (DBA/2) mice susceptible to high-phosphate diet–induced calcification, intravenous injections of a synthetic miR-142-3p mimic restored acetylcholine induced smooth muscle relaxation but showed no effect on vascular calcification.[69]

Mineralocorticoid receptor antagonism

Mineralocorticoid steroid hormones, such as aldosterone, are secreted in response to an increase in extracellular potassium ion concentration or activation of the renin–angiotensin system. Mineralocorticoid receptor (MR) activation by aldosterone regulates blood pressure by modulating renal sodium reabsorption and body fluid volume through myogenic tone, vasoconstriction, and redox signaling.[70] In addition to its traditional role as a blood pressure regulator, MRs are now increasingly recognized as playing a role in arterial stiffness independently of blood pressure regulation. MR activation may have profibrotic actions mediated by multiple mechanisms including oxidative stress, inflammation, and associated increase in connective tissue growth factor, MMP-2, and BMP-4.[71] In animal models, MR expression in VSMCs increases with increasing age.[72] MR activation activates NADPH oxidase-dependent superoxide production and inactivation of

NO.[9,73] MR antagonists (MRA) reverse this with a reduction in NADPH oxidase activity, reduction in superoxide formation, and improvement in NO bioavailability.[74] In mice fed a high fat/high sugar western diet, administration of the MRA spironolactone for 4 months prevented stiffening, inflammation, and fibrosis[75] without a change in mean arterial pressure or heart rate.[75] In spontaneously hypertensive rats, 4-month treatment with spironolactone prevented collagen accumulation in the presence of a small antihypertensive effect.[76] In old normotensive rats, 8-week treatment with spironolactone reduced arterial collagen and elastin densities alongside a reduction in arterial stiffness compared to placebo-treated animals.[77] These changes occurred independently of any change in intraarterial blood pressure and arterial wall thickness. In a rat model of chronic kidney disease, treatment with finerenone, a novel nonsteroidal potent MRA, lowered arterial stiffness in parallel with a change in collagen and elastin organization, reduction in MMP-2, MMP-9, and oxidative stress.[78] Low intracellular potassium in VSMC is associated with a prolonged increment of intracellular calcium linked to osteogenic differentiation of VSMC.[79] In an apolipoprotein-E deficient mouse model, Sun et al.[79] demonstrated that dietary potassium supplementation attenuated vascular calcification and aortic stiffness. Elevation of intracellular potassium by mineralocorticoid receptor antagonism could, therefore, be another mechanism through which these agents may influence arterial stiffening.

Amyloid-β and arterial stiffness

In humans, amyloid protein known as medin, which binds to tropoelastin, is deposited in the media of the aged arterial wall.[80] This has raised interest in the possibility that amyloid deposition in the arteries and brain is a mechanism to explain the association between arterial stiffness and cognitive decline. However, it should be remembered that both of these processes are strongly age-dependent and there are other potential mechanisms to explain the association such as the susceptibility of the cerebral microvasculature to high pulsatile pressure induced by arterial stiffening. There have been limited animal studies on the role of amyloid in arterial stiffening as most animal models do not naturally accumulate amyloid-β.[81]

Clinical studies on aortic and large artery destiffening

Clinical studies on arterial stiffness have largely focused on existing drugs that have established indications for conditions known to relate to cardiovascular disease and may also reduce arterial stiffness through various mechanisms. In addition, there have been a few studies on drugs specifically designed to reduce stiffness. Most studies have used a measure of pulse wave velocity (PWV) over a pathway that incorporates the aorta, usually carotid-femoral PWV (cfPWV) but with some including additional conduit pathways such as brachial-ankle PWV (baPWV). Some studies have used other measurements thought to relate in part to arterial stiffness such as augmentation index. With the recognition that the latter is influenced by many factors other than arterial stiffness, this review concentrates mainly on PWV data.

Drugs inhibiting the renin−angiotensin−aldosterone system and mineralocorticoid antagonists

Angiotensin II and aldosterone may promote inflammation and fibrosis within the arterial wall and there has been interest in whether antihypertensive drugs that inhibit the renin−angiotensin−aldosterone system (RAAS) such as angiotensin-converting enzyme inhibitors (ACEis), angiotensin receptor blockers (ARBs), and mineralocorticoid receptor antagonists (MRAs) may have a specific action to reduce arterial stiffness. Evaluation of this in clinical studies is complicated by the fact that these drugs also relax vascular smooth muscle and reduce blood pressure. Elastic properties of the arterial wall are dependent on stretch of the wall which may transfer load from highly elastic components such as elastin to stiffer components such as collagen. Stretch is dependent on ambient blood pressure and therefore any intervention that lowers blood pressure would be expected to lower stiffness by an indirect action. Similarly, relaxation of smooth muscle within the wall of the aorta may modulate stiffness independent of any action on wall structure. Thus, although almost all studies of antihypertensive drugs show a reduction in cfPWV, interest has been in comparing effects at comparable levels of blood pressure reduction. One metaanalysis suggested that ACEi do have a small but significant blood pressure−independent action to lower cfPWV and baPWV[82] but others have shown no specific effect.[83,84] MRA may have a more specific effect to inhibit fibrosis in the arterial wall and one well-controlled trial examining effects of spironolactone on cfPWV in patients with early chronic kidney disease demonstrated a blood pressure independent effect of spironolactone to reduce cfPWV.[85] However, this was not confirmed in the recent Vasera trial comparing spironolactone to doxazosin.[86]

Statins and other lipid lowering therapy

Although the etiology of arterial stiffening differs from that of atherosclerosis, there may be some overlap between the two pathologies and statins have pleiotropic effects including antiinflammatory and antioxidant effects that could reduce arterial stiffening. Results of RCT involving

statins have been somewhat discordant. However, two relatively recent metaanalyses have been performed which both suggest a modest positive effect to lower cfPWV.[87,88] The most recent identified 11 RCT in which treatments with and without statins were compared involving 573 individuals. This demonstrated modest 6.8% [95% CI 1.8−11.7] reduction in cfPWV.[87] There was significant heterogeneity between studies but the effect was independent of change in blood pressure. There is little relationship between cfPWV and low-density lipoprotein cholesterol (LCL-C) or ratio of LDL-C to high-density lipoprotein cholesterol (HDL-C) in epidemiological studies[89] and in the interventional studies with statins no relationship between change in cfPWV and that in LDL-C was seen[87] suggesting effects may be more likely to be due to pleiotropic effects of statins. However, in an observational study in which ezetimbe or a PCSK9 inhibitor was added to high dose statin therapy in patients with familial hypercholesterolaemia achieving a large range of reduction of low-density lipoprotein cholesterol (LDL-C), an improvement in PWV was seen which correlated with the change in LDL-C.[90] Thus, the mechanism by which statins and other lipid lowering drugs may reduce PWV remains uncertain.

Antioxidant vitamins and vitamin B12/folate supplementation

Clinical trials examining effects of antioxidant vitamins include early trials of vitamins C, E, A, and beta-carotene. These were performed in small numbers of individuals and although a metaanalysis suggested a small but significant positive effect on various measures of arterial stiffness including cfPWV,[91] the finding that supplementation with these vitamins does not reduce cardiovascular risk (or may increase risk)[92,93] raises the question as to whether this positive finding with regard to effects on arterial stiffness was due to publication bias and there has been little enthusiasm for further large studies. However, it should be noted that lack of efficacy of conventional antioxidant vitamins to reduce cardiovascular risk or arterial stiffness does not necessarily disprove the importance of oxidative stress since these vitamins are weak antioxidants which may not decease oxidative stress at a cellular level.[94]

Elevated homocysteine is associated with increased cardiovascular risk[95] and increased arterial stiffness[96] and alongside trials to determine if homocysteine lowering therapy with vitamin B12 and folic acid decreases cardiovascular risk, effects of this supplementation on PWV have been examined. A number of small studies have been positive. However, in a substudy of the B-PROOF study involving supplementation of 569 elderly individuals with B12/folic acid for 2 year, achieving a lowering of homocysteine of 3.6 µmol/L in the active treatment group, there was no significant effect of homocysteine lowering on cfPWV.[97] This trial is notable for being one of the few relatively long-term clinical trials of an intervention to lower cfPWV.

Antidiabetic drugs and advanced glycosylation end-product breakers

Presence of type 2 diabetes is associated with increased arterial stiffness,[98] and with the recognition that antidiabetic drugs may differ in their effects on cardiovascular outcomes, there has been interest in whether these drugs influence arterial stiffness. However, studies have been predominantly exploratory with small sample size (typically <50 patients) and not all have been controlled or randomized. A metaanalysis suggests that dipeptidyl peptidase-4 (DPP-4) inhibitors and glucagon-like peptide-1 receptor agonists (GLP-1 RA) have modest effects to lower PWV.[99] However, there was significant heterogeneity between studies. In a randomized controlled cross-over study, the selective sodium−glucose cotransporter 2 inhibitor empagliflozin resulted in a reduction in measures of central blood pressure and a small but significant reduction in an indirect estimate of PWV.[100] Hypertension and diabetes are associated with the accumulation of advanced glycation end products (AGEs) formed from nonenzymatic cross-links between glucose and amino groups on proteins. These accumulate in the extracellular matrix to cause stiffening and also bind to AGE receptors (RAGEs) to generate oxidative stress and inflammation and increase stiffness as described above (Fig. 50.2). Preclinical experimental studies in animals using AGE cross-link breakers show an impressive reduction of arterial stiffening and improvement in hemodynamics. A notable early RCT using the cross-link breaker ALT-177 (alagebrium) in hypertensive patients with high pulse pressure demonstrated a reduction in pulse pressure. However, this was a relatively small study and there was no significant reduction in cfPWV.[101] Despite some positive findings in open label uncontrolled studies,[102,103] subsequent RCTs have been largely negative. No benefit was seen in exercise tolerance or secondary measures of cardiac function in patients with heart failure.[104] Another randomized controlled study in healthy, previously sedentary seniors showed no effect on hemodynamics, LV geometry, or exercise capacity. However, it did show a modestly favorable effect on age-associated LV stiffening (measured from LV pressure−volume curves obtained from echocardiography and right heart catheterization during modulation of preload).[105] Thus, while a well-powered RCT remains to be performed to address effects of cross-link breakers on arterial stiffness, these negative results underline the difficulty in extrapolating from experimental animal studies to clinical studies.

Antiinflammatory drugs

Given the evidence for the role of inflammation and inflammatory cytokines in arterial stiffening and preclinical studies indicating a positive effect of antiinflammatory drugs on arterial stiffening, there has been much interest in the biological therapies for inflammation, that are markedly effective in reducing the clinical burden of diseases such as inflammatory arthritidies,[106] inflammatory bowel,[107] and skin disease.[108] Studies on arterial stiffness have been mainly in these cohorts of patients in whom there is a clinical indication for an antiinflammatory drug and most involving biological agents inhibiting tumor necrosis factor-α or various interleukins. Early studies reported positive effects in uncontrolled studies[109] but later RCTs have been largely negative. A recent systematic review identified 22 studies comparing effects of TNFα biologics on arterial stiffness mostly assessing cfPWV but only four of these were RCT and all of the RCT were negative.[110] A discrepancy between uncontrolled and randomized trials on various measures of subclinical atherosclerosis and arteriosclerosis was a common finding, suggestive of significant publication bias toward positive studies.[110]

Drugs targeting arterial calcification and bone mineral metabolism

Arterial calcification is particularly prevalent in patients with end-stage renal disease (ESRD) who exhibit accelerated stiffening strongly predictive of poor clinical outcome.[111] It is characterized by low plasma concentrations of vitamin D, raised parathyroid hormone, and hyperphosphatemia. In small cohort studies of patients with CKD and ESRD not all of which have been randomized and controlled, there is no consistent evidence of benefit from vitamin D analogues and calcimimetics that act as allosteric modulators of the calcium signaling receptor (CaS).[112] Treatment of hyperphosphatemia with sevelamer attenuates progression of aortic calcification in hemodialysis patients[113] and one small cohort study has suggested that sevelamer decreases PWV in hemodialysis patients without affecting blood pressure. A limitation of this study, however, was the lack of control for baseline calcium and phosphorus.[114] In kidney transplant patients the immunosuppressant sirolimus reduced arterial stiffness alongside a reduction in blood pressure, but effects on calcification were not measured and effects were postulated to be due to inhibition of mTOR.[115] Renal disease is associated with vitamin K deficiency, and in an open uncontrolled trial in patients with renal transplants, vitamin K2 supplementation reduced cfPWV.[116] A new molecule SNF472 inhibits the development and progression of ectopic calcification by binding to the growth sites of hydroxyapatite (HAP) crystals and has been shown to inhibit the progression of arterial calcification in ESRD patients on haemodialysis.[117] In the general population and in specific groups there is some evidence that vitamin D may have a beneficial effect on cfPWV but only in individuals who are vitamin D deficient.[118] Bisphosphonates have been shown to retard vascular calcification in patients with ESRD but there have been few studies on arterial stiffness with no consistent effects to reduce PWV.[119]

Summary

In summary, most clinical studies of interventions to lower PWV through a blood pressure−independent mechanism are negative or at best show small effects. It might therefore be concluded that arterial stiffening is largely irreversible. This may be true but epidemiological evidence does suggest that accelerated age-related stiffening can be prevented. It is notable that age-related stiffening takes place over decades. A major limitation of clinical trials to date is that these have been of relatively short duration. A major challenge for the future, therefore, is to perform well-controlled adequately powered trials over the long term.

Conclusion

Inflammation, oxidative stress, and calcification are implicated in structural change of the arterial wall leading to arterial stiffening. Preclinical studies suggest that this can be reversed through a number of potential interventions including antiinflammatory therapies, MRA antagonists, inhibitors of vascular calcification, collagen cross-linking inhibitors, elastase/elastin-related peptide signaling inhibition, and miRNAs. Clinical trials to date have been limited by small cohort size and short-term duration. The challenge for the future is to perform well-controlled adequately powered trials over the long term.

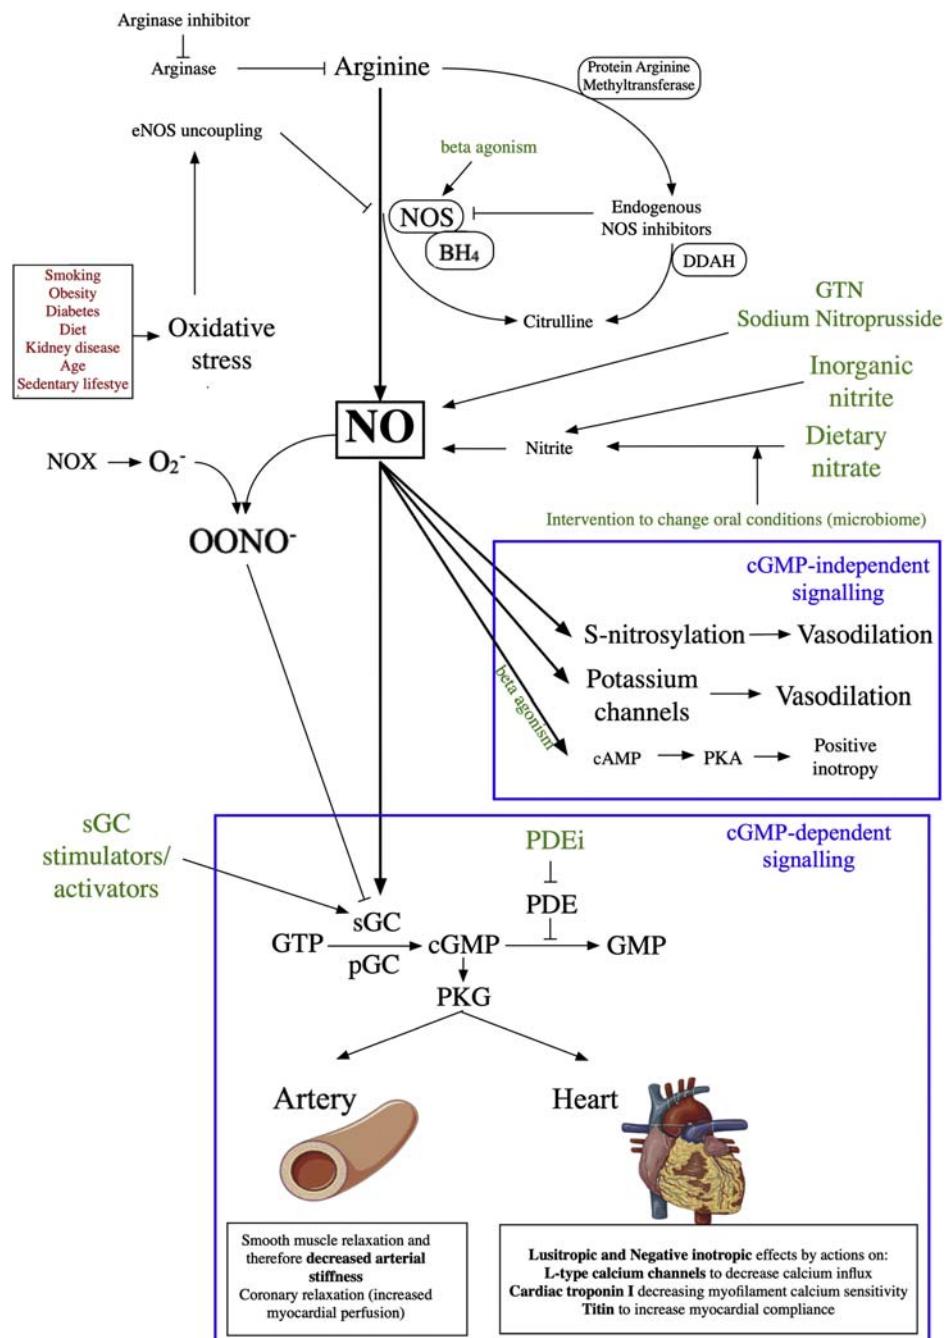
Organic and dietary nitrates, inorganic nitrite, nitric oxide donors, and soluble guanylate cyclase stimulation

Kevin O'Gallagher and Andrew James Webb

Department of Clinical Pharmacology, School of Cardiovascular Medicine and Sciences, King's College London British Heart Foundation Centre, St. Thomas' Hospital, London, United Kingdom

Part 1: introduction

First described as endothelium-derived relaxing factor (EDRF),[1,2] over the last four decades nitric oxide (NO) has been identified as a key signaling molecule in the cardiovascular system and multiple other organ systems. The importance of the discovery and identification of NO as EDRF is reflected by the award of 1998 Nobel Prize in Medicine to Furchgott, Murad, and Ignarro.[3]

NO is a free radical gas, with a half-life in the circulation of ~ 20 ms[4]. In humans, it is produced via two key pathways: the "L-arginine-nitric oxide pathway" as originally described by Moncada[5] and the more recently discovered nitrate-nitrite-NO pathway.[6] The latter significantly impacted our understanding of the role of inorganic nitrate and nitrite in relation to the cardiovascular system from inert by-products of NO oxidation (at physiological concentrations) to important sources of NO,[7,8] and will be considered in a later section.


The L-arginine-NO pathway involves the generation of NO via the conversion of L-arginine to L-citrulline by heme- and flavin-containing nitric oxide synthase (NOS) enzymes[9] in a process that requires dimerism of the NOS enzyme and the presence of the co-factors tetrahydrobiopterin (BH$_4$), NADPH, and O$_2$.[10] Three NOS isoenzymes have been identified in humans: endothelial (eNOS), neuronal (nNOS), and inducible (iNOS). eNOS and nNOS are constitutively expressed and have distinct roles in the regulation of cardiovascular function. This is in contrast to iNOS, which is a major player in the host response to infection and inflammation. While the production of NO by eNOS and nNOS is Ca^{2+}/calmodulin-dependent, production of NO by iNOS continues until the enzyme is degraded, generating higher local concentrations of NO.[11]

Nitric oxide signaling in the vasculature and vasodilatation

NO's role as a signaling molecule in the vasculature occurs primarily in a paracrine fashion, i.e., NO produced by NOS (eNOS in the vascular endothelium, nNOS in nitrergic nerves) diffuses into the vascular smooth muscle cell, whereby it binds to the heme moiety of soluble guanylate cyclase (sGC). This in turn leads to the activation of cyclic guanosine monophosphate (cGMP) and subsequently protein kinase G (PKG), resulting in relaxation of the smooth muscle cell with consequent vasodilatation. Additionally, s-nitrosylation (the NO-mediated modification of cysteine residues in proteins) affords a mechanism by which NO can exert a number of effects, including vasodilatation, in a cGMP-independent manner. Examples include NO's effect on calcium-dependent potassium channels in vascular smooth muscle[12] and the vasodilatory actions of the nitrosothiol S-nitrosoglutathione.[13] The pathways of cardiovascular NO signaling are illustrated in Fig. 51.1.
In the healthy human vasculature, eNOS and nNOS have relatively distinct roles: nNOS is responsible for basal regulation of microvascular tone (and therefore systemic vascular resistance and peripheral blood pressure[14]) and the vasodilatory response to mental stress,[15] while eNOS is responsible for the dilatory response to increased shear stress or agonist stimulation.[16,17] The L-arginine-NO pathway also mediates the vasodilatory response of beta-2-agonism, as demonstrated in the human forearm.[18]

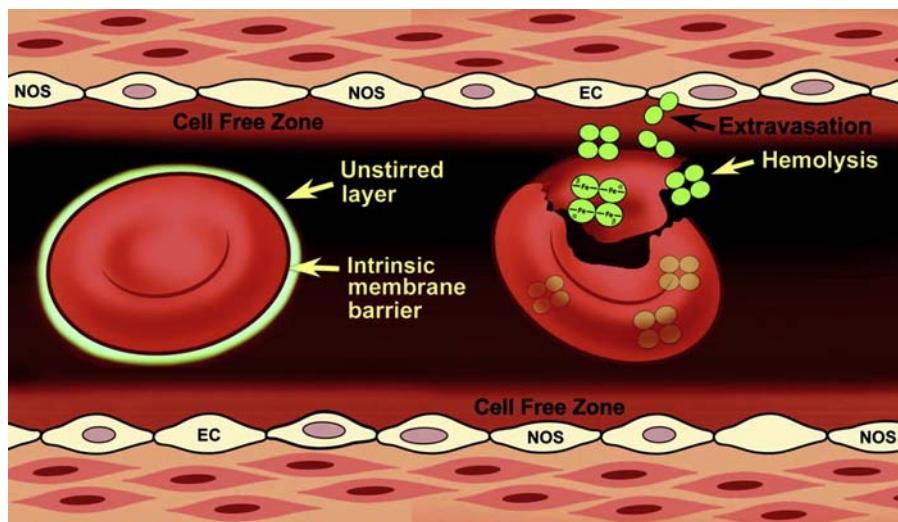
There are potential limiting factors to the ability of NO to diffuse from the vascular endothelium to adjacent smooth muscle. Firstly, as noted above, the half-life of NO is approximately 20 ms in whole blood, due to NO's status as a reactive oxygen species (ROS). This innate reactivity limits


FIGURE 51.1 Cardiovascular nitric oxide signaling: pathways to vasodilatation, myocardial relaxation, central and peripheral hemodynamic changes. NO to diffusion from adjacent cells rather than being transported in blood as free NO. Secondly, NO is avidly scavenged by hemoglobin in both its deoxy- and oxy-hemoglobin forms. The reaction of NO with oxyhemoglobin to produce methemoglobin and inorganic nitrate is described below:

$$HbO_2 + NO \rightarrow MetHb + NO_3^-$$

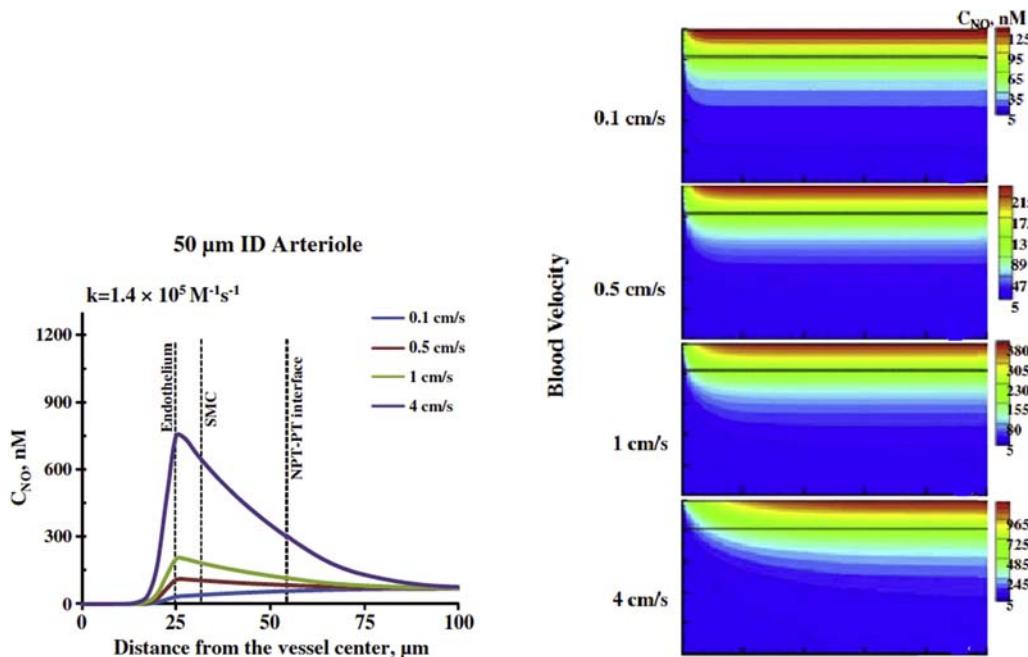
As pointed out by Kim-Shapiro et al. in their review,[19] this presents an apparent paradox: NO is produced by the vascular endothelium in extremely close proximity to a substance (the blood) which would prevent it enacting its role in relaxation of vascular smooth muscle, especially as any NO concentration gradient would, in fact, favor

FIGURE 51.2 Factors involved in mitigating nitric oxide scavenging by RBCs. *Reproduced from Kim-Shapiro DB, Schechter AN, Gladwin MT. Unraveling the reactions of nitric oxide, nitrite, and hemoglobin in physiology and therapeutics.* Arterioscler Thromb Vasc Biol. *2006;26:697−705.*

diffusion *away* from the vascular smooth muscle cell and into the bloodstream to be scavenged (see Fig. 51.2).

Several mechanisms have been described which limit NO scavenging by Hb and therefore ensure that eNOS-derived NO can indeed diffuse from the vascular endothelium into the vascular smooth muscle and initiate relaxation. Firstly, hemoglobin is encapsulated within the erythrocyte, which decreases the magnitude of scavenging when compared with free Hb.[20] Secondly, due to the dynamics of blood flow within the vessel, there exists a "cell-free layer" in the blood immediately adjacent to the vascular endothelium (faster blood flow velocity in the middle of the vessel lumen leads to a pressure gradient within the vessel and relative concentration of erythrocytes in the middle of the vessel), resulting in a "barrier" between free NO and erythrocytes. Thirdly, in a moving/mixing fluid (in this case the blood), there exists an "unstirred layer"[21] around a cell membrane (in this case the erythrocyte membrane) in which there is static fluid, i.e., a region adjacent to a cell membrane when there is low flow, which, like the cell-free layer, acts as a barrier to diffusion.

Deonikar et al.[22] modeled the concentrations of NO from endothelium-derived NO in the luminal subregions representing the RBC rich core and cell-free zone (CFZ), and the abluminal regions including endothelium, interstitial space, smooth muscle cell later, nonperfused tissue, and parenchymal tissue perfused with capillaries in larger arterioles (200 μm) and smaller arterioles (50 μm) as shown in Fig. 51.3.

Notably, there was an important effect of flow velocity. As the flow increased from 0.1 to 4 cm/s, the NO concentration in the CFZ increased up to eightfold. Also, Chen X et al. identified an important role for the glycocalyx.[23] While the modeling suggested that the presence of RBCs in


the boundary layer near the endothelium had a larger effect on NO than on O_2 transport, as the thickness of the glycocalyx increased, scavenging of NO by hemoglobin decreased, such that the presence versus absence of RBCs equated to a difference in glycocalyx thickness of ∼0.8 μm (see Fig. 6 from Chen X et al.,[23] https://journals.physiology.org/doi/full/10.1152/japplphysiol.00633.2005 [free access]).

The effect of nitric oxide on cardiac function

NO exerts an effect on cardiovascular function in a number of ways. From a vascular point of view, its role in the regulation of systemic arterial hemodynamics[14,17,24] affects cardiac loading conditions. NO also regulates cardiac function via a direct myocardial effect, through both paracrine (NO from the coronary endothelium[16]) and autocrine (NOS enzymes expressed within cardiomyocytes[25]) processes.

Endothelial paracrine regulation of left ventricular function

NO released from vascular (and endocardial) endothelium exerts a paracrine effect on cardiac function, while NO generated within cardiomyocytes exerts an autocrine effect.[26] The paracrine effect has been demonstrated in both animal preparations and in human in vivo experiments using substance P (a known stimulator of eNOS-derived NO release).[27] Disruption of NO signaling can have deleterious effects on cardiac function. In dogs, prolonged NOS inhibition with L-NAME resulted in decreased LV compliance and markers of cardiac efficiency, with additional changes to LV afterload.[28]

FIGURE 51.3 Nitric oxide concentration profiles across and relationship to blood velocity. The left-hand panel shows [NO] across all the regions (including *NPT*, nonperfused tissue; *PT*, parenchymal tissue; and *SMC*, smooth muscle cell later) of an arteriole (50 μm internal diameter) at the end of the arteriolar segments, plotted as a function of distance from the vessel center and increasing blood velocity range from 0.1 cm/s (lowest trace) to 4 cm/s (top trace). The right-hand panel shows [NO] in the vascular lumen of an arteriole (50 μm internal diameter, 500 μm length) with an NO−RBC reaction rate constant of 0.2×10^{-5} M^{-1}/s, and increasing blood velocity range from 0.1 to 4 cm/s from the top to the bottom panel. NO availability in the vascular lumen cell-free zone (CFZ) increased with increase in blood velocity. *Adapted from Deonikar P, Kavdia M. A computational model for nitric oxide, nitrite and nitrate biotransport in the microcirculation: effect of reduced nitric oxide consumption by red blood cells and blood velocity.* Microvasc Res. *2010;80:464−476.*

Effects of nitric oxide signaling at the myocardial level

In the myocardium, there is subcellular localization of NOS isoenzymes (eNOS localized to caveolae,[29] nNOS to sarcoplasmic reticulum[30]), which allows NO to have varying effects on myocardial function, including contractility.[31]

NO stimulation of sGC results in increased levels of intracellular cGMP; see Fig. 51.1. cGMP in turn stimulates PKG. Through PKG-mediated phosphorylation of L-type calcium channels[32] (decreasing calcium influx) and cardiac troponin I (decreasing myofilament calcium sensitivity[33]), NO exerts a negatively inotropic effect. Conversely, in response to stimulation by beta-agonism,[34] nNOS-derived NO can exert a positively inotropic effect, via cAMP-mediated protein kinase A action on ryanodine receptors and phospholamban, which has the net result of increasing sarcoplasmic reticulum calcium release.[31] In addition to sGC, cGMP is also produced in an NO-independent fashion by a membrane-bound guanylate cyclase isoform known as particulate guanylate cyclase which acts as a receptor for natriuretic peptides.

Interaction with phosphodiesterase

Phosphodiesterases (PDE) are a family of cyclic nucleotide-hydrolyzing enzymes, which play a key role in the regulation of second messenger signaling. cGMP interacts with members of the phosphodiesterase (PDE) family in a number of ways. PDE5 hydrolyzes cGMP to 5′ GMP, therefore regulating NO-mediated PKG activity by exerting an inhibitor effect on cGMP. PDE5 inhibitors were initially developed as potential therapies for coronary artery disease, but are currently established as effective treatments for erectile dysfunction[35] and pulmonary arterial hypertension.[36]

At the level of the cardiomyocyte, PDE5 inhibition promotes negative inotropic effects. By increasing cGMP levels, PDE5 inhibition promotes increased PKG-mediated phosphorylation of both L-type calcium channels (decreasing calcium influx) and also troponin I (decreasing myofilament sensitivity), thus opposing beta-adrenergic stimulation. In mice, PDE5 inhibition with sildenafil blunts LV hypertrophic remodeling in response to transverse arterial constriction and reverses existing LV hypertrophy, all in the context of increased PKG-1 activity.[37]

PDE2 and PDE3 provide a mechanism by which cGMP (and therefore NO signaling) interacts with cAMP (and

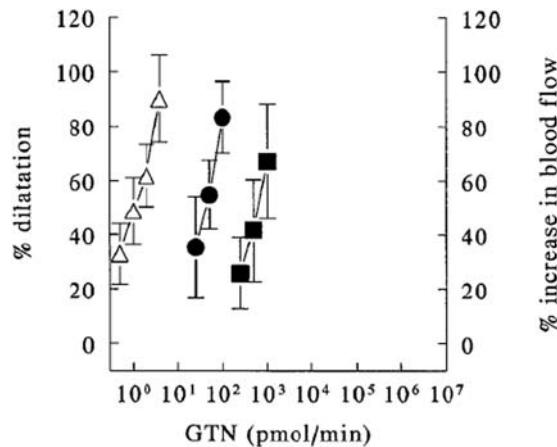
therefore adrenergic signaling). PDE2 is cGMP stimulated, acting to hydrolyze cAMP, therefore inhibiting its activity.[38] Conversely, PDE3 hydrolysis of cAMP is competitively inhibited by cGMP, by virtue of PDE3 having a higher substrate affinity for cGMP than cAMP.

Accordingly, inhibition of PDE2 improves NO signaling in animal models of pulmonary hypertension and pressure overload-induced heart failure,[39,40] while cilostazol, a PDE3 inhibitor, induces arterial dilation and reactivity through both endothelium dependent and independent mechanisms.[41−43]

While endogenously produced NO has important effects on the vasculature, targeted delivery of NO to the vasculature has proved challenging given its extremely short half-life. Thus, the strategy of prolonging its effects with PDE inhibitors as described above.

PDE inhibition has been studied as a potential therapy in heart failure with preserved ejection fraction (HFpEF). In addition to beneficial effects on RV function, sildenafil improves left sided hemodynamics,[44] however the RELAX trial (n = 216) failed to demonstrate any improvement in exercise capacity from sildenafil treatment in HFpEF patients.[45]

An alternative approach to increase intravascular NO is via the use of nitrates which are metabolized to NO as discussed in the next section.

Part 2: organic nitrates


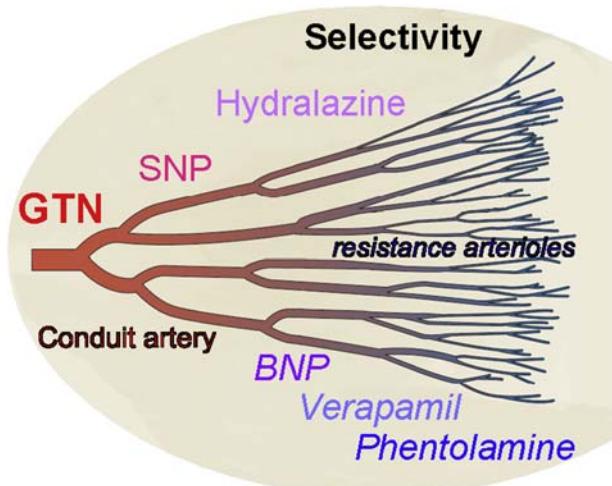
Organic nitrates are usually laboratory synthesized chemicals. A notable exception is ethyl nitrite, which is formed in the human stomach following ingestion of lettuce (dietary nitrate as a source of nitrite as described below) and red wine or whisky (ethanol),[46−48] with potent vasodilatory properties.

Clinically, organic nitrates are used in a number of conditions. For example, acute administration of glyceryl trinitrate (GTN) is effective for the relief of angina caused by myocardial ischemia, for hypertensive emergencies, and for acute heart failure.[49] In combination with hydralazine, organic nitrates (isosorbide dinitrate) have been shown to reduce mortality and improve outcomes in African Americans with HFrEF.[50] However, in HFpEF organic nitrates did not improve quality of life (QOL) or outpatient physical activity.[51] Regular/chronic administration of isosorbide mononitrate (ISMN) is useful for relief of angina. The use of nitrates is limited by their side effect profile (headaches), interactions with other vasodilator medications,[52] and tachyphylaxis. As further discussed in Chapter 36, in patients with HFpEF, inorganic nitrate therapy seems to be associated with particular high incidence of side effects, including headaches and dizziness.[50,53]

Pulsatile hemodynamic effects of organic nitrates

GTN and amyl nitrite were identified as antianginals and treatments for elevated arterial pressure (and heart failure) identified through palpation or sphygmographic recording of the arterial pulse in the late 19th century by Broadbent (1875) and Murrell (1879), respectively.[54,55] In response, Mahomed, who had modified and improved the sphygmograph at Guy's Hospital (where the co-author to this Chapter, A.W. runs hypertension clinics), highlighted the significance of a modifiable functional component of high arterial tension, as opposed to fixed structural changes in the arterial wall.[56] However, as GTN was not found to consistently lower brachial blood pressure (systolic or diastolic) as estimated by the occlusive cuff method of Scipione Riva Rocci in 1896,[57] interest in its use for chronic hypertension waned. The relationship between the effects of GTN on arterial waveform, different vessel types and effect on aortic versus brachial systolic pressure were not fully appreciated until over a century later, as reviewed and further investigated by Jiang et al.[58]

As initially described by Winbury M et al., in the coronary circulation in 1969,[59] organic nitrates were further characterized as being selective for conduit versus resistance arteries by Barba et al.[60]; see Fig. 51.4.

FIGURE 51.4 Arteriovenous profiles of dilators. Dilator responses of dorsal hand veins (Δ; n = 6; left axis), the radial artery (●; n = 4; left axis), and the forearm resistance bed (■; n = 4−5; right axis) to local infusions of glyceryl trinitrate. Allowing for the approximately 50-fold differences in blood flow between dorsal hand veins and the forearm arterial bed, these results suggest that nitric oxide donors are approximately equipotent in dorsal hand veins and the radial artery and 10-fold less potent in the resistance vasculature. *Reproduced from Figure 1A from Barba G, Mullen MJ, Donald A, MacAllister RJ. Determinants of the response of human blood vessels to nitric oxide donors in vivo.* J Pharmacol Exp Ther. *1999;289:1662−1668.*


In a recent study utilizing the human forearm model, Fok et al. assessed changes in conduit (radial) artery diameter (measured by ultrasound) in response to intrabrachial infusion of various vasodilators.[61] Fig. 1 from that article[61] (free access: https://www.ahajournals.org/doi/10.1161/HYPERTENSIONAHA.112.198788?url_ver=Z39.88-2003&rfr_id=ori:rid:crossref.org&rfr_dat=cr_pub%20%200pubmed) shows that for the same degree of effect on resistance arterioles (assessed by forearm blood flow [FBF]), GTN, had the largest effect on conduit artery dilatation, followed by sodium nitroprusside (SNP): these agents are metabolized to NO or donate/release NO, respectively, suggesting selectivity for larger (conduit) arteries versus smaller (resistance) arterioles, via a mechanism relating to NO. By comparison, the other vasodilators, such as alpha-adrenergic blockers (phentolamine) and calcium channel blockers (verapamil) had little or no effect on conduit arteries but were highly effective at increasing FBF (resistance arterioles). We have summarized these comparative differences in selectivity in Fig. 51.5. In addition, changes in local PWV in the conduit arteries and impedance (Zc) were closely correlated with changes in radial artery diameter.[61]

Key evidence to explain the hemodynamic effects of organic nitrates is provided in the Jiang et al. paper mentioned above.[58] By assessing the effect of increasing doses of GTN patches on peripheral and central (aortic) blood pressure, the investigators identified GTN's related

effects on aortic augmentation pressure (AP) and ejection duration. While GTN only decreased brachial blood pressure at the highest dose, it decreased aortic pressures (systolic blood pressure [SBP], pulse pressure, and augmentation index) at all doses, which was considered to be due to a selective effect on conduit versus resistance vessels.

A subsequent study by Pauca et al., using invasive measures of aortic pressure, found that the decrease in central aortic systolic and pulse pressures is attributable to its effect on peripheral conduit arteries: GTN acts to dilate conduit vessels therefore decreasing aortic wave reflections.[62] These results are consistent with the current clinical uses of organic nitrates: they are effective at dilating conduit arteries, e.g., the epicardial coronaries and are therefore an effective antianginal therapy (however the main mechanism is via venous dilatation with decreased preload and therefore LV wall stress). At low doses they are relatively ineffective at dilating resistance arterioles, therefore restricting their use as antihypertensive agents (at least with respect to peripheral BP), unless at high doses, e.g., via an intravenous infusion for hypertensive crises.

A further complementary insight into the mechanism of GTN was provided by Cecelja M et al. in the Twins UK Study. Here the ∼10 mmHg increase in central pulse pressure over a decade in 411 female twins was accounted for mainly by an increase in AP. GTN (in a subsample, n = 42) transiently "reversed this decade of aging"—decreasing the cPP by 10 mmHg; this was entirely by decreasing the AP.[63] Gu et al. recently developed a novel echocardiographic parameter, the first-phase ejection fraction (EF1), which is the fraction of left ventricular volume ejected from the start of systole to the time of the first peak in left ventricular pressure (corresponding to the time of maximal ventricular shortening).[64] The EF1 was found to be diminished in patients with hypertension and diastolic dysfunction: a pattern of sustained myocardial contraction, which preserves systolic ejection fraction but at the expense of impairing diastolic function was identified. Moreover, EF1 was improved by GTN, as was diastolic function, with the onset of ventricular relaxation also being hastened. The hemodynamic effects of organic nitrates and the other NO-related therapeutics, to be discussed below, are summarized in Table 51.1.

Part 3: inorganic nitrite

Early pharmacological studies of nitrite on arterial tension/waveform

Considerable interest in the cardiovascular effects of pharmacologically administered sodium and potassium nitrite developed shortly after Broadbent (1875) and Murrell (1879) had explored the effects of the organic nitrates, as described above,[54,55] and partly in the search for other agents given the short duration of action of amyl nitrite for

the treatment of angina, as reviewed by Butler and Feelisch.[65] Reichert and Mitchell in 1880 showed that intravenous doses of potassium nitrite reduced arterial blood pressure in cats and dogs, while orally administered potassium nitrite was found to have effects on pulse rate and character in humans.[66] Five years later, Leech published an extensive series of sphygmographs in the British Medical Journal in 1885[67] demonstrating while the onset of action of nitrite on the arterial waveform was delayed (6—10 min) relative to that of nitroglycerine (2 min), the durations of action of sodium and potassium nitrite were more prolonged (strongly for 2.5 h, altogether for 4—5 h) than those produced by nitroglycerine (marked for 30—45 min, detectable for 2.5—3 h) and both were longer than amyl nitrite (10—20 min). This helped fuel the ongoing interest in the use of (inorganic) nitrite as a potentially superior drug, which then appeared in Materia Medica, was manufactured by Squibb in 1906, and was available as an injectable solution for vasospasm and hypertension in the 1920s.

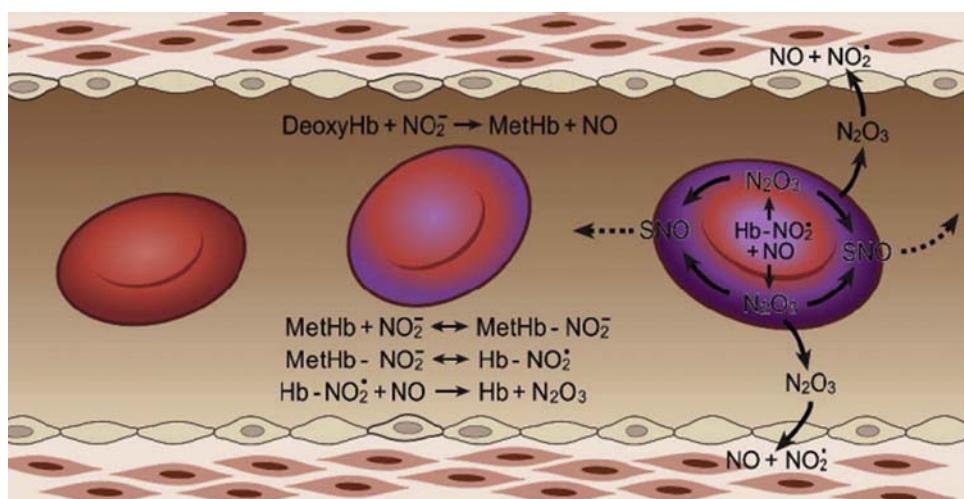
Ben Densham, from King's College London (where this Chapter's co-authors are based), described in experiments performed in the cat fore- and hindlimb in 1927 "A species of 'unlocking effect' of the hydrogen ion on the vasodilator action of sodium nitrite and acetyl choline…" and "A specific adjuvant action of the lactate ion on the vasodilator action of sodium nitrite…,"[68] thus identifying the role of lower pH in the physiological responses to nitrite.

While Furchgott and Bhadrakom explored nitrite's vasodilatory potential in high concentrations with isolated strips of rabbit aorta in 1953[69] by that time, nitrite's clinical use had declined, due to its side effects and the availability of other agents, including longer-acting organic nitrates.

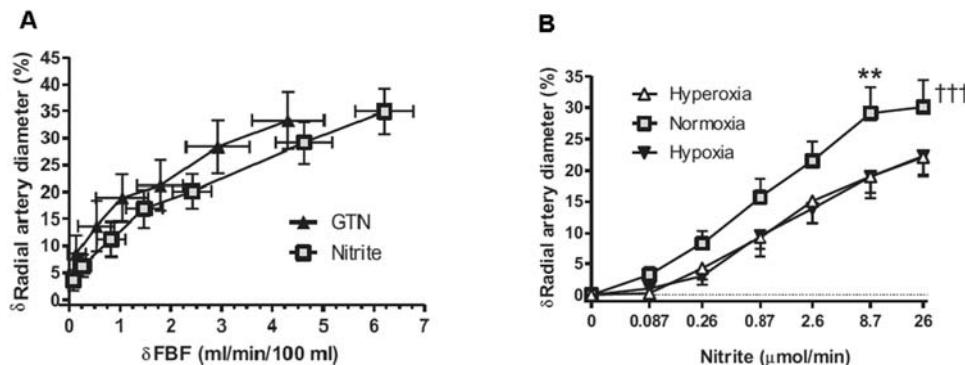
Reevaluation of nitrite in the "nitric oxide era"

Some 27 years after Furchgott's studies on nitrite in rabbit aorta, he discovered EDRF, which was followed by its identification as NO, see Palmer, Ferrrige and Moncada.[1,2] Against the huge amount of interest in NO, inorganic nitrite was considered to be "an inert oxidative end product of endogenous NO metabolism" in 1993 by Moncada and Higgs[5] and thus lack physiological effects. Even with the demonstration by Zweier in 1995 that nitrite is reduced to bioavailable NO during ischemia-reperfusion in the isolated perfused Langendorff rat heart,[70] nitrite appeared to have a deleterious effect and interest in nitrite waned again. Coupled with concerns about the potential to cause cancer (discussed below), nitrite was considered at worse toxic, and at best inactive. Interest in nitrite was not restored until this century, with the finding of cardiovascular effects under physiological conditions[71] in addition to beneficial effects under ischemic/hypoxic conditions.[72] This led to a proliferation of studies exploring nitrite's physiological role and therapeutic potential in a range of disease states.

Nitrite is formed endogenously in cells from the oxidation of NOS-derived NO by cytochrome C oxidase in mitochondria,[73] in the circulation by ceruloplasmin in plasma,[74] and in the gastrointestinal tract from the reduction of inorganic (including dietary) nitrate in the saliva,[75,76] by bacterial nitrate reductases (though nitrite

thus generated was not originally thought to be absorbed systemically, as discussed further in inorganic nitrate section below). Nitrite is now proposed to comprise the largest vascular storage pool of NO.[71]


Recent assessment of vascular effects of nitrite

Blood flow studies in the human forearm allow observation of the effect of drugs on small resistance arteriolar function. Following intra-arterial infusion of a drug (via brachial artery cannulation), the effect on resistance arterioles is observed by measuring the change in estimated forearm blood volume, a technique known as forearm venous occlusion plethysmography. Although an initial study by Lauer et al. did not demonstrate any increase in FBF (representing small resistance arterioles) in response to an intrabrachial infusion of sodium nitrite (n = 3),[77] a landmark study by Cosby et al. found that infusion of supraphysiological and near-physiological concentrations of nitrite did increase FBF.[71] Vasodilatation was enhanced during handgrip exercise, and, the rate of NO formation was enhanced with lower oxygen saturations in ex vivo experiments, suggesting that nitrite bioactivation is regulated by a hypoxia-dependent mechanism. Maher et al. went on to show that at several doses, the nitrite-induced increase in FBF was enhanced under hypoxia conditions (vs. normoxia).[78] Nitrite is therefore recognized as a hypoxia-dependent dilator of small resistance arterioles, and this is entirely consistent with the proposed mechanism of nitrite bioactivation, such as deoxyHb and xanthine oxidase, which are hypoxia-dependent mechanisms.[7] On this point, however, the key question has been, how does the NO formed from nitrite/catalyzed by deoxyHb in the


RBC escape scavenging by Hb/the RBC to reach the vessel wall and effect vasodilatation? Basu et al. proposed a mechanism via dinitrogen trioxide formation (N_2O_3), which is a small and uncharged molecule with a greater diffusion coefficient than NO and the capacity to readily form vasodilating nitrosothiols; see Fig. 51.6.[79]

The human forearm model can also be used to assess conduit artery function through 2D ultrasound assessment of radial artery diameter, which we performed simultaneously with FBF. With ∼100% arterial hemoglobin oxygen saturation in healthy volunteers, nitrite would not be expected to result in vasodilatation in conduit vessels, as this would not support reduction of nitrite to NO and NO is rapidly oxidized to nitrite and nitrate. However, we found pronounced radial artery dilatation following intrabrachial infusion.[80] Moreover, this was relatively greater than the effect on FBF, suggesting a selective dilatory effect of nitrite on medium-sized conduit arteries. Indeed, the degree of selectivity almost matched that of GTN (see Fig. 51.7A)—the most selective larger artery (i.e., of medium sized conduit arteries) dilator yet identified, as we have described above.[61]

Furthermore, the impact of hypoxia was opposite in the radial (conduit) artery compared to resistance arterioles: nitrite's vasodilatory effect was maximal in normoxia and inhibited by hypoxia (and by hyperoxia); see Fig. 51.7B.[80] Given this surprising finding, identifying the precise mechanism has proven challenging. However, nitrite infusion was associated with local forearm increases in cGMP production, albeit collected in the returning venous circulation; thus, while this supported generation of NO from nitrite, to what extent this occurred in the radial artery was not clear. We also showed that the use of raloxifene to

FIGURE 51.6   Model of nitrite- and Hb-mediated N_2O_3 export and nitrosation. Hemoglobin deoxygenation (purple) occurs preferentially at the submembrane of the red blood cell as it traverses the arteriole. Nitrite reacts with deoxyHb to make MetHb and NO. Much of this NO binds to hemes of deoxyHb or undergoes dioxygenation to form nitrate and MetHb from oxyHb. MetHb binds nitrite to form an adduct with some Fe(II)−NO2 character (Hb−NO2). This species reacts quickly with NO to form N2O3, which can diffuse out of the red cell, later forming NO and effecting vasodilation and/or forming nitrosothiols (SNOs). Low-molecular-weight nitrosothiols may contribute to exportable vasodilatory activity. *Reproduced from Figure 7 from Basu S, Grubina R, Huang J, et al. inhibit aldehyde oxidase (AO)—an important producer of ROS in humans, enhanced nitrite-induced dilatation. Since hypoxia, as well as hyperoxia, predisposes to ROS production, this provides indirect evidence for varying dilatory responses in light of the prevailing levels of oxygenation.
We have also demonstrated nitrite's selectivity for conduit over resistance arteries in human coronary arteries. Intracoronary infusion of sodium nitrite demonstrates a dose-dependent dilatory effect on epicardial (conduit) coronary arteries, but without any significant effect on coronary blood flow or coronary artery resistance (which reflect resistance arteriolar function)—despite being observed in the metabolically active (beating) heart[81]; see Fig. 51.8. The effect of nitrite was compared to that of GTN, which dilated epicardial coronary arteries, but also increased coronary flow and decreased coronary resistance. These findings suggest that nitrite was at least as selective for large versus small vessels as GTN.

When given via an intravenous infusion, inorganic nitrite causes systemic vasodilatation of conduit arteries—i.e., the radial artery by ∼11%, and a decrease in central (aortic) systolic blood pressure (and augmentation index, AIx),[80] without effect on peripheral brachial systolic blood pressure (or on FBF/small resistance artery dilatation); see Fig. 51.9.

The finding described above is consistent with nitrite's selectivity for conduit arteries, given the similar relationship described for GTN.[58,62] The benefit of a circulating pool of nitrite is its stability in whole blood. Nitrite has a half-life following intravenous infusion in vivo of approximately 50 min[82,83] compared to the extremely short half-life of molecular NO (∼20 ms).[4] This disparity in half-life therefore allows effective delivery of the NO precursor nitrite to the target tissue, whereby local reduction yields bioactive NO.

The effect of inorganic nitrite on the cardiovascular system—ventricular hemodynamics

Limited animal and human data exist to describe the effect of nitrite on cardiac function. In the rat heart, nitrite exerts a concentration-dependent lusitropic effect[84] and augments the Frank Starling response[85] in an NO and cGMP/PKG-dependent, but NOS-independent manner. Nitrite's effect on the human heart has been studied in HFpEF, in which it improves ventricular performance during exercise (a greater increase in cardiac output with exercise vs. placebo),[86] as well as decreasing aortic wave reflections and inducing improvements in arterial elastance[87]; see below.

Clinical applications of inorganic nitrite

The therapeutic role of inorganic nitrite has been extensively studied in a number of conditions in which dysfunctional or dysregulated NO signaling has been demonstrated, including ischemia-reperfusion injury (IRI)[88−91] and cerebral vasospasm following subarachnoid hemorrhage (SAH).[92−94] Although not directly relevant to the theme of this text, the current lack of definitive RCT evidence for therapeutic use of nitrite in IRI and SAH highlights the difficulty often seen in therapeutic translation from "bench to bedside."

More relevant to the theme of arterial stiffness and pulsatile hemodynamics is nitrite's effect in conditions such

as arterial hypertension and HFpEF, as discussed in Chapter 36. HFpEF is of particular relevance to the therapeutic potential of nitrite in that it is a disease that is both associated with dysfunctional NO signaling on a cellular basis (eNOS uncoupling,[95] decreased myocardial PKG activity,[96] and decreased phosphorylation of cytoskeletal proteins[96,97]) while also on a systems basis being associated with abnormalities in arterial stiffness and pulsatile hemodynamics. For these and other reasons (such as lack of tolerance, Table 51.1), nitrite would appear to be an attractive therapy to target the key pathophysiological abnormalities in HFpEF.

Mechanistic studies have demonstrated the potential beneficial effects of nitrite in HFpEF, with benefits on resting hemodynamics[98] and also following exercise.[99] In the INDIE-HFpEF trial, however, inhaled nitrite failed to improve exercise capacity in patients with HFpEF compared to placebo,[100] nor did it improve any of the secondary endpoints (QOL, activity levels, ventricular filling pressures, or biomarkers). It has been suggested that the short half-life of nitrite (∼50 min) is the key reason why the findings of acute dosing were not confirmed with a four-week course of inhaled nitrite. It may also be that inhaled nitrite is more akin to local rather than systemic dosing.

There are several limitations of the current evidence base for inorganic nitrite in HFpEF. For example, on a mechanistic level, it is not clear whether systemic delivery of nitrite acts solely via changing cardiac loading conditions or whether there is a direct myocardial effect. Furthermore, on a

therapeutic level, although dietary nitrate—in contrast to organic nitrates—has been shown to improve exercise capacity in patients with HFpEF, there is a lack of placebo-controlled data to suggest that the effects seen with acute dosing persist with extended duration of therapies.

Part 4: inorganic (dietary) nitrate

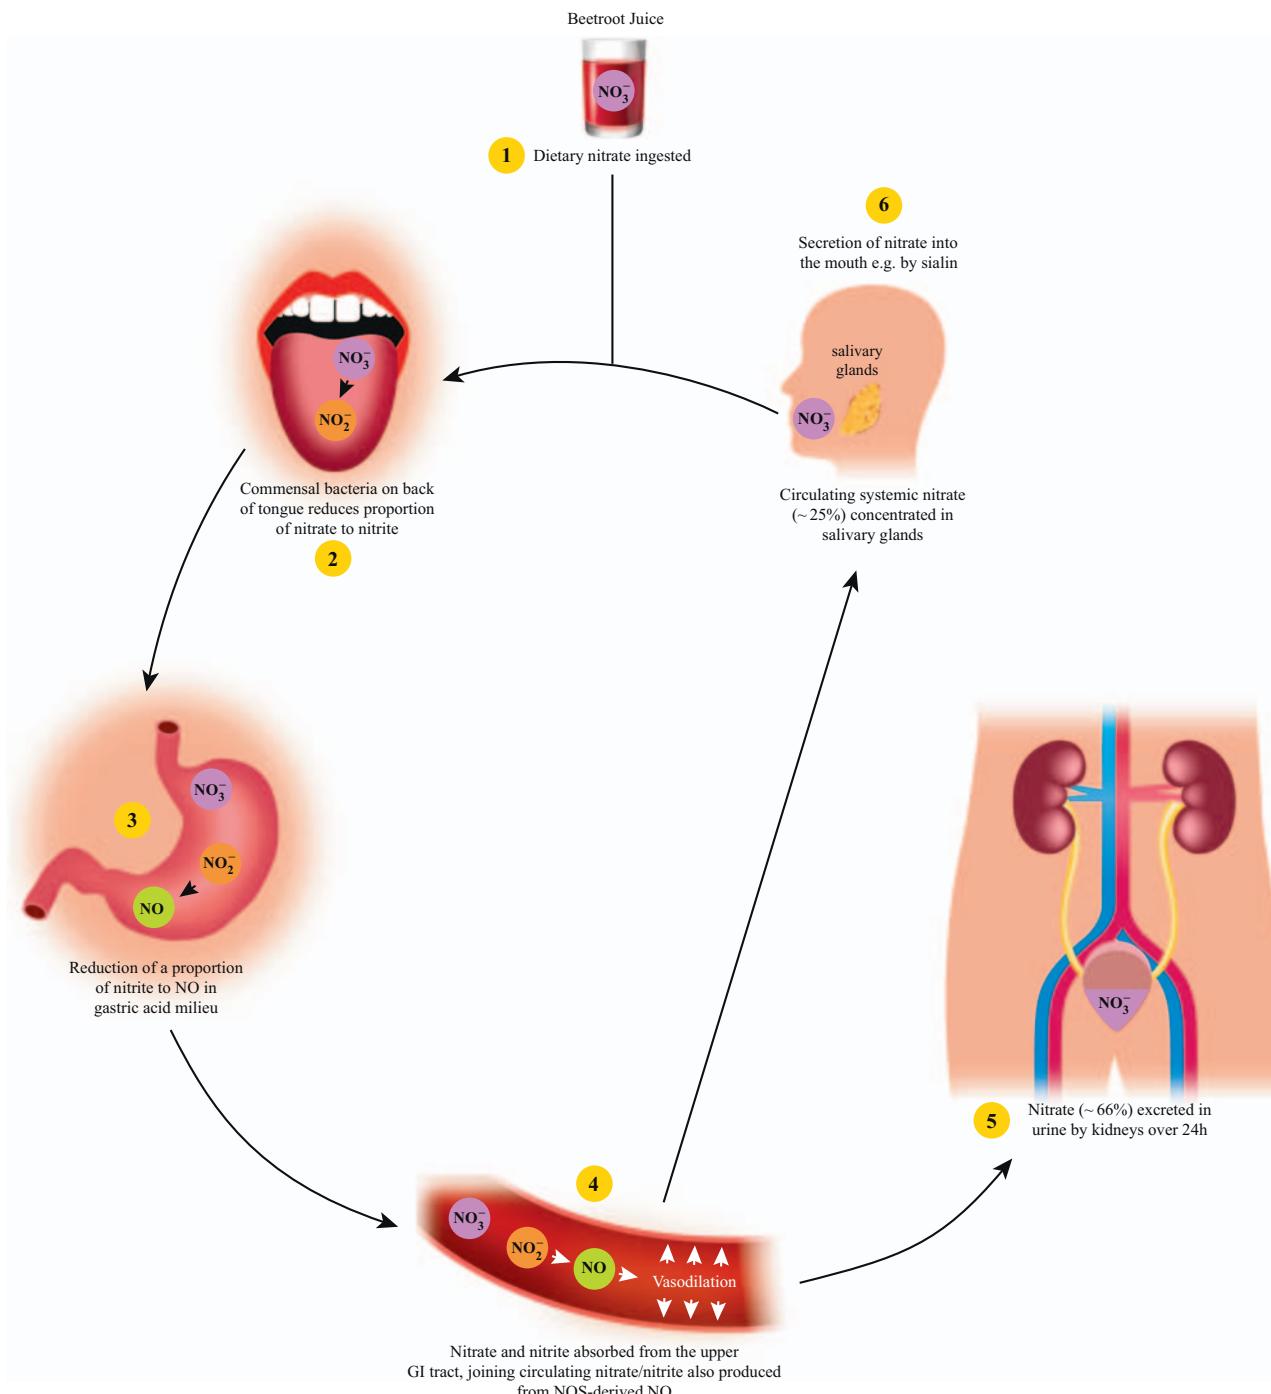
Discovery of the inorganic nitrate-nitrite-NO pathway and its cardiovascular relevance

The medicinal purposes of nitrate have been utilized as early as the ninth century, when the Chinese documented the ability of wall saltpetre (calcium nitrate) to relieve "acute heart pains, and cold in the hands and feet".[101] However, the nitrate-nitrite-NO pathway was not realized and described as such until 2008[6]; see Fig. 51.10.

The nitrate-nitrite-NO pathway (which includes the enterosalivary circulation) describes the two-step process by which NO is produced from orally ingested, and endogenously produced, inorganic nitrate (NO_3^-), via inorganic nitrite (NO_2^-). Inorganic nitrate is readily absorbed by the upper gastrointestinal tract with a bioavailability of $\sim$100%,[102,103] peak plasma [nitrate], Cmax is achieved from $\sim$60 to 90 min, with a half-life of 5—8 h in the circulation.[104,105] Approximately 25% is concentrated in the salivary glands, with the majority of the remainder being excreted via the kidneys.[106] Following salivary secretion into the oral cavity, nitrate is reduced to nitrite, mainly by strict anaerobes (e.g., *Veillonella species*) and by facultative anaerobic bacteria (*Actinomyces odontolyticus* and *Rothia mucilaginosa*) on the posterior surface of the tongue[107] resulting in a salivary nitrite concentration >1000 times the plasma nitrite concentration.[108]

A proportion of the nitrite in swallowed saliva is subsequently converted in the acidic stomach environment in a nonenzymatic fashion to NO, i.e., nitrite disproportionation via nitrous oxide and dinitrogen trioxide[109] (which is also a mechanism of NO generation from nitrite in ischemic tissues, where the local pH is low[70,110]). However, at physiological and dietary-derived concentrations, nitrite was not originally thought to be absorbed systemically, e.g., with no increase in plasma nitrite concentrations found in 2003 following lettuce ingestion,[111] and therefore would lack physiological effect. With high pharmacological doses of nitrite, it was easier to demonstrate that it entered the circulation (due to absorption across the upper gastrointestinal tract) as shown in 2009.[112] Lundberg and Govoni showed in 2004 that ingested nitrate did result in an increase in plasma (nitrite).[108]

Dietary nitrate and blood pressure

The functional effect of dietary nitrate was initially revealed by Larsen et al. who found a decrease in diastolic blood pressure following three days of sodium nitrate ingestion in healthy volunteers in 2006.[113] We demonstrated in 2008 that a single ingestion of beetroot juice by healthy volunteers, as a source of dietary nitrate, acutely decreased systolic and diastolic blood pressure with peak effects from approximately 2—3 h, in parallel with the peak increase in plasma [nitrite].[105] The importance of the salivary conversion of nitrate to nitrite was demonstrated by the finding that if subjects spit rather than swallow their saliva (and therefore expel salivary nitrite), the rise in plasma nitrite associated with ingestion of dietary nitrate is abolished[108] as is the blood pressure-lowering effect.[105] The term "nitrate-nitrite-NO pathway" was thus coined in 2008.[6] Since, besides beetroot, green leafy vegetables are a rich source of dietary nitrate, and they are widely consumed in Mediterranean and Japanese diets which are associated with greater longevity and diminished cardiovascular disease, it has been proposed that nitrate is a key component of a healthy diet and accounts for the blood pressure lowering and other cardiovascular benefits, for example, as demonstrated in the DASH study,[114]


Besides spitting, the nitrate-nitrite-NO pathway may be interrupted by mouthwash such as chlorhexidine, which reduces the amount of nitrate-reducing bacteria on the posterior surface of the tongue (by 80% for bacterial counts from tongue scrapings), almost abolishing the increase in salivary [nitrite] and plasma [nitrite] in healthy volunteers, following an oral nitrate load.[115] Furthermore, under basal conditions with low-normal dietary nitrate intake, chlorhexidine increases systolic and diastolic blood pressure in healthy volunteers from the first day, and throughout a seven-day period of mouthwash use.[116] This highlights the potential implications of widespread mouthwash use on blood pressure and other cardiovascular parameters in the population.

A number of recent meta-analyses have been performed to address the overall effect of inorganic nitrate on BP. The findings of these analyses suggest that, for interventions of up to 15 days duration, inorganic nitrate supplementation is associated with a significant decrease in SBP of $\sim$4 mmHg.[117] A similar magnitude of effect on SBP was seen in a later meta-analysis of studies with an intervention duration of 1 week or more; however, the effect was only significant for clinic BP measurements, with no significant BP changes observed in studies using ambulatory and/or home BP monitoring.[118]

Dietary nitrate and arterial stiffness/pulse wave velocity

In addition to blood pressure, several studies have shown that inorganic nitrate improves arterial stiffness. This was first demonstrated in healthy volunteers by Bahra et al.,[119] whereby aortic pulse wave velocity (aPWV) was decreased by $\sim$0.3 m/s following potassium nitrate (8 mmol) ingestion ($P < .01$), associated with an almost 5 mmHg decrease

FIGURE 51.10 The nitrate-nitrite-NO pathway. *Based on an original drawing by Andres Jaramillo Moyano and Andrew Webb.*

in SBP.[119] Similarly, in patients with grade 1 hypertension, Ghosh et al. found that beetroot juice ($\sim$3.5 mmol nitrate) decreased aPWV by $\sim$0.8 m/s at 3h, again associated with a $\sim$10 mmHg decrease in SBP.[120] Velmurugan et al. showed that in a double-blind parallel group placebo-controlled study in 69 patients with hypercholesterolemia that the effect was maintained following a six-week course

of dietary nitrate (250 mL of beetroot juice/day), with a $\sim$0.2 m/s decrease in aPWV accompanied by a $\sim$4 mmHg decrease in SBP.[121] While as in the previous studies, these differences in PWV were only significant for before and after the active intervention, and not versus control, there was in this placebo-controlled study also a decrease in augmentation index between groups (-3.9%). In each of

the above studies with dietary nitrate, the decrease in aPWV was measured using the Vicorder device and was in the context of a decrease in blood pressure. However, whether dietary nitrate's effect on aPWV is all due to the change in BP, or whether it is possible to alter aPWV independently of BP (i.e., via effects on the arterial wall), and over a longer period was not clear. Therefore, we tested this in our "Vasera study," with Kennedy Cruickshank, a factorial design study in which we randomized 126 patients with hypertension and with Type 2 diabetes (T2DM), or at risk of T2DM (mainly BMI >27) to six months' active nitrate-containing beetroot juice or placebo nitrate-depleted beetroot juice and either spironolactone or doxazosin.[122,123] As two previous studies in patients with T2DM by Gilchrist and colleagues had not identified a blood pressure-lowering effect of dietary nitrate,[124,125] we were not anticipating a decrease in BP with the nitrate versus placebo in this cohort; this would allow comparison of any difference in arterial stiffness in the absence of any difference in BP, but we were also assessing arterial stiffness using cardio-ankle vascular index (CAVI) a nominally BP-independent measure. Indeed, nitrate did not decrease peripheral brachial BP versus placebo beetroot juice, and there were no differences in CAVI. Instead, dietary nitrate resulted in a significant decrease in central aortic SBP by ∼2.6 mmHg. Given the lack of effect on brachial BP, this represented a selective decrease in central BP, which is consistent with our previous findings described above with inorganic nitrite (selectively reducing central BP), with the associated mechanism of normoxia-dependent conduit artery dilation.[80] Therefore, dietary nitrate and inorganic nitrite may have their main effects on medium-sized conduit arteries in normoxia, associated with decreases in central aortic BP, rather than an effect on large artery (aortic stiffness) per se. For spironolactone versus doxazosin, there were also no differences between them in their effects on decreasing BP (as intended in the design of the study) but also no significant differences in CAVI (infact, CAVI was borderline lower for doxazosin than spironolactone). Thus, our data suggest that it is possible to alter aortic stiffness independently of BP and eluding to a role for sympathetic (nor)-adrenergic tone in regulation of large arterial stiffness, mechanisms which are supported by subsequent work by Faconti et al.[126] Here we used lower-limb venous occlusion (LVO; a similar intervention to lower-body negative pressure) which reduced mean arterial BP (by ∼1.8 mmHg) in 70 patients with hypertension but increases sympathetic activity (reflected by an increase in heart rate variability; HRV) and found that LVO elevated aortic and carotid-femoral PWV by ∼0.8 and ∼0.7 m/s, respectively. By comparison, device-guided breathing decreased BP, sympathetic tone/HRV and PWV by ∼1.2 m/s, exceeding

nifedipine's effect on PWV ∼0.7 m/s, despite the latter's greater effect on BP (but lack of effect on HRV).

Several other studies have been performed investigating pulsatile hemodynamics and arterial stiffness with dietary nitrate. For example, Liu et al. performed a study in 26 healthy volunteers (albeit with average BMI in the overweight range 25.4 [range 19.1−30.4]) with acute dosing with a spinach-rich meal (220 mg nitrate) which improved pulsatile hemodynamics (it reduced pulse pressure and SBP, but not DBP) but showed only a trend to improvement in carotid-femoral PWV (cfPWV).[127] The same group (Bondonno et al.) performed a crossover RCT assessing the effect of seven days' high-nitrate (>300 mg nitrate) versus seven days' low nitrate diet in 38 patients with high-normal blood pressure, who were on average in the overweight range BMI 27.1 (range 20.6−37.0): there was no effect on SBP or DBP or cfPWV (SphygmoCor).[128] Kim et al., studied 13 healthy postmenopausal women (Aged 63 ± 1 year; BMI 25.4 ± 1.4 [SEM]) and found that acute administration of nitrate-rich beetroot juice decreased peripheral and central (aortic) systolic and mean blood pressures, and increased pulse pressure augmentation, but had no effect on cfPWV, AP, or AIx; SphygmoCor).[129]

Whether age influences the hemodynamic responses before and after dietary nitrate was investigated by Hughes W. et al., who found that beetroot juice (nitrate 9.4 mmol) decreased aortic augmentation index (AIx@75 bpm; SphygmoCor) in 14 healthy young adults (aged ∼25 year) despite AIx@75 already being negative: from −4.3% at baseline to −8.8%, but did not decrease AIx in 12 healthy older normotensive individuals (aged ∼64 year; baseline AIx ∼28%), despite decreasing peripheral and central BP in both groups.[130] Walker M et al. studied 15 healthy older men of similar age (mean 69 years old, mean BMI 26.6) in an acute double blind randomized crossover study with a similar dose of dietary nitrate (800 mg) as beetroot juice, and found an improvement in AIx75 versus placebo, but no effect on BP or PWV.[131] The results of larger, longer intervention studies are awaited, such as the NITRATE-TOD study, a randomized, double-blind, placebo-controlled trial investigating the effects of inorganic nitrate in hypertension-induced target organ damage, in which reduction in PWV and central BP are primary outcomes along with change in LV mass.[132]

Augmentation index was also assessed in 17 patients with HFpEF (mean age 65.5 ± 8.9 years) in the randomized, double-blind, crossover study by Zamani et al.,[133] as discussed in Chapter 36. In brief, here a single dose of nitrate-rich beetroot juice (nitrate 12.9 mmol) significantly decreased AIx and systemic vascular resistance (vs. placebo), in parallel with the accompanying increases in total work performed, cardiac output, and peak oxygen

consumption (peak VO_2) during supine-cycle maximal-effort cardiopulmonary exercise tests. Chirinos and colleagues also tested the effects of organic and inorganic nitrates on carotid as well as aortic hemodynamics, using carotid tonometry in two separate studies (one being the above study by Zamani et al.) in patients with HFpEF.[134] Sublingual GTN (0.4 mg) (n = 26) produced marked vasodilation in the carotid territory, decreasing carotid bed vascular resistance, and carotid characteristic impedance, and while it diminished the real component of the reflection coefficient in the first harmonic, GTN lacked effect in the second harmonic and increased the third harmonic. These first three harmonics contain most of the pulsatile energy which is transmitted to the brain. This was also in the face of a significant ∼13 mmHg drop in central SBP, without a significant decrease in pulse pressure. Hence, GTN exhibited risks of hypotension and produced excessive brain vasodilation/without decreasing the arterial pulsatile load on the left ventricle. By contrast, oral dietary inorganic nitrate (n = 16) in the form of 12.9 mmol nitrate-rich beetroot juice, more consistently decreased central arterial wave reflections—across all three lower harmonics, without decreasing carotid vascular resistance, carotid characteristic impedance, or BP. Further analysis revealed that GTN significantly elevated total transmission, from the aorta to the carotid, of hydraulic power by ∼50% and energy penetration by ∼33%, with reciprocal losses in aortic hydraulic power and energy.[135] These findings may underpin GTN's common adverse effects such as headaches and highlight concerns of increased pulsatile hemodynamic stress of the cerebral microcirculation in HFpEF. Dietary nitrate lacked such deleterious effects. Additionally, inorganic nitrate, but not GTN, improved the Buckberg index (ratio of diastolic to systolic pressure-time integrals[136]). This suggests that inorganic nitrate, but not GTN, improves the relationship between pulsatile hemodynamics and myocardial oxygen supply:demand matching. While the study found that GTN reduced central systolic blood pressure, but inorganic nitrate had no significant effect, this was carried out in 16 patients, comparing BPs only at ∼2.5h postjuice ingestion in patients with an elevated BMI 34.4 (SD 3.5). As we have described above, several other studies in varied patient/participant groups provide evidence that inorganic nitrate/beetroot juice lowers central SBP both acutely, and, for example, in our study with chronic ingestion over six months, among others.[122,123,129,137−139] Moreover, a very recent meta-analysis by Li et al. provides further confirmatory support from 47 trials with 1101 participants which used repeated dosing of nitrate over at least three days, with overall significant effects on decreasing: peripheral SBP by ∼3 mmHg, peripheral DBP ∼1.5 mmHg, central SBP ∼1.6 mmHg, central DBP ∼2 mmHg; while for PWV there was a borderline effect −0.24 m/s (95% CIs −0.50,

0.01; $P = .06$) along with borderline effects on AIx and 24h SBP and DBP.[140]

The above data highlight several important differences between organic and inorganic nitrates in the context of HFpEF. The ventricular and arterial dysfunction and stiffening seen in HFpEF renders patients susceptible to hypotension in the setting of excessive peripheral vasodilatation. Given inorganic nitrate/nitrite's relatively selective action on conduit versus microvascular arteries (and theoretically central over peripheral BP) in normoxia as well, this confers a potential advantage versus organic nitrate. Furthermore, in exercising tissues (local hypoxia), the effect of inorganic nitrate/nitrite on the microvasculature may enhance blood flow to exercising muscles. An additional, likely related and potentially beneficial cardiac effect that we identified, was that dietary nitrate (beetroot juice) ingestion over six months decreased left ventricular end-diastolic and end-systolic volumes by ∼5% (vs. placebo) in our Vasera study.[141]

Inorganic nitrate and angina

A number of studies have assessed the effect of inorganic nitrate on angina. In the "Inorganic Nitrate in Angina Study," 600 mg sodium nitrate for 7−10 days increased plasma [nitrate] and [nitrite] in 70 patients with stable angina, associated with a trend to an increase in time-to- 1 mm ST depression on treadmill testing and significantly increased total exercise time by ∼16 s versus double blind placebo.[142] The NITRATE-OCT study is an ongoing randomized-double-blind, placebo-controlled trial testing the effect of six months' nitrate-containing versus nitrate-depleted beetroot juice on vascular function, platelet reactivity and coronary restenosis (the primary outcome measure, assessed by quantitative coronary angiography and optical coherence tomography; OCT) in 246 patients undergoing percutaneous coronary intervention for stable angina.[143]

Limitations of organic and dietary/inorganic nitrates

In the published literature regarding inorganic nitrate, it is common to see comparisons with organic nitrate in which the limitations of organic nitrate are listed.[144] Key examples of such limitations include: the rapid development of tolerance; side effects such as headache; and the tendency of organic nitrates to induce a state of endothelial dysfunction.[145,146] Indeed, in the NEAT-HF study, organic nitrate actually worsened activity levels in patients with HFpEF, a finding that has been attributed to endothelial dysfunction due to ISMN,[51] or could be related to its side effect profile from nonselective hemodynamic effects (including brain vasodilation and hypotension) as discussed above.

Although dietary nitrate is often considered synonymous with beetroot juice, nutritional studies may consider a range of green leafy vegetables as dietary nitrate. In such studies, calculation of daily dietary nitrate intake may involve calculation of the total amount of dietary nitrate using participant food diaries. Estimations such as this are highly prone to error. Beetroot juice as dietary nitrate has issues with palatability. In a recent study, we asked volunteers to give concentrated beetroot juice a score for taste on a scale of 0 to 10 (0 for disgusting, 10 for delicious). The average score for concentrated beetroot juice (diluted in water) was only 4 out of 10[147] (of note in this particular study, taste was improved by mixing the beetroot juice with golden grapefruit juice, a combination which potentiated beetroot juice's effect on lowering SBP and pulse pressure). This is in addition to discoloration of urine and stool due to beetroot which, although harmless, may be distressing to patients. While most studies to date suggest that individuals taking inorganic nitrate (and nitrite) do not develop tolerance, a recent study in which 20 patients with hypertension and metabolic syndrome took sodium nitrite for 12 weeks has suggested that tolerance to inorganic nitrite may indeed occur (the BP-lowering effect was sustained for the first 10 weeks, but not present at week 12).[148] Also, a recent, relatively large study in 231 patients with hypertension, found no overall effect on ambulatory blood pressure of nitrate pills (300 mg nitrate), or leafy green vegetables containing 300 mg nitrate versus low-nitrate vegetables or placebo pills taken daily over five weeks.[149]

These data are in contrast to the other studies described above, with long term evidence from our findings of the (central) BP-lowering effect of dietary nitrate is seen at 6 months.[122] Further studies are required to assess whether this effect is consistently seen with longer term treatment with nitrite and also whether a similar phenomenon is seen with dietary nitrate.

As is discussed in detail later in this chapter (Part 6), the pathophysiology of some disease states involves abnormalities in the redox state of sGC which becomes NO-unresponsive. This may therefore decrease the effectiveness of any therapies, organic and inorganic nitrates included, that act via NO signaling.

Safety concerns regarding dietary nitrate and inorganic nitrite

Although inorganic nitrate is not associated with the side-effects commonly seen with organic nitrates, e.g., headache, acute side effects can occur, depending on mode of delivery. For example, as noted above, approximately 10% of patients who receive oral sodium nitrate experience gastrointestinal side effects such as nausea, vomiting, and/or abdominal discomfort.[142]

Methaemoglobinaemia (oxidation of hemoglobin to methemoglobin which lacks oxygen-carrying capacity) is considered to be a possible side effect of treatment with inorganic nitrate/nitrite; however, the doses used in clinical studies have not resulted in clinically significant methaemoglobinaemia (generally considered as a methemoglobin level of greater than 5%−10%).

The most concerning potential adverse effect of dietary nitrate is perhaps also the most contentious, i.e., whether or not consumption of dietary nitrate causes gastrointestinal malignancy. Definitive data are absent with some studies suggesting a positive association yet others suggesting that higher levels of dietary nitrate are associated with *decreased* incidence of malignancy.[150−153] The conflicting data may be due to different effects from dietary inorganic nitrate (beetroot, green leafy vegetables which may confer a protective effect) versus inorganic nitrate and nitrite used as both food preservative in curing meats and as a colorant, which may be harmful. This tension is reflected in the guidance from the International Agency for Research on Cancer guidance that it is nitrate/nitrite consumed under "conditions that result in endogenous nitrosation" that is probably carcinogenic to humans, rather than dietary nitrate/nitrite in themselves.

Part 5: nitric oxide donors
Sodium nitroprusside

In current cardiovascular clinical practice, the role of SNP is largely restricted to hypertensive crises and is used less frequently than in the past. Nonetheless, SNP displays some interesting characteristics which provide further insights related to NO physiology and deserves a brief mention here. For example, in the rabbit heart, SNP exerts a negatively inotropic effect in a cGMP-mediated manner, disproportionately decreasing myocardial oxygen consumption and consequently increasing economy of cardiac muscle contraction.[153] In humans, SNP (like GTN and inorganic nitrite) demonstrates relative selectivity for conduit over resistance arteries.[61] When delivered via the intracoronary route, SNP decreases LVEDP, heart rate, and the time to end-systole (i.e., hastens the onset of diastole), while increasing the LV end-diastolic volume.[154] Indeed, such studies utilizing intracoronary SNP were the first to suggest a direct myocardial effect of NO.

Part 6: soluble guanylate cyclase
The role of soluble guanylate cyclase in the cardiovascular system

As we have described above, sGC is a key component in NO signal transduction, generating cGMP in the presence of NO stimulation. Vascular disease, e.g., hypertension, is associated with decreased expression and activity of sGC.[155−157]

Dysfunctional soluble guanylate cyclase signaling

sGC is itself under redox regulation[158] and exists in both reduced, heme-containing and oxidized, heme-free forms. Heme-free sGC is unresponsive to NO. In the setting of oxidative stress, free radicals such as peroxynitrite oxidize sGC, resulting in an increased proportion of oxidized, heme-free sGC. A concept has emerged which hypothesizes pathological "NO resistance" within cardiovascular disease states such that oxidative stress results not only in a free radical-induced decrease in NO bioavailability, but also in a peroxynitrite-induced decrease in sGC function via an increased proportion of NO-unresponsive oxidized sGC.[159]

Drugs that target soluble guanylate cyclase

Two main classes of drugs exist that target sGC directly: the sGC *stimulators* and the sGC *activators*.

Soluble guanylate cyclase stimulators

sGC stimulators (e.g., Riociguat, Vericiguat) act in both an NO-dependent and NO-independent manner. They have both the ability to directly stimulate heme-containing sGC[160,161] and also to sensitize sGC to low concentrations of NO. In the clinical setting, riociguat improves exercise tolerance in pulmonary arterial hypertension.[162,163]

Following phase II studies of Vericiguat,[164] the VIC-TORIA trial was the first large scale RCT assessing the effect of vericiguat in HF.[165] In this study, in patients with symptomatic HFrEF (NYHA II−IV, EF<45%) vericiguat decreased the composite endpoint of cardiovascular death and first hospitalization for HF. Side effects of vericiguat included symptomatic hypotension, syncope, and anemia.

In a placebo-controlled, double-blind phase IIb trial exploring the effects of vericiguat in 789 patients with HFpEF, vericiguat failed to improve the primary end points of function, symptoms, and QOL.[166]

Soluble guanylate cyclase activators

Cinaciguat is an *sGC activator* which binds to the heme pocket of heme-free sGC.[167] It has been studied in patients with acute decompensated heart failure. Initial studies suggested that an intravenous infusion of cinaciguat was associated with favorable effects on cardiac loading, but with hypotension as a frequent adverse effect.[168,169] However, the COMPASS series of randomized controlled trials were halted early due to an excess of (nonfatal) hypotension and an absence of effect of cinaciguat on either cardiac index or symptom burden (all in the context of difficulty in patient recruitment).[170]

Nitroxyl

In addition to the sGC stimulators and activators, nitroxyl has an NO-like effect on sGC, triggering cGMP-dependent signaling. Nitroxyl (HNO) is the protonated, reduced form of NO,[171,172] with vasodilator[173] and positive inotropic effects,[174] which does not develop tolerance.[175] While the positive inotropic effects of nitroxyl are sGC-independent, experimental work in mice suggests that the vasodilatory effect is mediated by sGC signaling; nitroxyl's vasodilatory effect is abolished by the sGC inhibitor 1H-[1,2,4]oxadiazolo-[4,3-a]quinoxaline-1-one (ODQ) and is absent in sGC knockout mice.[176] In humans in vivo (patients with systolic heart failure), nitroxyl decreases cardiac filling pressures, with a decrease in systemic vascular resistance and increase in cardiac output.[177]

Conclusions and future directions

In conclusion, therapeutic strategies targeted at NO signaling are of value (or potential value) in addressing arterial stiffness and abnormal pulsatile hemodynamics and associated conditions.

However, therapies for chronic pathology such as arterial stiffness, hypertension, and heart failure necessarily need to be long-term therapies. Therefore, future clinical studies focused on chronic conditions will require longer durations of treatment to be studied, reflecting the chronic nature of treatment that would be required in the relevant condition. While organic nitrates have been studied for decades, the field of inorganic nitrate/nitrite therapeutics is still in the process of progressing to large scale, long-duration randomized control trials, a step that will be necessary if these approaches are to become widely adopted in clinical practice. Following recent studies such as our Vasera study with 126 patients treated for six months,[178,179] and Sundqvist et al., with 231 patients treated for five weeks,[149] the results of several ongoing studies are awaited. These include the studies described above: NITRATE-OCT,[143] NITRATE-TOD (target organ damage and central BP/PWV in 160 patients with hypertension treated for 4 months),[132] and also NITRATE-CIN (prevention of contrast-induced nephropathy with five days' nitrate in 640 patients with acute coronary syndrome)[180] and the KNO3CK OUT HFpEF (Effect of KNO_3 Compared to KCl on Oxygen UpTake in HFpEF) in 76 patients, assessing the effects of a six-week' potassium nitrate administration on aerobic capacity.[181] This requirement for longer and larger trials is true for the other therapeutic strategies discussed in this chapter. In addition to the need for such trials, further study of the complex mechanisms relating to the biochemistry, (patho)-physiology, pharmacology, and hemodynamics are required. The figure by Vanderpool and Gladwin,[182] available free access (https://www.ahajournals.org/doi/10.1161/CIRCULATIONAHA.114.014149?url_ver=Z39.88-2003&rfr_id=ori:rid:crossref.org&rfr_dat=cr_pub%20%200pubmed), provides a summary of how the nitrate-nitrite-NO pathway influences central and peripheral hemodynamics and how this relates to potentially beneficial effects in HFpEF pathophysiology.

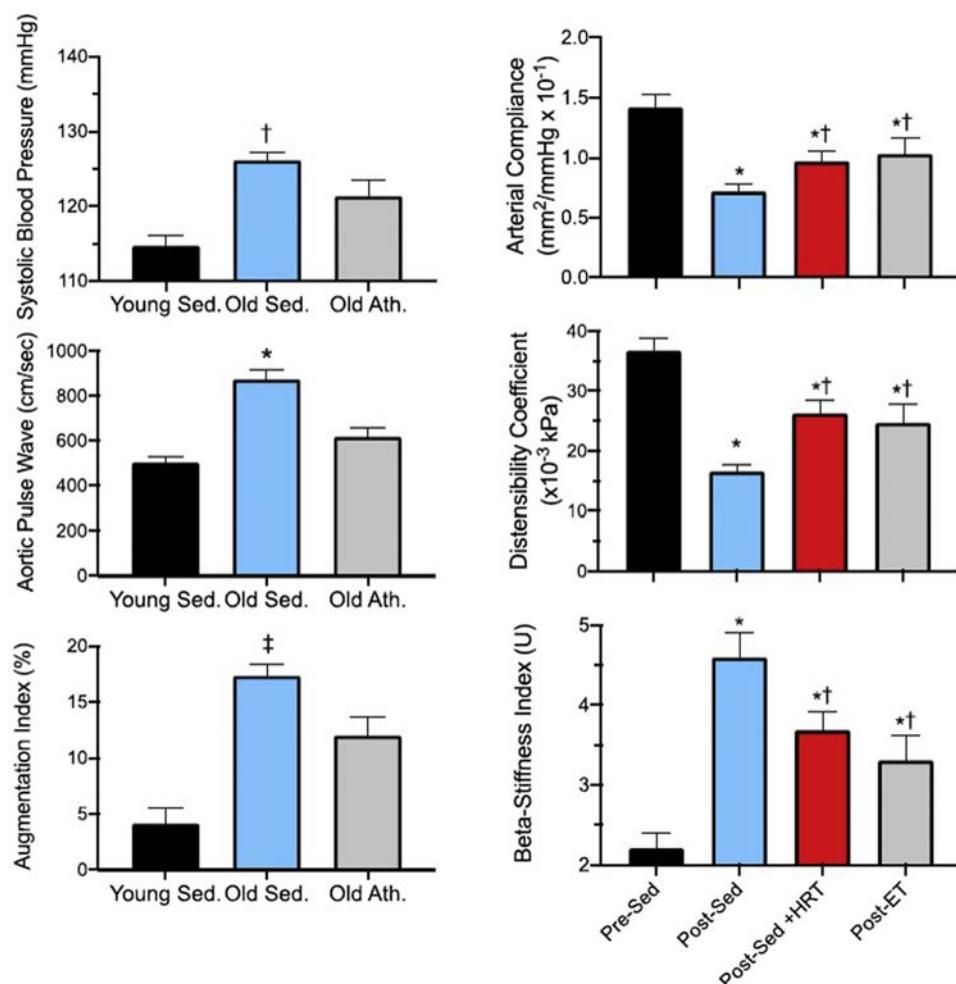
Effect of exercise training and weight loss on arterial stiffness and pulsatile hemodynamics

Gary L. Pierce[1], Kevin S. Heffernan[2] and Kevin P. Davy[3]

[1]University of Iowa, Iowa City, IA, United States; [2]Syracuse University, Syracuse, NY, United States; [3]Virginia Tech, Blacksburg, VA, United States

Introduction

The large elastic central arteries, including the aorta and common carotid arteries, stiffen with advancing age in humans even in the absence of significant cardiovascular disease (CVD) risk factor burden. Both aortic and carotid stiffness are robust predictors of future CVD morbidity and mortality independent of blood pressure and other cardiovascular risk factors.[1,2] Higher large central artery stiffness is associated with numerous pathological conditions associated with older age including isolated systolic hypertension, heart failure, orthostatic hypotension, myocardial ischemia, chronic kidney disease, cognitive impairment, and cerebral white matter lesions, the latter three conditions likely from penetration of damaging excessive pulsatile pressure into the microcirculation of these high flow target organs.[3] The rate of increase of aortic stiffness, in particular, over the lifespan can be accelerated in the presence of hypertension,[4] whereas other traditional risk factors such as dyslipidemia, smoking, and glucose appear to have a more modest or minor influence with advancing age.[5] In contrast, high levels of habitual aerobic physical activity (PA)[6,7] and cardiorespiratory fitness (CRF)[8-12] are associated with an attenuated age-related increase in central artery stiffness among middle-age/older (MA/O) adults without hypertension. However, the benefits of habitual aerobic PA and high CRF on aortic stiffness are largely absent among MA/O adults with treated and treatment-naïve hypertension,[13-17] although carotid artery stiffness appears to be more modifiable.[18] Interestingly, in contrast to habitual aerobic PA or structured aerobic exercise training, heavy volume/intensity resistance exercise training (RET) may cause increases in central artery stiffness,[19-22] whereas moderate intensity RET appears to not have adverse effects and may even be

beneficial.[23,24] Finally, obesity is associated with higher central artery stiffness and weight (body fat) loss is generally associated with reductions in central artery stiffness among MA/O adults; in this setting, the change in stiffness appears to be associated with abdominal visceral fat.[25,26] This chapter will discuss the evidence for the beneficial effects of aerobic PA/aerobic exercise training, RET, and weight gain and loss on central artery stiffness in young and MA/O adults with and without hypertension.


Effect of high cardiorespiratory fitness and habitual aerobic PA on central artery stiffness and pulsatile hemodynamics with aging

Given the strong relation between higher central artery stiffness and CVD risk[1,2] and the inverse association between higher CRF and high PA with lower CVD morbidity and mortality,[27-31] it reasons that maintaining higher CRF and levels of aerobic PA with advancing age would have a favorable effect of attenuating age-related central artery stiffening compared with lower CRF and physical inactivity. To test this hypothesis investigators have conducted cross-sectional studies of MA/O adults without hypertension who have been performing moderate-to-vigorous habitual aerobic exercise 5–6 days/week, typically "master's athletes" competing in competitive endurance events and comparing them to physically inactive, age- and sex-matched adults. Thus, these endurance-trained MA/O adults maintain a higher CRF than the physically inactive adults and in most studies demonstrate a complete or partial prevention of the age-related increase in aortic and/or carotid artery stiffness. In the first such study, Vaitkevicius

et al.[8] demonstrated that Doppler flow−acquired aortic pulse wave velocity (PWV) was significantly lower among MA/O men and women who had been engaging in vigorous endurance exercise for multiple years compared with physically inactive age-matched adults, and this was in the absence of any differences in blood pressure between groups (see Fig. 52.1). Also, aortic PWV did not differ between the endurance-trained MA/O and younger adults, consistent the idea that high CRF from chronic moderate-to-vigorous aerobic exercise, abrogated the age-related elevation in aortic stiffness among physically inactive MA/O men. Furthermore, maximal CRF, measured as the rate of oxygen consumption at maximal exercise (VO$_2$max), was inversely correlated with aortic PWV and the relation was strongest among older men >70 years of age. Thus, these data suggest that high CRF from habitual moderate/vigorous aerobic exercise in middle- to older age, or perhaps other factors associated with higher CRF (e.g., genetics, low adiposity), blunt the age-related elevation in aortic stiffness in MA/O men without hypertension.

Numerous other cross-sectional studies since have confirmed these findings related to aortic stiffness in both MA/O men and postmenopausal women who perform moderate-to-vigorous aerobic exercise.[9,11,32] Similar age- and aerobic exercise training status-cross-sectional findings in MA/O men and women have also been reported with carotid artery compliance or β-stiffness index.[10,33,34] Moreover, these beneficial alterations in central artery stiffness associated with high CRF appear to be largely independent of lower blood pressure and less CVD risk factor burden. Although these studies suggest a favorable direct effect of repeated bouts of aerobic exercise and/or high CRF on the elastic properties of the arterial wall, other lifestyle or unmeasured biological and social factors (e.g., healthy diet, low inflammation, higher socioeconomic status, etc.) in individuals with high CRF may have also contributed in part to lower aortic stiffness. Interestingly, in a study by Moreau et al.[33] physically inactive post-menopausal women on hormone replacement therapy demonstrated similar carotid artery compliance and

FIGURE 52.1 Left panel: Bar graphs of systolic blood pressure (upper), aortic pulse wave velocity (middle), and augmentation index (lower) are compared among young sedentary, old sedentary, and old athletic adults by analysis of variance. Values are mean ± SEM. A, SBP: †old sedentary different from young sedentary controls $P < .01$; B, APWV: *old sedentary controls differ from young sedentary controls and older athletes at $P < .001$; C, AGI%: ‡all groups differ at $P < .001$. Right panel: Carotid arterial compliance (top), arterial distensibility coefficient (middle), and beta-stiffness index (lower) of women in the cross-sectional study. *$P < .001$ versus Sed; †*Pre*, premenopausal; *Post*, postmenopausal; *HRT*, hormone replacement therapy; *ET*, endurance training. *Left panel: Vaitkevicius PV, Fleg JL, Engel JH, et al. Effects of age and aerobic capacity on arterial stiffness in healthy adults.* **Circulation**. *1993; 88:1456−1462 with permission. Right panel: Moreau KL, Gavin KM, Plum AE, Seals DR. Oxidative stress explains differences in large elastic artery compliance between sedentary and habitually exercising post-menopausal women.* **Menopause**. *2006; 13:951−958 with permission.*

β-stiffness index as endurance-trained postmenopausal women who were not on hormone replacement, although carotid compliance/stiffness was not back to levels of young premenopausal women (see Fig. 52.1). Given the potential adverse health effects of prolonged hormone replacement therapy on increased risk of breast cancer[35] and lack of CVD benefit in randomized, controlled trials,[36–38] habitual aerobic exercise may be a valuable alternative therapeutic strategy to improve central artery stiffness in estrogen-deficient postmenopausal women.

Because many MA/O adults cannot perform the high volume of moderate-to-vigorous aerobic exercise as endurance-trained master's athletes, it is important to determine whether daily occupational and leisure levels of PA may lower central artery stiffness among MA/O adults in the community.[6,7] In this regard, among a cohort of multiethnic older community-dwelling adults, moderate and higher volumes of PA (computed from duration, frequency, and intensity of PA) expressed as metabolic equivalents (METs) in minutes/week from the self-report Baecke PA Questionnaire, were associated with lower carotid-femoral PWV compared with no PA in models adjusted for age, sex, education, race-center, smoking status, and mean arterial pressure.[7] Indeed, those with moderate and high volume of aerobic PA demonstrated −0.30 and −0.38 m/s slower carotid-femoral PWV, respectively, compared with no PA, consistent with the idea that aortic stiffening is less prominent in more physically active MA/O adults. Interestingly, low volume of aerobic PA was not associated with a lower aortic stiffness indicating that at least a moderate volume of PA may be required to destiffen the aorta in older adults. In a subsample of the cohort who maintained a high volume of PA between study visits 1 and 3 (∼6 years), the favorable relation with carotid-femoral PWV was even larger with a reduction of −0.73 m/s. Moreover, these results were maintained after further adjustment for presence of hypertension (which was present in ∼3/4 of the cohort) but was attenuated when adjusted for prevalence of diabetes. These data suggest that persistent high volume of PA from middle age into older age has a favorable association with slower aortic stiffness progression even if hypertension is present but perhaps not diabetes.

In one of the only longitudinal studies performed to date investigating whether moderate-to-vigorous PA can alter the progression of aortic stiffness, Ahmadi-Abhari et al.[6] studied change in carotid-femoral PWV over 5 years among MA/O adults from the Whitehall II cohort consisting of >4300 participants. Using questionnaire-based estimates of PA over the previous 4 weeks and converted to METs at two visits between 4 and 6 years apart, activities were stratified into mild (<3 METS), moderate (3–5.9 METS), or vigorous (≥6 METS) PA and then expressed as weekly total PA in MET-h/week. Importantly, the authors

also collected data on sedentary time spent sitting at home (watching television, sitting at desk) or at work/commuting. They found that adults with higher baseline levels of PA (i.e., more MET-h/week) had slower carotid-femoral PWV compared with low levels PA, but that baseline total PA was not associated with change in carotid-femoral PWV over the subsequent 5-year follow-up. Interestingly, each additional hour of moderate-to-vigorous PA at baseline was associated with a −0.02 m/s smaller increase in carotid-femoral PWV compared with the average 5-year increase of +0.76 m/s, suggesting that moderate-to-vigorous PA (e.g., sports, cycling, swimming, mowing) and not mild PA (e.g., gardening, housework) was necessary to attenuate the rise in aortic stiffness from age 65 to 70 years. In the longitudinal analysis, participants who *increased* their PA over the 5-year follow-up demonstrated a smaller increase in carotid-femoral PWV compared with those who did not increase PA (+0.60 vs. +0.76 m/s, P for trend <0.001). Importantly, adults who *decreased* their PA over the 5-year follow-up had larger increases in carotid-femoral PWV compared with those who did not increase PA (+0.85 vs. +0.76 m/s, *P* for trend <.001) confirming that becoming more inactive was associated with accelerated age-related aortic stiffening. Furthermore, with each additional hour of leisure-time sitting a larger increase in carotid-femoral PWV over 5 years was observed independent of total PA. Taken together, engaging in and sustaining moderate-to-vigorous PA with advancing age possibly slows the progressive stiffening of the aorta independent of most conventional CVD risk factors, but mild levels of PA such as housework, gardening, and leisure walking may not be protective. Furthermore, reductions in PA, in particular excessive sitting, was associated with accelerated aortic stiffening over the 5 years indicating that adopting sedentary behaviors among MA/O adults should be avoided.

An important finding from these previous studies is that they suggest that low levels of PA is not sufficient to reduce aortic stiffness. However, these studies are limited by reliance on self-report of PA via questionnaires that can be less reliable and lead to misclassification of magnitude of PA, particularly quantifying light PA that tends to be unstructured activities of daily living (e.g., housework, gardening, etc.).[39] To address these limitations, PA accelerometers have been employed in some studies to better characterize the relation between volume and intensity of PA and central artery stiffness. In this regard, studies using uniaxial accelerometers confirm self-report studies that "light" PA is not sufficient to alter aortic stiffness in older men and postmenopausal women.[40,41] However, uniaxial accelerometers can underestimate light PA because horizontal movements are not detected. Therefore, in a study using triaxial accelerometers that measure movements in three dimensions, Gando et al.[42] investigated whether

higher amounts of "light" PA over 14 days was associated with lower aortic stiffness in a cross-sectional cohort of 538 healthy, nonsmoking young (age <40 years), middle-aged (age 40−59 years), and older (age ≥60 years) men and women. Importantly, they also considered the influence of CRF (from directly measured VO_2max) on whether PA alters aortic stiffness differently in individuals with high versus low CRF. They observed that time spent in "light" PA was longer, but time spent in vigorous PA was shorter, among MA/O compared with the young adults. Importantly, older adults who performed high amounts of "light" PA demonstrated slower carotid-femoral PWV compared with older adults who performed low amounts of "light" PA (8.8 vs. 9.5 m/s, $P < .05$) which remained significant after adjusting for sex and for moderate and vigorous PA, but this same effect was not found among young or middle-aged adults. However, the older adults with higher levels of "light" PA also had lower mean blood pressure (−6 mmHg) and higher CRF than the "low" PA group, but the model did not adjust for these important confounders. Thus, it is possible that disparities in blood pressure and CRF could explain the differences in carotid-femoral PWV between high and low amounts of "low" PA. Furthermore, the finding that light and moderate PA predicted carotid-femoral PWV in the older adults was driven by the relation among the unfit (i.e., low CRF) older adults because there was no relation between "light" PA and carotid-femoral PWV among the older adults with high CRF. Taken together, these data suggest that CRF may moderate the relation between PA and aortic stiffness, particularly in older adults who have low CRF. This finding has important implications because older unfit adults may more easily incorporate light PA into daily activities rather than initiate organized moderate-to-vigorous exercise training at a level sufficient to increase CRF.

Effect of aerobic exercise interventions on central artery stiffness and pulsatile hemodynamics in young and MA/O adults with and without hypertension

Effects of aerobic exercise on aortic stiffness among normotensive MA/O adults. An important question that cannot be answered by cross-sectional studies is whether an aerobic exercise training intervention initiated by previously sedentary MA/O adults without hypertension can reverse or improve (decrease) aortic and/or carotid artery stiffness. Results from intervention studies have been mixed largely because the studies differ in mode, intensity, and frequency of exercise training, consist of small sample sizes, some lack of control groups and randomization, consist of a short duration of the intervention (3−4 months) or do not adjust for changes in blood pressure.[43−47] In

addition, the results differ depending on whether aortic or carotid artery stiffness is the primary outcome.[10,18,33] For example, Hayashi et al.[43] found that 16 weeks of walking/jogging in middle-aged normotensive men reduced carotid-femoral PWV by 0.5 m/s and increased carotid artery compliance by 30%, in the absence of any changes in femoral-posterior tibial PWV and femoral artery compliance (i.e., peripheral muscular artery stiffness). However, the lack of adjustment for the 3 mmHg reduction in mean arterial pressure and no randomized, parallel-time control group makes it difficult to conclude that the observed changes were mediated by reductions in passive elastic properties of the arterial wall rather than just distending pressure (see Table 52.1). In a study of 35 middle-aged women randomly assigned to aerobic exercise, resistance exercise or a nonexercise control group for 12 weeks, Yoshizawa et al.[44] found a −0.4 m/s reduction in carotid-femoral PWV in the aerobic exercise group after 12 weeks along with a 9% increase in VO_2max, in the absence of changes in carotid-femoral PWV after resistance exercise or nonexercise time control. However, this small change in carotid-femoral PWV after aerobic exercise was not significantly more than the resistance exercise group and was not adjusted for the 3 mmHg decrease in mean arterial pressure, again suggesting that the decrease in distending pressure and not wall stiffness likely explains the results (see Table 52.1). Lastly, in a randomized, controlled trial, 48 previously inactive older adults without hypertension were randomized to 12 months of aerobic exercise or nonexercise control in combination with or without advanced-glycation end-product cross-link breaker alagebrium.[47] They reported that no change was observed in carotid-femoral PWV among the aerobic exercise alone or combination with alagebrium groups, despite a 15% increase in CRF. Although it is possible the total volume of exercise required to increase CRF in healthy older adults is less than what is required to reduce aortic stiffness, it is possible that aortic stiffness may not be modifiable in older healthy adults age >65 years. Alternatively, it is plausible that more frequent exercise than three sessions per week and/or longer than 1 year is required to induce clinically meaningful reductions in aortic stiffness in previously inactive older (>70 years of age) adults (see Table 52.1). In this regard, Shibata et al.[12] investigated this question of frequency in a cross-sectional cohort of older adults (mean age 70 years) who had performed a consistent frequency of aerobic exercise training for at least 20 years. Participants were stratified based on frequency: <2 days/week ("sedentary"), 2−3 days/week ("casual exercisers"), 4−5 days/week ("committed exercisers"), and 6−7 days/week ("Master's athletes"). They found that carotid-femoral PWV was lower in the "committed exercisers" compared with "casual exercisers" suggesting that 4−5 days/week was the minimal frequency required to

TABLE 52.1 Randomized and nonrandomized intervention studies of effects of aerobic exercise training in middle-aged and/or older nonhypertensive adults on carotid-femoral pulse wave velocity (upper panel) or carotid artery β-stiffness index (lower panel).

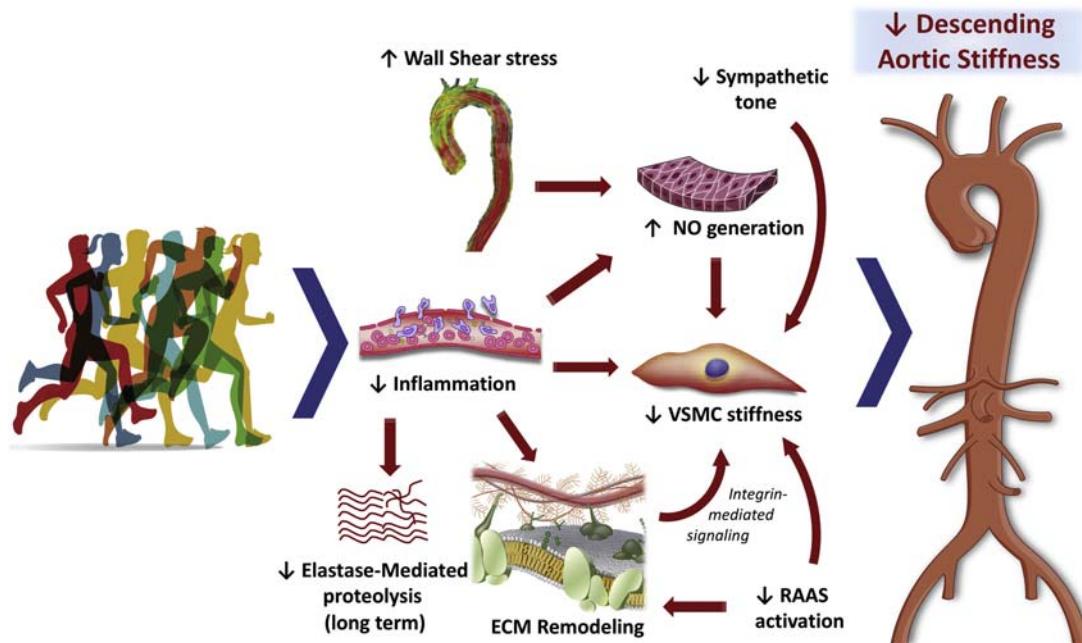
Data are mean ± SD or (95% CI); HTN, hypertension; HRmax, heart rate maximum; *CFPWV*, carotid-femoral pulse wave velocity; *HRR*, heart rate reserve; *MAP*, mean arterial pressure; *n/a*, not available; *RT*, resistance training; *VT*, ventilatory threshold.
Note: Studies were only included if casual/office MAP was reported or could be computed from systolic and diastolic pressure reported pre- versus postexercise intervention.

attain the destiffening benefits of habitual aerobic exercise and that there was no added benefit with 6−7 days per week (no difference with Master's athletes). Interestingly, carotid artery β-stiffness index was lower among the "casual exercisers" compared with the "committed exercisers" indicating that less frequent aerobic exercise (2−3 days/ week vs. 4−5 days/week) appears sufficient to attenuate carotid artery, but not aortic, stiffness among older adults.

Taken together, these studies reveal that short-term (3−4 months) aerobic exercise interventions in middle-aged adults result in small reductions in carotid-femoral PWV but may be a result of concomitant decreases in blood pressure, and longer (12 months) aerobic exercise 3 days/week among older adults without hypertension have little effect, suggesting that longer duration and/or higher frequency of exercise per week is likely required to alter age-related aortic stiffness. Importantly, a critical component of the beneficial effects of habitual aerobic exercise on aortic stiffness appear to be that a minimum threshold of 4−5 days/week is obligatory that was not achieved in the aforementioned intervention studies.

Effect of aerobic exercise on carotid artery stiffness among normotensive middle-aged/older adults. In contrast to inconsistent findings related to aortic stiffness, common carotid artery stiffness appears to be more amenable to shorter duration interventions of habitual aerobic exercise. Tanaka et al. [10] studied MA/O healthy men before and after a 3-month aerobic exercise intervention consisting of walking 4−6 days/week (see Table 52.1). Although there was no significant increase in VO$_2$max after 3 months of training, carotid artery compliance increased 25% and carotid β-stiffness index decreased 20% to levels similar with MA/O endurance athletes but not back to levels of young adults, and this occurred in the absence of any changes in CVD risk factors such as body fat%, blood pressure, and cholesterol fasting glucose. Moreau et al.[33] conducted a similar aerobic exercise intervention design that resulted in significant 20% increase in maximal treadmill test time and 6% improvement in VO$_2$max in previously physically inactive postmenopausal women who had previously taken, but not currently using, hormone replacement therapy (see Table 52.1). They reported that carotid compliance was similarly increased 40% and carotid β-stiffness was reduced 25% after 3 months of training. Importantly, carotid artery elastic properties in the postmenopausal women after the exercise intervention were reversed back to levels of young premenopausal women similar to the previous study in MA/O men. Furthermore, Sugawara et al.[40] found similar 27% reductions in carotid artery β-stiffness in postmenopausal women after both a moderate and vigorous intensity of aerobic exercise training for 12 weeks. Together, these data suggest that carotid artery stiffness is very amenable to change after moderate, short duration aerobic exercise training among both MA/O men and postmenopausal women, and that are not explained by improvements in CVD risk factors.


Potential mechanisms for selective improvements in carotid and aortic stiffness among healthy middle-aged/ older adults. The mechanisms for the observed consistent improvements in carotid artery compliance/stiffness but not aortic stiffness in healthy MA/O adults in response to aerobic exercise interventions are unknown. Higher carotid artery stiffness is modulated at least in part by reduced nitric oxide bioavailability[48] and augmented sympathetic nervous system mediated α-adrenergic vasoconstriction.[49,50] Therefore, the selective favorable adaptation in the carotid arteries versus aorta in response to aerobic exercise training may be related in part to reductions in tonic α-adrenergic tone and/or augmentation of nitric oxide−mediated endothelial function, or "functional stiffness" of the carotid arteries that is absent in the aorta. In addition, the small blood pressure−dependent changes or lack of change in aortic stiffness in intervention studies among MA/O adults may also be related to the regional differences in the relative content of elastin and VSMCs in the aorta. In this regard, the proximal ascending aorta has higher elastin content relative to the more VSMC content of the carotid arteries, therefore passive elastic "intrinsic" stiffness in the aorta may be less amenable to change than the "functional stiffness"of the carotid arteries in response to short-term aerobic exercise training among older adults. Consistent with this idea, a detailed study of young and middle-aged adults who initiated a 6-month running program to complete a marathon race demonstrated regional differences in improvements in proximal ascending aorta versus descending thoracic and abdominal aorta measured by MRI.[51] Specifically, following the running program there was no change in the distensibility of the proximal ascending aorta, whereas there was an increase in both the proximal descending and distal distending aorta that was at least partially independent of reductions in mean arterial pressure. Thus, these data suggest that more distal aortic segment, which consists of more VSMCs and less elastin in the medial wall compared with the proximal ascending aorta,[52] may be more amenable to favorable alterations in wall stiffness over the short 6-month duration than the ascending elastic aorta. Thus, similar to the common carotid artery, the more muscular descending aorta perhaps is responsive to short-term aerobic exercise training via favorable reductions in VSMC tone/stiffness from either enhanced nitric oxide−mediated endothelial function and/ or less sympathetic nerve adrenergic vasoconstrictor tone, whereas the more elastic proximal ascending aorta does not adapt in this short-term intervention.[53] One possible mechanism may be repeated bouts of augmented wall shear stress in the distal aortic segments during repeated bouts of aerobic exercise leading to regional differences in stiffness of ascending and descending aortic segments. In addition,

regions of enhanced wall shear stress are associated with reduced vascular inflammation, oxidative stress, renin—angiotensin aldosterone activation, extracellular matrix remodeling (elastin and collagen ratio), and elastin proteolysis of elastin lamellae (see Fig. 52.2).[53]

Finally, rodent models provide some insight into the mechanisms by which habitual aerobic exercise potentially modifies age-related aortic or carotid stiffness in older humans.[54,55] Indeed, late-life initiated voluntary wheel running in old mice for 10 weeks ($\sim$1–3 km per day) results in decreases in collagen-1, advanced glycation end-products, oxidative stress, TGF-β, and calcification in the absence of alterations in medial elastin in aorta or carotid arteries.[54,55] However, it should be noted that these late-life initiated, short-term exercise interventions in older mice demonstrate more robust reductions in aortic PWV than in normotensive older humans.[54–56] Thus, the structural and elastic properties of the older mouse aorta appear much more amenable to late-life aerobic exercise; therefore, extrapolating cellular mechanisms in aorta from rodents to humans should be done with caution.

Effect of aerobic exercise interventions on aortic and carotid stiffness among MA/O adults with hypertension. The presence of hypertension is not only associated with higher aortic stiffness (matched for age and blood pressure)[57] but also with an accelerated *rate* of increase in aortic stiffness with advancing age even after adjusting for antihypertensive medications.[4] However, elevated aortic stiffness may precede the development of hypertension suggesting a bidirectional relation between central artery stiffness and hypertension.[58,59] In this regard, it reasons that initiating habitual aerobic exercise among MA/O adults with hypertension may result in reductions in blood pressure and subsequently central artery stiffness, or conversely, exercise may lead to decreases in central artery stiffness and then subsequently blood pressure. Although the direction of this cause and effect pathway is difficult to dissect, intervention studies that have investigated the effects of aerobic exercise training on aortic or carotid stiffness among MA/O adults with treatment-naïve or treated hypertension have largely been ineffective with a few exceptions (see Table 52.2). The earliest study to test this

FIGURE 52.2 Exercise increases aortic blood flow and wall shear stress (WSS), which is normally greater in the descending aorta and can be preferentially affected by lower-extremity exercise (such as running). WSS in turn enhances endothelial nitric oxide (NO) generation, which decreases vascular smooth muscle cell (VSMC) tone/stiffness. Reductions in sympathetic nervous system and renin—angiotensin—aldosterone system (RAAS) activation, which have been reported with exercise training, could also affect VSMC tone/stiffness. Given the greater content of VSMCs in distal aortic segments, VSMC stiffness is more likely to affect descending versus ascending aortic wall stiffness. Aerobic exercise also appears to reduce systemic inflammation, although it is unclear to what extent this is independent of changes in adiposity. Reduced inflammation may have downstream effects on oxidative stress, extracellular matrix composition, and elastase-mediated proteolysis; however, reduced elastin degradation is unlikely to explain changes over 6 months. Changes in other components of the extracellular matrix (ECM) may also affect VSMC stiffness through integrin—cytoskeletal interactions. However, the key molecular mediators of the exercise-related effect on large artery stiffness remain to be identified and represent an important area for future research. *Chirinos JA. The run against arterial aging. J Am Coll Cardiol. 2020 Jan 7;75:72–75. with permission.*

hypothesis, Ferrier et al.[14] randomized 10 MA/O adults with treatment-naïve stage 1 systolic hypertension to 8 weeks of moderate intensity cycling exercise and then crossed-over to 8 weeks of sedentary activity. As expected, the group with stage I hypertension had significantly higher BP, carotid-femoral PWV, aortic characteristic impedance and lower systemic arterial compliance at baseline compared with age-matched control adults without hypertension. Although cycling exercise training resulted in a 13% in VO_2max, there was no change in any of the expressions of central artery stiffness suggesting that elastic properties of the central arteries are resistant to improvement in older adults with hypertension. Seals et al.[13] randomized 35 healthy postmenopausal women with treatment-naïve pre- or stage 1 systolic hypertension to either 3 months of moderate intensity walking exercise, or moderate dietary sodium restriction (~1200 mg/day sodium reduction). Although the exercise group exhibited a significant increase in maximal treadmill time/work consistent with a physiological training effect, they found no change in carotid-femoral PWV or 24-h ambulatory systolic BP after 3 months of aerobic exercise. In contrast, 3 months of sodium restriction resulted in a significant decrease in carotid-femoral PWV and carotid augmentation index that was associated with significant decreases in casual and 24-h ambulatory systolic BP. Thus, these data indicate that moderate sodium restriction has a more powerful influence on lowering aortic stiffness and wave reflection than 3 months of habitual aerobic exercise among postmenopausal women with untreated hypertension (see Table 52.2). Similarly, Stewart et al.[15] randomized MA/O adults with treatment-naïve stage 1 systolic or diastolic hypertension 6 months of either combined aerobic or resistance training or usual care control. Despite a small reduction in diastolic blood pressure and 16% increase in VO_2max in the exercise group compared with controls, there was no significant change in Doppler flow−acquired aortic PWV after 6 months (see Table 52.2).

In contrast to the aforementioned negative studies, Collier et al.[60] reported that carotid-femoral PWV was reduced ~1 m/s after 4 weeks of aerobic exercise but increased ~1.7 m/s after 4 weeks of resistance training group in a randomized study of middle-aged adults with treatment-naïve pre- or stage 1 hypertension despite both aerobic exercise and resistance training groups demonstrating a 3−4 mmHg reduction in mean arterial pressure (see Table 52.2). Although the mechanisms for the divergent results in aortic stiffness in this study are unclear, it may have been related to differences in sympathetic nerve activity activation to the heart and α-adrenergic tone of central elastic and muscular arteries, because heart rate was reduced in the aerobic exercise group and increased in the resistance exercise group and sympathetic nerve activity is known to modulate central elastic artery tone in addition to

heart rate.[49] Lastly, Fantin et al.[45] studied 21 older women (~1/2 of whom were treated for hypertension) before and after a 6 month walking exercise program 2 times/week. They reported a −0.75 m/s reduction in carotid-femoral PWV that remained significant after adjusting for changes in mean arterial pressure. Interestingly, much of the change was driven by the subset of women with hypertension (n = 11) because they exhibited a larger decrease in carotid-femoral PWV (−1.29 m/s) than the normotensive women (−0.40 m/s). However, given the small sample with poorly controlled hypertension (systolic BP = 156 mmHg), lack of a randomized control group or information related to the timing of antihypertensive medication dosing, the overall effects of aerobic exercise program are difficult to interpret (see Table 52.2). Nonetheless, the preponderance of the evidence of the current prospective, randomized intervention studies suggest that habitual aerobic exercise training in the form of walking/jogging or cycling initiated in MA/O adults with treated or treatment-naïve hypertension has small or no beneficial effects on reducing aortic stiffness.

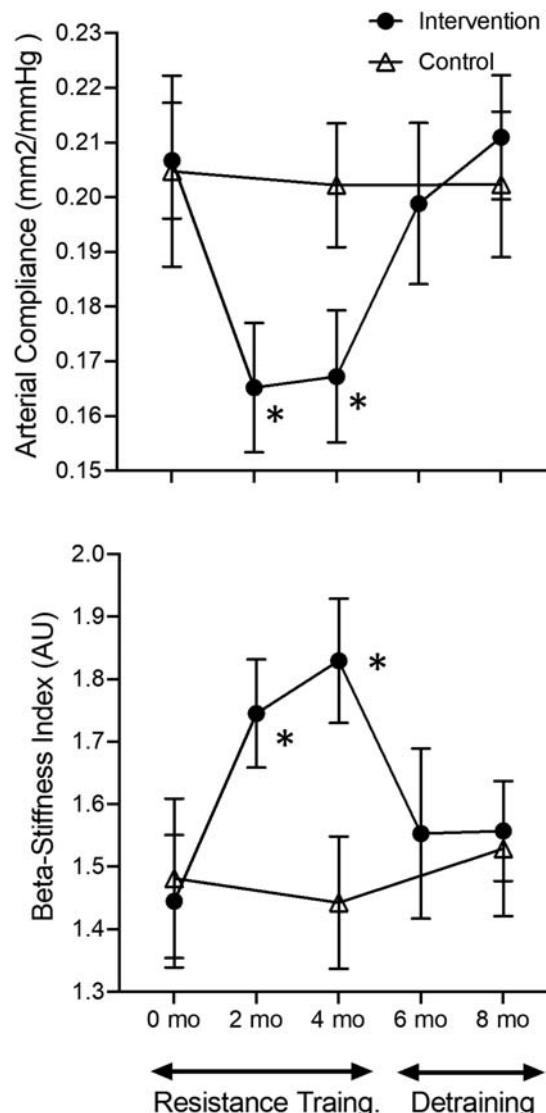
CRF and aortic stiffness in MA/O adults with hypertension. As noted, these intervention studies often result in small or no changes in CRF suggesting that perhaps a greater exercise stimulus is necessary to raise VO_2max to a greater extent to modify aortic stiffness. Contrary to this hypothesis, in a cross-sectional study, Kraft et al.[16] found that aortic PWV, measured by MRI of the descending aorta, did not differ between "high fit" and "low fit" middle-aged adults with hypertension but "high fit" adults without hypertension demonstrated the expected lower aortic PWV compared with "low fit" adults. In accordance, aortic PWV was correlated with VO_2max only among the middle-aged adults without hypertension and not those with hypertension; and this was true for both younger (<50 years) or older participants suggesting that CRF does not modulate aortic stiffness with hypertension present. Moreover, those treated with antihypertensive medications exhibited the expected lower systolic and diastolic blood pressure than the treatment-naïve group, but the groups did not differ in aortic PWV indicating that current antihypertensive drugs that lower blood pressure do not necessarily modify the elastic wall properties of the aorta.

Non−weight-bearing exercise (swimming) and central artery stiffness among MA/O adults with hypertension. Although most of the exercise intervention studies employing continuous exercise protocols in MA/O adults with hypertension have employed typical walking or cycling exercise interventions, they also have reported exclusively on aortic stiffness. Other modalities popular with MA/O adults such as swimming have not been studied extensively nor have many focused on local carotid artery stiffness, compliance, or distensibility. In this regard, Nualnim et al.[18] randomly assigned 43 healthy MA/O

adults with prehypertension or untreated stage 1 hypertension to 12 weeks of swimming exercise or control. The swimming exercise group exhibited an impressive 9 mmHg reduction in casual and 24-h ambulatory systolic blood pressure with a concomitant 21% increase in carotid artery compliance in the absence of any changes in carotid AIx. Interestingly, these changes occurred in the absence of any changes in VO$_2$max, body weight/fat, or other CVD risk factors and the increase in carotid compliance was not correlated with the reduction in blood pressure. Thus, 12 weeks of habitual swimming exercise appears to result in clinically meaningful reductions in blood pressure and improvements in carotid artery stiffness in previously inactive MA/O adults with untreated stage 1 hypertension (see Table 52.2). Although it remains unknown if swimming exercise reduces aortic stiffness, given the low impact and non−weight-bearing advantages of swimming, this exercise might be a feasible option for MA/O adults with hypertension to destiffen central arteries who have orthopedic or mobility issues that limit performing weight-bearing exercise.

Effect of resistance exercise training on large central artery stiffness and central pulsatile hemodynamics

Engaging in habitual RET (also known as strength training) confers numerous systemic health effects beyond those afforded by aerobic/endurance exercise alone. In addition to favorable effects on musculoskeletal health (i.e., bone health, muscle mass, muscular strength), RET has favorable effects on metabolism, insulin sensitivity, inflammation, and overall cardiovascular health.[61] Numerous metaanalyses now support the idea that dynamic RET (when performed as recommended by the American College of Sports Medicine for general muscular fitness—operationally defined as 2−3 days/week, 8−15 repetitions for major muscle groups performed at a moderate-to-vigorous intensity or 60%−70% of 1RM) favorably lowers blood pressure.[62,63] Reductions in blood pressure are comparable to that seen with traditional aerobic/endurance exercise with most studies noting ∼4 mmHg reductions in systolic and diastolic blood pressures in adults with hypertension and prehypertension and reductions of ∼3 mmHg in normotensive adults.[64] At a population level, this modest level of blood pressure reduction translates to decreases in coronary artery disease risk by 5%−9%, stroke risk by 8%−14%, and all-cause mortality risk by 4%.[64] As such, several professional medical societies such as the American College of Sports Medicine and the American Heart Association recommend RET for cardiovascular health promotion.[65−67] Despite the favorable effect of habitual RET on measures of CVD risk, controversy still remains regarding the effects of this exercise modality on

vascular health, because some studies have reported that heavy volume/intensity RET may cause increases in carotid artery and aortic stiffness.[19−21] Therefore, this section will explore the effect of habitual RET on large central artery stiffness and central pulsatile hemodynamics. There are now 50+ studies on this very topic with several systematic reviews and metaanalyses.[68] This section will attempt to offer a thematic overview of seminal studies, key findings that have advanced this area of research, commentary on potential implications of findings, mechanisms, and future directions.


RET and large central artery stiffness. Among the first to explore the effect of habitual RET on large central artery stiffness and pulsatile hemodynamics, Bertovic et al.[21] performed an expansive vascular and hemodynamic assessment on 19 strength-trained men, comparing them with age-matched controls (mean 26 years of age). All participants were healthy and nonsmokers and strength-trained adults were not concomitantly performing aerobic exercise and were not using anabolic agents. Both groups enjoyed a moderately high level of CRF (above average—good) as evidenced by a VO$_2$max of ∼41−44 mL/kg/min. Overall, the authors found that the strength athletes had higher brachial and carotid pulse pressure coupled with lower systemic arterial compliance, higher input and characteristic impedance, and higher aortic β-stiffness and elastic modulus. Aortic geometry was similar between groups as well as carotid-femoral PWV, wave reflection magnitude, relative left ventricular mass, and left ventricular function (i.e., fractional shortening, E/A ratio, and deceleration time). Thus, the habitual strength-trained individuals had greater pulsatile blood pressure that was likely a result of greater proximal aortic stiffness and impedance that was not revealed by carotid-femoral PWV. Authors concluded that the group differences in proximal aortic stiffness were likely of structural origin, alluding to the possibility that chronic elevations in central pulsatile load may cause proximal aortic remodeling and changes in vessel wall composition with increases in smooth muscle and collagen at the expense of elastin. Interestingly, the differences in afterload did not equate to alterations in relative left ventricular mass or function. In summary, this seminal study incorporating numerous measures of central artery stiffness and pulsatile hemodynamics obtained from pressure-flow measures and wave separation analyses raised a provocative question—what are the clinical implications of such large artery adaptations with regard to CVD risk? Twenty years later, the answer to this question posed by Bertovic is still unclear.

In 2003, Miyachi et al.[19] extended the work by Bertovic by studying both young and middle-aged habitually resistance-trained and untrained men (n = 62 total) and incorporated a several measures of large central artery stiffness. Overall, there were no differences in common carotid artery compliance between younger sedentary and

resistance-trained adults. But compared to middle-aged sedentary controls, middle-aged resistance-trained individuals had lower carotid compliance and higher carotid augmentation index. Interestingly, middle-aged resistance-trained individuals also had higher carotid intima-medial thickness (IMT) and left ventricular mass and there were associations between carotid compliance with IMT and a left ventricular hypertrophy index (a ratio of left ventricular wall thickness to left ventricular internal end-diastolic diameter). Miyachi and colleagues reiterated that the clinical significance of the greater age-associated decline in large artery compliance in RET athletes was unclear, in light of the fact that other studies reported that habitually strength-trained adults do not have higher carotid-femoral PWV.[69,70] Indeed, additional studies confirmed RET-trained adults may have increased proximal aortic stiffness[71] and carotid stiffness,[72] findings that have also been extended specifically to women.[73]

Although cross-sectional studies are informative, they are limited because they do not allow for testing of direct exposure to the stimulus. In this regard, Miyachi et al.[20] followed up with the first randomized intervention study to examine the effect of RET on large central artery stiffness in young and middle-aged men (n = 28) (see Fig. 52.3). Fourteen previously untrained men underwent 4 months of RET (3 days per week). After the intervention, there were significant reductions in carotid artery compliance and parenthetically significant increases in carotid β-stiffness in the absence of changes in carotid augmentation index. Making these findings even more compelling, after a 4-month detraining epoch (i.e., removal of the resistance exercise stimulus), carotid artery compliance and stiffness returned completely back to baseline values. There were also significant increases in left ventricular mass following RET and changes in carotid compliance were strongly associated with changes in left ventricular mass. The authors highlighted that their findings supported those of previous cross-sectional studies. However, the authors also stressed that the volume, frequency, and intensity used in their intervention study was greater than the recommended dosage for general health and muscular fitness and questioned whether such an approach would be appropriate for older and clinical high-risk populations. Thus, the clinical relevance of these findings remained to be determined.

This pivotal study generated considerable conversation and debate and instigated several immediate follow-up investigations. How could a mode of exercise with numerous health benefits possibly be detrimental to large central artery buffering reserve and thus cardiovascular function? Over the next few years, additional studies were conducted. A few supported that RET increased large central artery stiffness,[22] while others emerged noting no negative effect on large central artery stiffness.[23,24,74,75] Over the past 15 years, well over 20 studies have been done on this topic.

Results from well-done meta-analyses with stringent but slightly variable inclusion criteria have concluded the following (presented in chronological order):

1. Higher volume/intensity RET may increase large central artery stiffness in younger individuals with lower baseline stiffness values but may not affect large central artery stiffness in MA/O individuals with higher baseline stiffness (derived from 8 RCTs including 193 participants).[76]
2. RET has no effect on large central artery stiffness (14 studies involving 278 participants) in healthy adults with/without obesity/overweight and prehypertension.[77]

3. RET has no effect on large central artery stiffness in adults with CVD (2 studies involving 27 participants).[78]
4. RET has no effect on large central artery stiffness in adults at risk for CVD (13 RCTs including 651 participants with established CVD risk factors).[79]
5. RET has no effect (favorable or detrimental) on large central artery stiffness in healthy adults (10 studies involving 310 participants).[80]
6. RET has no effect on large artery stiffness in adults with hypertension (2 studies involving 28 participants).[81]

In summary, there is a growing body of evidence that contradicts earlier findings of negative effects of RET on large central artery stiffness. Most contemporary studies note that RET does not increase large central artery stiffness (and may even reduce arterial stiffness in select studies) in a variety of healthy and clinical populations, regardless of participant characteristics, training volume, or load.[82–86] The reason for the marked vascular heterogeneity in intraindividual responses to RET is unknown and will be addressed below.

RET and central pulsatile hemodynamics. As alluded to in the previous section, initial cross-sectional studies suggested that habitually resistance exercise-trained adults may have increased central pulsatile hemodynamics. Bertovic et al. noted increased carotid wave reflection magnitude (determined from wave separation analysis) and Miyachi et al. noted increased carotid augmentation index in those engaging in habitual RET.[19,21] In general, far fewer cross-sectional studies have explored central pulsatile hemodynamics in strength-trained individuals with aforementioned studies noting differences with RET status and others noting no differences.[70]

For intervention studies, the literature is as similarly inconsistent for the effects of RET on central hemodynamic pulsatility as it is for the effects of RET on large central artery stiffness. Miyachi et al. were among the first to explore the effect of RET on global wave reflections and noted no change in carotid augmentation index following RET in men. Soon after, Cortez–Cooper et al.[22] found that higher intensity RET increased carotid augmentation index in women. Subsequent studies revealed no effect of RET on augmentation index either when assessed from direct carotid pressure waveforms or from synthesized aortic pressure waveforms using radial tonometry and a generalized transfer function.[74,87] Accordingly, recent metaanalyses have concluded that RET has no effect on augmentation index.[77,78]

Relying exclusively in augmentation index to infer change in wave reflections is not without limitation. For example, RET may result in slight decreases in heart rate and there is a well-known inverse association between heart rate and augmentation index.[88] Many studies report augmentation index as a contrived measure standardized to an arbitrary heart rate of 75 bpm (based on an early cardiac pacing study performed in a small sample).[88] Augmentation index also suffers from what Dr. Gary Mitchell refers to as the "tip of the iceberg" effect.[89] That is, based on the timing of wave reflections and the magnitude of the forward wave, the augmented pressure used to calculate augmentation index may not be truly reflective of wave reflection magnitude. As such, the American Heart Association encourages use of wave separation analyses wherever possible when assessing central pulsatile load and wave reflection magnitude.[90] In this regard, Heffernan et al.[91] explored the effect of a 12-week randomized RET intervention on measures of central pulsatile hemodynamics in a small group of adults with prehypertension and hypertension (n = 11). Compared with a nonexercise control group (n = 10), RET resulted in significant reductions in both brachial and aortic blood pressure in the absence of changes in augmentation index derived from pulse contour analysis or backward pressure wave amplitude derived from wave separation analysis. Interestingly, there were reductions in forward pressure wave amplitude and reservoir wave pressure. Taken together within the context of the broader literature, RET does not appear to have a detrimental effect on central pulsatile hemodynamics including wave reflection.

Potential reasons for discrepancies in the literature on RET and arterial stiffness. RET imposes a very different stress on the cardiovascular system than aerobic exercise and can be conceptualized as a series of static muscular contractions performed dynamically. Although aerobic exercise induces a volume load on the heart and vasculature, resistance exercise imposes a pressure load. Classic findings from MacDougall et al.[92] found that dual-leg leg press performed at near maximal effort can result in brachial pressures exceeding 320/250 mmHg (with some individuals recording systolic and diastolic pressures >400/300 mmHg). This pressor response with subsequent effects on large central artery stiffness can vary with amount of muscle mass activated, lower- versus upper-body exercise, static/isometric versus concentric versus eccentric muscle contraction, timing and composition of last meal, intrinsic muscular strength, and breathing technique/incorporation of a Valsalva maneuver.[93–95] Moreover, the arterial response may also vary based on phase of menstrual cycle and use of hormonal contraceptives in women, although this is not a universal finding.[96,97] Thus, the "same" exercise stimulus can be quite different across individuals.

There is also physiological plausibility for interindividual biological variability in response to RET. Unlike animal studies showing that aerobic exercise can affect arterial structural wall components and stiffness,[54,98] there are no such data to support that RET results in passive (structural) changes to vessel wall material properties (i.e., changes in extracellular matrix components elastin or

collagen composition). Changes in large central artery stiffness with RET may be related in part to active (functional) changes in VSMC tone.[99,100] In animal models, up to half of total aortic wall stiffness is attributable to active stiffness of the VSMCs.[101] Dynamic changes in VSMC plasticity may explain disparate reports in the literature regarding the effects of RET on large central artery stiffness. Excessive increases in blood pressure coupled with Valsalva maneuver exposes the aorta to unique cycles of both static and cyclic stretch and strain. Habitual exposure of the aorta to such hemodynamic perturbations may alter VSMC stiffness as a means of regulating cellular mechanotransduction (i.e., VSMC-ECM interactions redistributing tensile forces across elastin and collagen) as a defense mechanism to "normalize" wall stress and prevent dissection or aneurysm.[101,102] Indeed, the "tensegrity hypothesis" implies that cell stiffness must increase in proportion with the level of the tensile stress.[101]

Select studies note increased sympathetic modulation and elevations in norepinephrine concentrations following RET[103]; an effect that may be attenuated with habituation.[104] Acute hypertension from resistance exercise may possibly cause endothelial damage[105−107] and result in increases in the vasoconstrictor molecule endothelin-1.[108,109] Large central arteries have their own blood supply (vasa vasorum) and neural supply (nervi vasorum). Thus, vasoactive peptide-mediated and/or neurally mediated VSMC contraction and cross-bridge cycling could alter vessel wall (Young's) elastic modulus and increase PWV. Changes in VSMC stiffness may contribute to overall changes in large central artery stiffness with RET. In support of this possibility, studies that note elevations in central artery stiffness with habitual RET also note associations with increases in IMT,[19] and studies in vivo support that changes in VSMC tone can manifest as changes in vessel wall IMT.[110]

Implications and future directions for RET and central artery stiffness. In general, habitually strength-trained individuals do not experience increased incidence of hypertensive CVD and enjoy a typical lifespan (although not the extended lifespan conferred by aerobic/endurance training).[111,112] Structure and functionality of target organs susceptible to hemodynamic pulsatility stemming from age- or disease-associated increases in large central artery stiffness remain preserved with RET. When surveying risk for CVD, one can look to the outcome of the lifestyle behavior (i.e., strength) rather than the behavior itself (i.e., self-reported strength training). In this regard, Dankel et al. [113] demonstrated that strength is a more important predictor of all-cause mortality than self-reported strength training. Indeed, muscular strength is cardioprotective[114] and is inversely associated with aortic stiffness and carotid IMT and extramedia thickness.[115−117] Muscular strength is also associated with lower risk of developing obesity, metabolic syndrome, incident hypertension, sudden cardiac death, and CVD mortality.[114,118−126] Parenthetically, lower muscular strength is a significant predictor of the development of heart failure

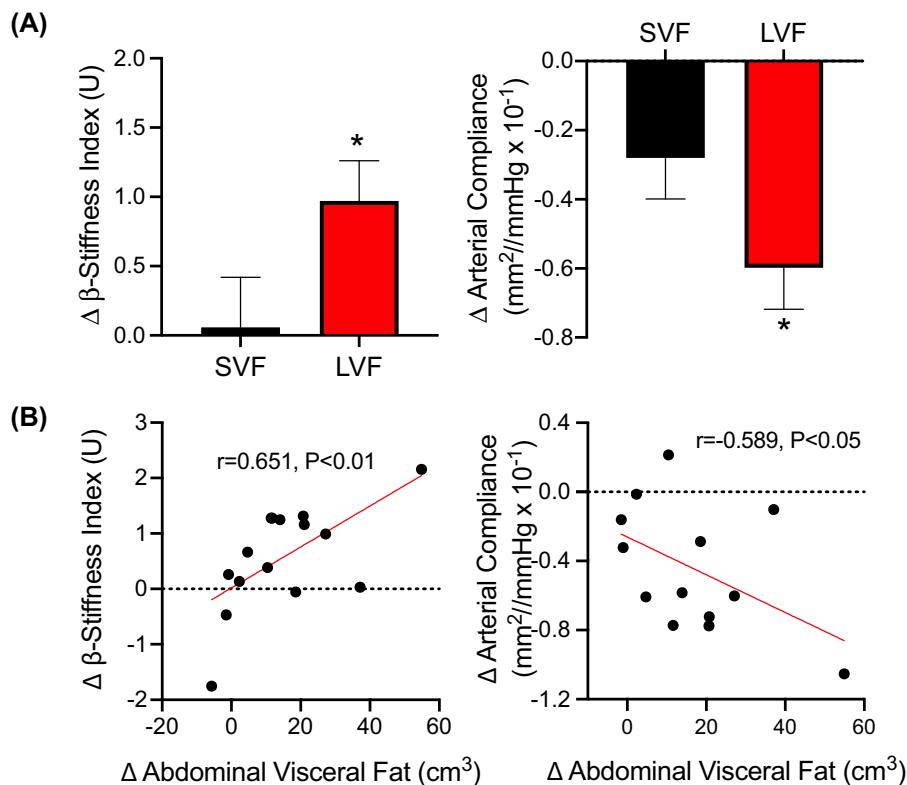
and CVD events later in life, independently of CRF.[127−129] Moreover, muscle mass is inversely associated with large central artery stiffness and augmentation index.[130−132] Thus, the "by-products" of strength training do not appear to be associated with detrimental cardiovascular adaptations.

In summary, it appears that RET has negligible adverse effects on large central artery stiffness and hemodynamic pulsatility in most individuals. However, large interindividual variation and observations of increases in large central artery stiffness and hemodynamic pulsatility in select studies cannot and should not be dismissed. Whether such changes confer increased risk (or resiliency) for CVD will need to be scrutinized. Attention to the effects of aging, sex, and ethnic/racial influence on variation will be required. Finally, given that RET is suggested as one part of a general exercise prescription that includes aerobic exercise and flexibility, both of which may reduce large central artery stiffness,[81,133,134] studies that explore the intersection of these exercise modalities for optimal vascular health will be needed.

Effect of obesity, weight loss, and weight gain on central arterial stiffness

Obesity is a major public health problem and the United States has the highest prevalence among high-income countries. The prevalence of obesity reached 42.4% and severe obesity 9.2% in 2017−18.[135] Current projections indicate 50% of the population will have obesity and one in four Americans will have severe obesity by 2030.[136] In addition, obesity is associated with a poor quality of life[137] and reduced life expectancy.[138] In turn, obesity-related illnesses place a significant burden on the economy by increasing rates of health care usage and associated costs.[139] Obesity increases the risk of CVD[140] and the increasing prevalence is contributing the rising adverse CVD mortality trends.[141] Importantly, the association of obesity with CVD is complex and highly dependent on the accumulation of visceral and ectopic fat.[142] The accumulation of visceral fat is associated with a clustering of CVD risk factors termed the "metabolic syndrome" and an increased risk of major adverse CVD outcomes even in the absence of general obesity.[143]

One mechanism by which obesity, particularly visceral obesity, increases CVD risk is by increasing stiffness of central elastic arteries. In this regard, the results of numerous studies suggest that obesity accelerates age-related central artery stiffening[144−148]; the relation between adiposity and arterial stiffness is evident throughout the nonobese range. Importantly, long duration obesity does not appear to be necessary to increase large central artery stiffening as the relation between obesity and arterial stiffness is evident even in young children.[149] Moreover, the location of the excess adiposity, such as visceral versus subcutaneous depots, also contributes to the degree of central artery stiffness among individuals with obesity.

Interindividual variability in central arterial stiffness among individuals of similar age. There is considerable variability in large central artery stiffening among individuals of similar age such that some display levels of central arterial stiffness resembling that of much older individuals and vice versa.[8] Indeed, aortic PWV can vary as much as fourfold among individuals of similar age. Visceral fat accumulation may be an important source of interindividual variability in central artery stiffness where it is more closely associated with visceral fat than other measures of total or regional adiposity.[144−148] The latter may be related, at least in part, to the clustering of cardiometabolic risk factors as well as the accumulation of certain ectopic fat depots (e.g., perivascular fat) in individuals with visceral obesity.[142] As such, the accumulation of body fat, particularly in the abdominal visceral depot, accelerates age-related central arterial stiffening and this can manifest across the age range.[150]


Visceral obesity, the metabolic syndrome, and arterial stiffness. MA/O adults are disproportionately affected by visceral obesity and the metabolic syndrome[151] that amplifies the increasing risk of CVD associated with advancing age. The presence of visceral obesity in MA/O adults is associated with higher levels of central artery stiffness compared with those with general obesity.[147] The closer association of central artery stiffness with visceral adiposity in MA/O adults may be related, at least in part, to

their correspondingly higher levels of blood pressure, circulating glucose, triglycerides, and lower HDL cholesterol,[152] i.e., the risk factors that comprise the metabolic syndrome. Furthermore, these metabolic syndrome risk factors that interact synergistically to increase in central artery stiffness among older adults.[152] In this regard, central artery stiffness can be considered a time-integrated index of an individual's risk factor exposure over time. Indeed, a healthy weight and favorable levels of CVD risk factors are consistent correlates of low carotid-femoral PWV (i.e., healthy vascular aging) in large cohorts.[153,154]

Weight change and central artery stiffness. Weight gain and loss are associated with increases and decreases in central artery stiffness, respectively.[155] Consistent with these observations, experimental weight gain over a period of 6−8 weeks resulted in increases in carotid artery β-stiffness index in young men with healthy weight at baseline. Importantly, the degree of carotid artery stiffening (and reduction in compliance) appears to be determined, in part, by the accumulation of visceral fat (see Fig. 52.4).[25]

Therapeutic weight loss can improve many CVD risk factors and, in many cases, can occur with a modest amount (5%−10%) of weight loss.[156] Weight loss via caloric restriction also reduces aortic stiffness in individuals with obesity across a wide age range.[157] A systematic review and meta-analysis concluded that weight loss achieved by caloric restriction with or without concomitant exercise,

FIGURE 52.4 (A) Change in carotid β-stiffness index (left panel) and change in carotid artery compliance (right panel) following weight gain in subjects with smaller and larger increases in visceral fat. (B) Relation between changes in abdominal visceral fat and changes in carotid β-stiffness left panel) and changes in arterial compliance (right panel) in pooled sample. *Orr JS, Gentile CL, Davy BM and Davy KP. Large artery stiffening with weight gain in humans: role of visceral fat accumulation.* **Hypertension**. *2008; 51:1519−1524 with permission.*

pharmacological intervention, or bariatric surgery was effective in reducing central artery stiffness.[157] Interestingly, caloric restriction plus exercise does not appear to reduce central artery stiffness more than caloric restriction alone.[158] In general, greater weight loss was associated with larger reductions in central artery stiffness irrespective of the mode of weight loss. The duration of weight loss does not clearly impact central artery stiffness as long as weight loss is maintained. Reductions in blood pressure with weight loss tend to be correlated with the decreases in aortic or carotid-femoral PWV, but this finding is inconsistent. Indeed, reductions in central artery stiffness with calorie restriction-induced weight loss have been observed in MA/O adults but the reductions were not correlated with reductions in mean arterial pressure.[26] Interestingly, these decreases in central artery stiffness (both carotid artery β-stiffness index and aortic PWV) were correlated with reductions in abdominal visceral fat. Furthermore, obstructive sleep apnea (OSA), a common comorbidity of severe obesity, is associated with elevated CVD risk, and short-term treatment of OSA with continuous positive airway pressure (CPAP) is associated with reductions in carotid-femoral PWV.[159,160] In contrast, in obese adults with OSA, randomization to 24 weeks of CPAP, caloric-restriction weight loss or combination weight loss plus CPAP (resulting in 6% weight loss), did not result in any change in carotid-femoral PWV in the combination weight loss plus CPAP group despite a significant reduction in central systolic and mean arterial blood pressure. Thus, future studies will need to test whether greater weight loss with longer duration CPAP is likely necessary to lower central artery stiffness among adults with severe obesity and OSA.

Mechanisms and consequences of age- and obesity-related large central artery stiffness. The mechanisms responsible for obesity-related central artery stiffening have not been completely elucidated but elastin fragmentation, collagen cross-linking, and the accumulation of advanced glycation end-products have all been implicated.[161] The mechanisms that contribute to central arterial stiffness with aging have been considered to occur earlier with obesity consistent with the idea of acceleration of age-related arterial stiffening.[162] As with aging, changes in the expression, organization, and function of the structural proteins comprising the medial layer contribute to stiffening of the aorta and carotid arteries in obesity. Remodeling of the extracellular matrix in the medial layer of the aorta and carotid arteries is characterized by collagen cross-linking, elastin fragmentation and degradation, and the formation of advanced glycation end-products.[163] Inflammation and oxidative stress appear to be primary underlying mechanisms.[164] Perivascular adipose tissue, an important source of inflammatory cytokines and oxidative stress, has been implicated in obesity-related arterial

stiffening.[164] Impaired endothelium-dependent dilation and elevated sympathetic nerve activity can contribute to both acute and chronic central artery stiffening by increasing VSMC tone.[49,165] In addition, reduced nitric oxide bioavailability, resulting from inflammation and oxidative stress, and transglutaminase-2 activity promote collagen cross-linking.[162] Activation of the sympathetic and renin—angiotensin systems also exacerbate extracellular matrix remodeling, endothelial dysfunction, vasoconstrictor tone, and carotid artery wall thickening.[164,166]

The association between obesity and hypertension is well documented.[167] Although activation of the renin—angiotensin and sympathetic nervous systems as well as a rightward shift in the renal pressure—natriuresis relation have been well described, the role of arterial stiffening in obesity-associated hypertension has not been systematically studied in humans. However, arterial stiffening occurs rapidly and precedes the increase in systolic blood pressure in mice fed a high-fat, high-sugar diet.[162] Carotid-femoral PWV increased after 1 month, whereas systolic blood pressure did not increase until after 6 months of consuming the high-fat, high-sugar diet. The latter was accompanied by increases in the aortic expression of the inflammatory cytokines tumor necrosis factor-α, monocyte chemoattractant protein-1, and macrophage inflammatory protein-1α and markers of oxidative stress. Impaired endothelium-dependent dilation of aortic rings isolated from the mice was evident after 2 months of consuming the diet and associated with an increase in transglutaminase-2 in aortic lysates. Weight loss reduced central artery stiffness and systolic blood pressure within 2 months of return mice to their chow diet. Markers of inflammation and oxidative stress, endothelium-dependent dilation, and transglutaminase-2 were also reduced following weight loss. Taken together with the observations that central artery stiffness is present in normotensive adults with obesity[26] and precedes the development of hypertension in MA/O humans,[58,59,168] these findings suggest large central artery stiffening may contribute to and precede the development of obesity hypertension.

Obesity-related central artery stiffening is associated with excessive pulsatile arterial load which lead to left ventricular hypertrophy and impaired diastolic function.[3] Indeed, in adolescents and young adults with obesity, augmented aortic forward wave pressure amplitude was a strong predictor of higher left ventricular mass index.[169] In turn, impaired diastolic function in obesity may contribute to the link between large central artery stiffening and HFpEF.[170] However, the impact of visceral obesity on the hemodynamic consequences of large central artery stiffening is not well studied. Nevertheless, the increase in pulsatile pressure with increasing adiposity would increase the transmission of excess pulsatile into the vulnerable microcirculations of the brain and kidney.[3] The increased

exposure of capillaries to pulsatile pressure and flow results in remodeling of the microcirculation to reduce cerebrovascular reactivity and repeated episodes of ischemia and tissue damage. In the brain, this microvascular damage and remodeling may be a link between arterial stiffness, white matter lesions, and cognitive impairment in obesity.[171] Similarly, increased flow pulsatility penetration in the kidney may damage small arteries and glomeruli in the renal cortex and impair function. The impact of large central artery stiffening and its hemodynamic consequence on target organ damage in obesity requires further study.

In summary, total and abdominal visceral adiposity contribute importantly to interindividual variability in age-related central artery stiffness. Weight maintenance is an important strategy for avoiding accelerated arterial stiffening and its adverse clinical sequelae. Future studies are needed to better understand the mechanisms and consequences of accelerated central artery stiffening associated with excess total and visceral adiposity so that targeted therapeutics can be developed. In addition, more information is needed on how to effectively implement and utilize measurements of central artery stiffness in clinical practice to improve risk stratification.

Chapter 53

Dietary salt and arterial stiffness

David G. Edwards and William B. Farquhar

Department of Kinesiology and Applied Physiology, University of Delaware, Newark, DE, United States

Introduction

Dietary sodium restriction is widely considered an important lifestyle modification to control blood pressure (BP) in individuals with hypertension with many organizations worldwide providing information on the benefits of reducing sodium in the diet. Although the increase in sodium consumption in our diets occurred ∼5000−10,000 years ago with the advent of agriculture and farming, the deleterious effects of salt were appreciated long ago by Chinese physician Huang Ti Nei Ching Su Wein in ∼1700 BC who said "therefore if large amounts of salt are taken, the pulse will stiffen and harden" (translated by Wan Ping AD 762).[1]

The average salt intake in most countries is approximately 8−10 g/day (or 3200−4000 mg/day of sodium)[2,3] far higher than our paleolithic ancestors who consumed less than 1g of salt per day.[4] Salt intake is an important factor in the development of hypertension.[5,6] Salt sensitivity of BP, an increase in BP going from a low salt to a high salt diet, is more common in older adults and African Americans.[7,8] Both normotensive and hypertensive individuals can be salt sensitive.[9] Salt sensitivity predicts future hypertension in normotensive individuals[10] and is associated with increased mortality in both normotensive and hypertensive adults.[9,10] While there is a large proportion of the population for which high salt intake will raise BP, the majority of young individuals are normotensive and salt resistant. There is evidence that high salt is detrimental beyond its effect on BP. For example, in the Trials of Hypertension, the long-term risk of cardiovascular events was reduced by dietary sodium reduction with very small changes in BP (SBP-1.7 mmHg, DBP-0.8 mmHg).[11] We will review the effects of dietary salt on BP as well as its BP independent effects in this chapter with an overall focus on arterial stiffness.

Salt vs. Sodium

The major source of sodium in the diet is salt (~90%).

The terms salt and sodium are often used interchangeably.

Salt comprises 40% sodium and 60% chloride based on mass.

1 gram of sodium = 2.5 grams of salt

Dietary salt and blood pressure

There is a large body of literature demonstrating a causal relation between dietary salt intake and BP (see He et al. 2019[12] for recent extensive review). Epidemiological studies have demonstrated a direct association between salt intake and BP.[13−15] Randomized trials of salt reduction have also demonstrated a decline in BP that varied depending on the group studied.[12] In studies where participants were assigned differing levels of salt intake, a dose response relation between salt intake and BP has been shown.[16,17] A number of meta-analyses have been conducted that demonstrate a reduction in BP with salt restriction.[18−21]

Increased dietary salt intake likely leads to increased BP through multiple mechanisms. In the setting of reduced renal function such as aging, an increase in BP may be required to excrete excess sodium in the setting of suppressed RAAS on high salt.[22] Extracellular fluid volume expansion also occurs to buffer the increase in plasma sodium that occurs with changes in salt intake.[23]

Additionally, there are direct BP independent effects of high salt on the vasculature, heart, and inflammation that can affect BP and over the long term will contribute to an increase in BP. The BP independent effects of salt will be discussed more fully below.

Dietary salt and cardiovascular outcomes

Although the focus of this chapter is on the role that dietary salt may have in arterial stiffness and related measures, it is important to briefly consider the association of dietary salt with cardiovascular outcomes. The appropriate level of salt consumption remains a highly debated area; however, there is plenty of evidence that high salt consumption is associated with poor cardiovascular outcomes, with global estimates of over 1.5 million cardiovascular deaths linked to increased BP due to high salt intake.[24] There is a large body of literature on the association between BP, an important cardiovascular disease risk factor, and dietary salt from both observational studies and randomized controlled trials.[25] Many studies have demonstrated a linear relation between dietary sodium intake and poor outcomes, whereas others have identified a "J" or "U"-shaped relation between dietary sodium intake and risk, suggesting an optimal range of sodium intake in the 3000−5000 mg/day range (for example, see References 26,27).

In the Trials of Hypertension Prevention (TOHP) phase 1 and 2, sodium intake was assessed using multiple 24-hour urinary sodium (24hU-Na$^+$) samples, and prehypertensive individuals were followed for 15 years in TOHP 1 and 10 years in TOHP 2. A 17% increase in CV events was found for every 1000 mg/day increase in sodium, and there was no evidence of a J-shaped association.[28] The findings were confirmed in an analysis of postsurveillance TOHP.[29] TOHP is considered representative of the general US population as the median 24hU-Na$^+$ excretion was 3630 mg/day. Similar results have been found in patients with kidney disease. Mills et al.[30] investigated the association between the average of three urinary 24hU-Na$^+$ excretion collections and clinical CV events in data from the Chronic Renal Insufficiency Cohort (CRIC) Study. There was a significant linear association between Na$^+$ excretion and CV events, and the cumulative incidence of CV events were greater in the highest quartile of sodium excretion compared with the lowest quartile.

As discussed elsewhere,[31,32] errors in study design and statistical power have contributed to some of the controversy generated by studies finding a "J" or "U"-shaped relation between sodium consumption and CV outcomes. One reason for the discrepancies in results is likely due to the estimation of dietary sodium intake.[12,33] A variety of methods have been used to estimate sodium intake including food frequency questionnaires, 24-h recall, and spot or overnight urine collection; however, a single 24hU-Na$^+$ may not be satisfactory as data have suggested that at least four collections are needed to reliably quantify dietary sodium intake.[34] Recently, He and colleagues[33] examined TOHP follow up data. They compared sodium intake assessed by measured 24hU-Na$^+$ excretion (average of three to seven measures during the trial) and estimations using three different formulas, Kawasaki,[35] Tanaka,[36] and INTERSALT.[37] Over a median follow-up of 24 years, they found that all estimated values of sodium intake were systematically biased with an overestimation at lower values and underestimation at high values. There was a significant linear relation between measured sodium intake and mortality, whereas there appeared to be a "J" or "U"-shaped relation with mortality for all the formula estimates of sodium intake. These findings highlight the importance of measuring sodium intake accurately when assessing the relation with outcomes and that commonly used estimates are inappropriate to use when assessing the relation between sodium intake and mortality. The biased estimates of sodium intake help explain the J-shaped findings in some cohort studies that are inconsistent with efforts to reduce sodium intake.[12,33]

Blood pressure independent effects of dietary salt

An awareness of the detrimental effects of dietary salt apart from raising BP is not new,[38−40] and studies of the independent effects of salt have increased over last 10 years. Dietary salt has been demonstrated to adversely affect a number of organs and systems independent of BP (Fig. 53.1). While some of these effects may initially occur independent of BP, they may lead to increased salt sensitivity and/or hypertension later in life. We briefly described some of these effects below with a greater focus on the adverse vascular effects and in particular on endothelial function.

Heart

As described above, high dietary salt is associated with poor CV outcomes. Dietary salt has been shown to have deleterious effects on the heart, and in some studies, these effects have been demonstrated to be independent of BP. Urinary sodium excretion has been shown to be independently associated with left ventricular (LV) mass in both normotensive and hypertensive individuals.[41−45] The risk of heart failure is increased in overweight individuals in the highest quartile of sodium intake compared to the lowest quartile even after correction for a number of variables

FIGURE 53.1 Blood pressure independent effects of dietary sodium. There is evidence that dietary salt has deleterious effects independent of, or in addition to, its effects on blood pressure.

including and BP.[46] In a three-year study of patients who underwent treatment of essential hypertension, 24-h urinary sodium was positively related with LV mass at baseline and at the end of the study, independent of age, sex, and systolic BP.[47] The change in LV mass in response to treatment was positively correlated with the changes in systolic BP, urinary sodium, and plasma aldosterone concentration.[47] The association with aldosterone suggests a potential role for a lack of aldosterone suppression on a high salt diet on LV mass.[47]

Inflammation

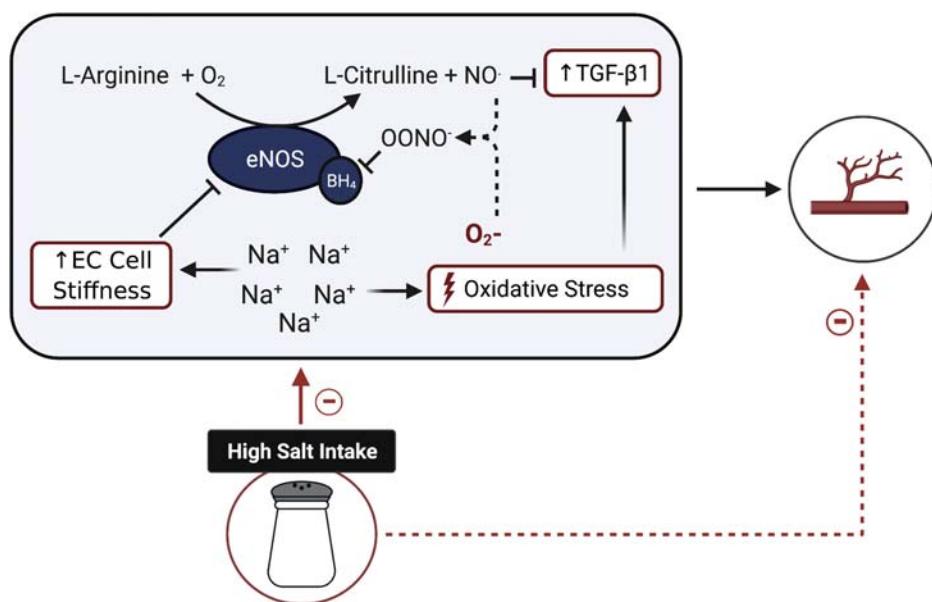
Excess dietary salt may result in end organ damage, including vascular damage/dysfunction, as a result of inflammation and an exacerbated immune response. High salt diets can promote inflammation through macrophages and proinflammatory T cells.[48–50] T cells exposed to high sodium polarize into proinflammatory TH17 cells producing inflammatory cytokines such as IL-17 that worsen experimental autoimmune disease and promote hypertension.[49,51] Isolevuglandins (IsoLGs), highly reactive lipid oxidation products,[52] have been shown to accumulate in dendritic cells (DCs), promoting T cell activation and hypertension.[53] Sodium stimulates IsoLG-adduct formation in DCs which leads to activation of NADPH oxidase and superoxide formation.[54] High salt intake is also associated with changes in the gut microbiome, which may partly mediate the inflammatory effects of high salt. High salt reduces *Lactobacillus* spp. (a loss of which has been shown to be proinflammatory) and increases TH17 cells.[55,56] A high-salt diet resulted in increased intestinal and vascular inflammation and the formation of IsoLG-adducts in DCs and IL-17A production by T cells in mice.[57] Taken together there is evidence for an inflammatory effect of high salt. The role of changes in the microbiome as a mediator of the immune response to high salt requires additional studies in humans.

Arteries

Endothelial function

An increase in basal NO synthesis occurs as a result of short term high salt intake that helps facilitate sodium excretion.[58,59] However, high salt reduces stimulated NO synthesis which has implications for local blood flow regulation.[39] A reduction in NO synthesis may also play a role in dietary salt-induced increases in arterial stiffness, as discussed below. There are a number of studies in rodents demonstrating that high salt leads to an impairment in endothelial function without a change in BP. Studies in spontaneously hypertensive rats, normotensive Wistar-Kyoto rats, and Sprague–Dawley rats, have demonstrated adverse vascular effects of high salt on the vasculature prior to an increase in BP.[60–62] Further, aortic and mesenteric endothelial function is impaired in Sprague–Dawley rats by high salt without an increase BP.[63–65] Deleterious effects of high salt on the vasculature have also been observed in mice.[66]

Studies in humans have reported findings consistent with the studies in rodents. A high salt diet reduced the vasoconstrictor response to L-NMMA, an eNOS inhibitor, in healthy, normotensive men, indicating lower basal NO synthesis induced by high salt intake.[67] One way to investigate the effects of salt intake on endothelial function independent of BP is to manipulate salt intake in normotensive individuals who are salt resistant. Seven days of a high salt diet impaired brachial artery flow mediated dilation (FMD), a measure of conduit artery endothelial function, in salt resistant individuals (defined as 24-h MAP $\leq$ 5 mmHg between low and high salt diets).[68] A high salt also reduced cutaneous vasodilation in response to local heating, a measure of microvascular function[69] which has been shown to be largely mediated by endothelial-derived NO.[70,71] These studies provide evidence that high salt impairs endothelial function in normotensive adults

without altering BP. Interestingly, the effects of high salt on FMD appear to be similar in salt resistant and salt sensitive individuals.[72] There may be sex differences in the vascular response to alterations in salt intake, with women potentially less sensitive to the vascular effects of high salt[73,74]; however, more work is needed in this area.


High salt has also been shown to have an adverse effect on vascular function in groups that are at a higher risk for cardiovascular disease. A low salt diet has been shown to improve brachial artery FMD and reduce BP compared to a usual diet in overweight and obese normotensive adults.[75] Because BP was also reduced, it is unclear if there are direct beneficial effects of salt reduction on endothelial function in this study. However, a modest reduction of dietary salt of 3 g/day improved FMD in normotensive overweight and obese individuals independent of BP.[76] There is also evidence that a lower salt diet has beneficial effects on endothelial function in middle age and older adults with elevated BP. Middle-aged and older adults with elevated systolic BP who habitually consumed a low salt diet had a higher FMD compared to a group that consumed higher salt.[77] Dietary sodium restriction in a similar group of middle aged and older adults with moderately elevated systolic BP (130–159 mmHg) improved both brachial artery FMD and the forearm blood flow response to acetylcholine.[78] Although there was a reduction in systolic BP (~12 mmHg), the improvement in endothelial function was still evident after correcting for BP providing evidence that the improvement in endothelial function as a result of sodium restriction occurred independent from the reduction in BP.

Potential mechanisms of reduced endothelial function by high salt (Fig. 53.2)

Oxidative stress

A well-known mechanism of reduced bioavailability of NO occurs through the rapid reaction of NO with elevated levels of superoxide, reducing NO bioavailability, and resulting in the formation of peroxynitrite ($OONO^-$). An increase in oxidative stress as a result of excess superoxide production appears to be a primary mechanism by which high dietary salt impairs endothelial function. Studies in rodents provide evidence that higher levels of superoxide occur as a result of a high salt diet in resistance arteries[63–65] and venules.[63,64] A high salt diet also decreases stimulated NO production as a result of increased reactive oxygen species (ROS).[64,65] Human studies provide additional evidence to support a role for oxidative stress as a mechanism for salt-induced declines in endothelial function as a result of high salt intake.[69,78,79] Local infusion of ascorbic acid reversed the salt-induced impairment in cutaneous vasodilation in normotensive salt resistant subjects.[69] Systemic infusion of ascorbic acid improved both conduit and resistance vessel endothelial function in middle age and older adults with elevated SBP on a normal salt diet, but had no effect following dietary salt restriction.[78] ROS may also result in the oxidation of tetrahydrobiopterin (BH_4), a critical cofactor for eNOS, leading to reduced NO synthesis and generation of superoxide by eNOS. A high salt diet reduced BH_4 levels as a result of BH_4 oxidation in rodents,[80] and oral supplementation of BH_4 improved both conduit and resistance vessel function in middle age and

FIGURE 53.2 Proposed mechanisms by which high salt intake leads to impaired endothelial function/reduced nitric oxide (NO) bioavailability. NO bioavailability is decreased due to reaction of NO with O_2 to form peroxynitrite ($OONO^-$); oxidation of endothelial nitric oxide synthase (eNOS) cofactor tetrahydrobiopterin reducing NO synthesis; and an increase in endothelial cell stiffness which leads to decreased synthesis of NO. Oxidative stress also leads to increased TGF-β which is no longer suppressed by NO.

older adults on a normal salt diet but had no effect following dietary salt restriction.[78]

As described above, superoxide appears to be the primary ROS mediating the impairment of endothelial function on a high salt diet.[65,66] There is evidence that superoxide production is increased on a high salt diet by NADPH oxidase,[64,65] xanthine oxidase,[64,65] and eNOS[66] via uncoupling. The role of NADPH oxidase has received the most attention. The NADPH oxidase inhibitor, apocynin, has been shown to restore vasodilation in mesenteric arteries of rats on a high salt diet.[65] Additionally, NADPH oxidase protein expression has been shown to be increased in the femoral arteries of rats on a high salt diet.[81] Studies in humans also support a role for NADPH oxidase in salt induced increases in ROS. Apocynin ameliorated the salt-induced declines in cutaneous vasodilation in response to both local heating[79] and acetylcholine[82] in normotensive adults. Taken together, it appears that NADPH oxidase is a likely source of ROS as a result of high dietary salt intake.

Oxidative stress as a result of high salt may be related to reduced endogenous antioxidant capacity in addition to increased ROS production. Superoxide dismutase (SOD) is important for scavenging superoxide and is located in both the cytosol (SOD-1) and the mitochondria (SOD-2). High salt diets have been shown to reduce SOD expression and activity.[83,84] Inhibition of SOD-1 in rats on a high salt diet resulted in an attenuated increase in superoxide suggesting that SOD activity or expression was already reduced on the high salt diet.[84] Circulating SOD activity has been found to be greater on a low salt compared to normal salt diet in middle aged and older adults with elevated BP;[78] however, additional investigations are needed to understand the role of reduced SOD in dietary salt-induced declines in vascular function. The mechanism by which salt reduces SOD may be due, at least in part, to the suppression of angiotensin II (Ang II) that occurs as a result of a high salt diet. Sub-pressor doses of Ang II prevented oxidative stress and endothelial dysfunction when given to rodents on a high salt diet.[85,86]

Endothelial cell stiffening

A high salt diet may directly affect endothelial function by altering endothelial cell stiffness. Cell culture studies have shown that increased extracellular sodium stiffens endothelial cells and reduces NO synthesis.[87] This effect is dependent on the presence of physiologic levels of aldosterone and can be inhibited by amiloride which inhibits the epithelial sodium channel (ENaC).[87] The abundance of ENaC present on endothelial cells is increased by elevated extracellular sodium levels.[88] Additionally, excess sodium damages the endothelial glycocalyx (eGC)[89] which allows for increased sodium to enter endothelial cells via ENaC and stiffens cells.[88,90] Damage to the eGC also allows for

monocyte adhesion and inflammation further reducing endothelial function.[91] High extracellular sodium levels disturb the eGC, increase ENaC abundance, stiffen endothelial cells, and reduce NO synthesis;[90] however, the role the eGC and ENac channels on vessel function during high salt in humans has yet to be investigated.

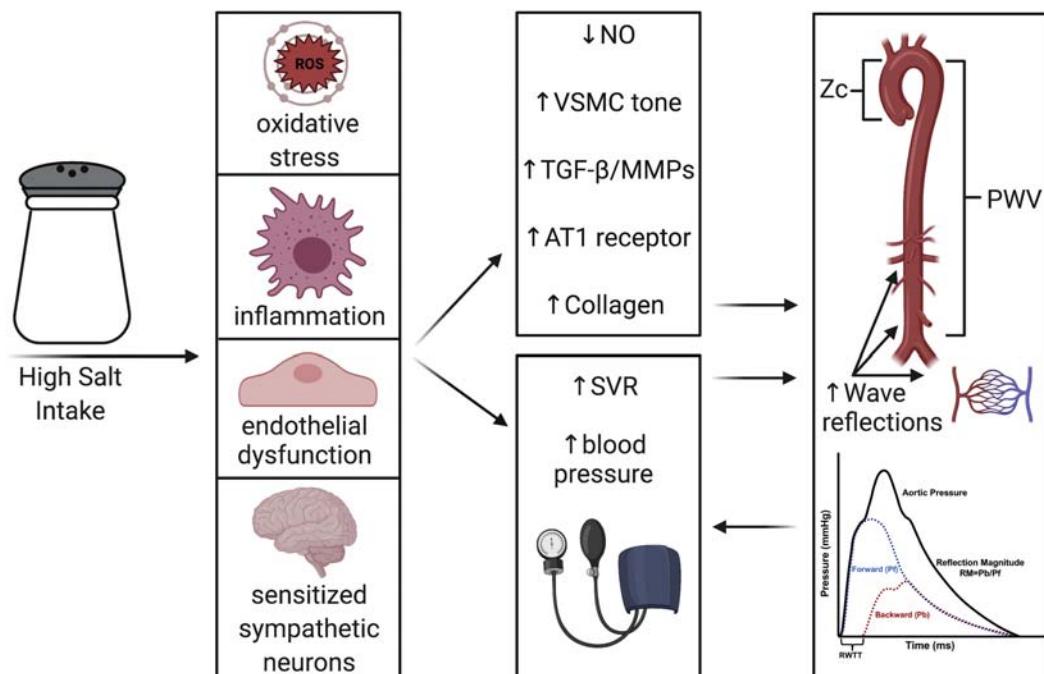
Brain and sympathetic outflow

Cerebrovascular function also appears to be adversely affected by high dietary salt. Epidemiologic evidence suggests that high salt intake is associated with increased mortality from stroke,[92,93] and data from rodent studies have shown that a high salt diet impairs cerebrovascular function via oxidative stress and inflammation.[94,95] Further, autoregulation, the ability of the brain to maintain blood flow in the face of changing BP, has also been shown to be impaired in rodents on a high salt diet.[96] In addition to adverse effects on cerebrovascular function, there is evidence that high salt may increase sympathetic responsiveness. Sympathetic nerve activity is enhanced by elevations in plasma and cerebrospinal fluid sodium concentration leading to an increase in BP in rodents.[97,98] One human study has demonstrated that a high salt diet increases cerebrospinal fluid sodium concentration[99] and BP in hypertensives. Also, there is evidence that a high salt diet alters cardiovagal baroreflex sensitivity in healthy adults.[100] Additional work is needed in humans including clinical populations to fully elucidate the role of sympathetic activation in the deleterious effects of high salt.

Dietary salt and arterial stiffness

An increase in arterial stiffness leads to an increase in LV systolic load, which contributes to ventricular remodeling, and an increase in pulsatile flow into the microcirculation, which contributes to target organ damage.[101] Data from the Framingham Heart Study indicate that aortic stiffness, as assessed by carotid-femoral PWV (cfPWV), was associated with BP progression and incident hypertension.[102] This study and others suggest arterial stiffness is a cause of hypertension rather than a consequence.[102–105] Measures of arterial stiffness have been shown to be predictors of cardiovascular events in clinical populations[106–109] as well as in apparently healthy subjects.[110] Understanding the role of dietary salt as a mediator of arterial stiffness is of clinical importance. It is appreciated that there is a BP-independent effect of dietary salt on arterial stiffness[40] and recent evidence suggests an increase in arterial stiffness partly mediates the effect of a high salt diet on systolic BP.[111]

As described above, a high salt impairs vascular function through a number of mechanisms, and these same mechanisms may affect the structure and function of large elastic arteries in addition to more distal conduit and

resistance vessels. Several studies using rodent models of hypertension have shown that arterial structure is altered by high dietary salt, and that this effect is independent of BP.[40] For example, increased salt intake in spontaneously hypertensive rats resulted in thickening of the aortic media and excess collagen content during the initial time period when BP was not altered.[112,113]


Lower dietary salt intake has been shown to reduce arterial stiffness in hypertensive humans.[114,115] A cross-sectional study in Chinese populations provided the first human data to support a BP independent effect of salt on arterial stiffness.[116] In a study of two groups of Chinese populations, aortic arch-femoral PWV was lower in a rural population that consumed lower salt compared to an urban population that consumed higher salt when the groups were compared at similar BPs.[116] Additional evidence for BP independent effect of salt on arterial stiffness comes from a study that compared a group of normotensive adults who had followed a low salt diet and a control group who consumed a regular diet. When each of the groups were divided into three age groups (2–19, 29–44, 45–66 years), there was a marked increase in aortic arch-femoral PWV across age in the control group but not in the low salt group, and aortic arch-femoral PWV was greater in the middle age and older control groups despite no differences in BP between diets.[117]

A number of studies have examined the effect of reduced dietary salt or dietary salt loading on arterial stiffness. These studies have generally been smaller, and the results have been inconsistent.[76,115,118–121] The duration of interventions has varied from one to six weeks, and those that found improvements in arterial stiffness typically found that BP changed as well. Recently, D'Elia and colleagues[122] performed a systematic review and meta-analysis of the randomized controlled trials of dietary salt and arterial stiffness as assessed by cfPWV. In their pooled analysis, lower salt intake was associated with a significantly lower cfPWV compared to higher salt conditions. Pooled analysis of the effect of salt restriction on BP from the same studies showed a significant reduction in both systolic and diastolic BP on low salt compared to the higher salt condition. Interestingly, further analysis revealed that the changes in BP did not influence the relation between low salt and cfPWV suggesting a BP independent effect of salt on arterial stiffness.

Potential mechanisms of increased arterial stiffness by high salt

Arterial stiffness appears to be increased as a result of high salt due to both BP dependent and independent mechanisms (Fig. 53.3). In many studies of dietary salt, there is a concomitant change in BP along with changes in stiffness; however, the recent meta-analysis by D'Elia and colleagues suggests that the benefits of low salt on arterial stiffness go beyond any benefit from lowering BP.[122] The BP independent mechanisms by which dietary salt increases arterial stiffness are likely due to a combined effect of oxidative stress, inflammation, and endothelial dysfunction. Elevated sympathetic activation as a result of sensitized sympathetic neurons may also play a role. A reduction in NO and an

FIGURE 53.3 Proposed mechanisms by which high salt intake leads to an increase in arterial stiffness. High salt induces oxidative stress, inflammation, endothelial dysfunction, and sensitization of sympathetic neurons that lead to an increase in arterial stiffness through both BP dependent and independent mechanisms. In addition to increased arterial stiffness, alterations in wave reflection amplitude and timing further increase the load on the heart.

increase in vascular smooth muscle cell (VSMC) tone can result in a functional increase in stiffness. Endothelial dysfunction and a reduced bioavailability of NO occur in the setting of high salt diet primarily as a result of oxidative stress and endothelial cell stiffening as described above. Inhibition of NO synthesis has been shown to increase arterial stiffness[123,124] thus salt-induced endothelial dysfunction likely plays a role in increasing arterial stiffness. Endothelial cell stiffness may also contribute to overall vascular stiffness however this requires investigation.

Sympathetic neurons are sensitized by high salt as discussed above, and there is a growing appreciation that the sympathetic nervous system can modulate arterial stiffness.[125] In rodent models, α-adrenergic stimulation results in aortic VSMC proliferation and hypertrophy,[126] and sympathetic innervation increases VSMC contractile protein expression.[127] In humans resting muscle sympathetic nerve activity (MSNA) was positively correlated with cfPWV.[128] Studies utilizing lower body negative pressure to stimulate an increase in sympathetic activity without a change in MAP have found that an acute increase in MSNA is associated with an acute increase in arterial stiffness.[128–130] Dietary salt induced alterations in sympathetic activity may influence arterial stiffness, through both BP dependent and independent mechanisms; however, this remains to be determined. Acute increases in plasma osmolality have been shown to increase plasma norepinephrine levels and MSNA;[131,132] however, the long-term effects of a high salt diet on sympathetic activity have yet to be elucidated.

Inflammation as a result of high salt can increase cytokines and ROS contributing to the decrease in NO bioavailability[133,134] and increase in arterial stiffness. Inflammation and oxidative stress can also result in structural changes to the arterial wall by altering the equilibrium between matrix metalloproteinases (MMPs) and their inhibitors, tissue inhibitors of metalloproteinases.[135] Acute inflammation induced by *Salmonella typhi* vaccination increased MMP-9 levels in association with PWV.[136] MMP 2 and 9 correlated positively with aortic PWV in hypertensive individuals.[137] Dietary sodium intake has been shown to be related to carotid structure and stiffness as well as MMP-9 in hypertension.[138] Interestingly, the associations between dietary salt intake and carotid diameter and stiffness were independent of BP.

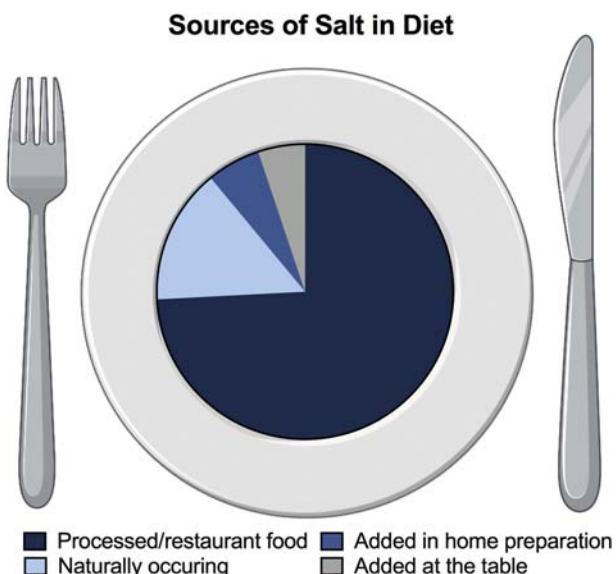
Structural alterations to the vasculature as a result of high salt are also due to the profibrotic effects of transforming growth factor-β (TGF-β).[139] Endothelial production of TGF-β has been shown to increase following 7 days of a high salt diet without an increase in BP.[59] Although basal levels of NO production may be increased short-term by high salt, via TGF-β signaling, and may help reduce the negative effect of TGF-β initially,[58,59] endothelial function and stimulated NO synthesis are reduced by high salt intake as described above. Therefore, high salt diets may lead to increased arterial stiffness due to increased and unrestrained TGF-β as a result of high salt induced reductions in NO bioavailability. This effect may be even greater in clinical populations with already impaired endothelial function.[140] Local RAAS signaling may also be an important determinant of collagen content as a result of high salt. Angiotensin II receptor type 1 (AT1) has been shown to be increased by high salt and AT1 blockade during high salt attenuates aortic collagen accumulation.[141]

Dietary salt and pulsatile load

A consequence of increased arterial stiffness and altered timing and magnitude of wave reflection as a result of high salt can lead to an increase in pulsatile load on the LV. High salt diets impair endothelial function which has the potential to alter wave reflection from the periphery and along with increased arterial stiffness increase the pulsatile load on the heart.[142] High dietary salt consumption may increase pulsatile load on the heart, which can lead to LV hypertrophy and ultimately heart failure.[143,144] Wave reflections can arrive back at the heart while the LV is still ejecting blood in mid-to-late systole.[145] Wave reflections thus increase the systolic workload of the LV and can profoundly impact the LV loading sequence. Data from animal studies indicate that late systolic loading from wave reflections promotes LV hypertrophy in rats and diastolic dysfunction in dogs.[146,147] In humans, reflected wave amplitude is independently associated with LV hypertrophy in the general population.[144] Additionally, the reduction of wave reflection has been shown to correlate with regression of LV mass independent of BP reduction.[148] Wave reflections/late systolic load have also been associated with diastolic dysfunction in humans, and to the presence of heart failure with preserved ejection fraction.[149–151] Further, the magnitude of wave reflection strongly predicted the new onset of heart failure in the Multiethnic Study of Atherosclerosis participants who were free from CV disease.[143] Therefore, the relation between a high salt diet and poor cardiovascular outcomes may be, at least in part, due to increased pulsatile load on the LV.

Cross-sectional data provides evidence that dietary salt increases measures of pulsatile load. In a study of black adults from Johannesburg, urinary sodium excretion was related to pulsatile load (forward wave amplitude, pressure augmentation, and augmentation index) and these relations persisted after controlling for MAP.[152] In hypertensive adults, 24-h urinary sodium excretion was independently associated with central pulse pressure (PP), augmented pressure, augmentation index, and PP amplification.[153] Once again, these findings occurred while controlling for MAP, suggesting the effects of sodium are independent of steady state pressure. In a crossover design comparing low and high salt diets, a high salt diet resulted in an increase in both forward and reflected wave

amplitudes in young and middle-aged normotensive adults.[154] Reflection magnitude, or the ratio of the reflected wave to the forward wave, has also been shown to be increased by high salt.[155] It has recently been reported that 24-hour urinary Na^+/K^+ was independently associated with characteristic impedance and that this explained the relation between 24-hour urinary Na^+/K^+ and pulse or systolic pressure.[156] Taken together there is a growing body of evidence suggesting that high salt results in an increase in components of pulsatile load which may partly explain the association between a high salt diet and LV hypertrophy as well as poor cardiovascular outcomes.

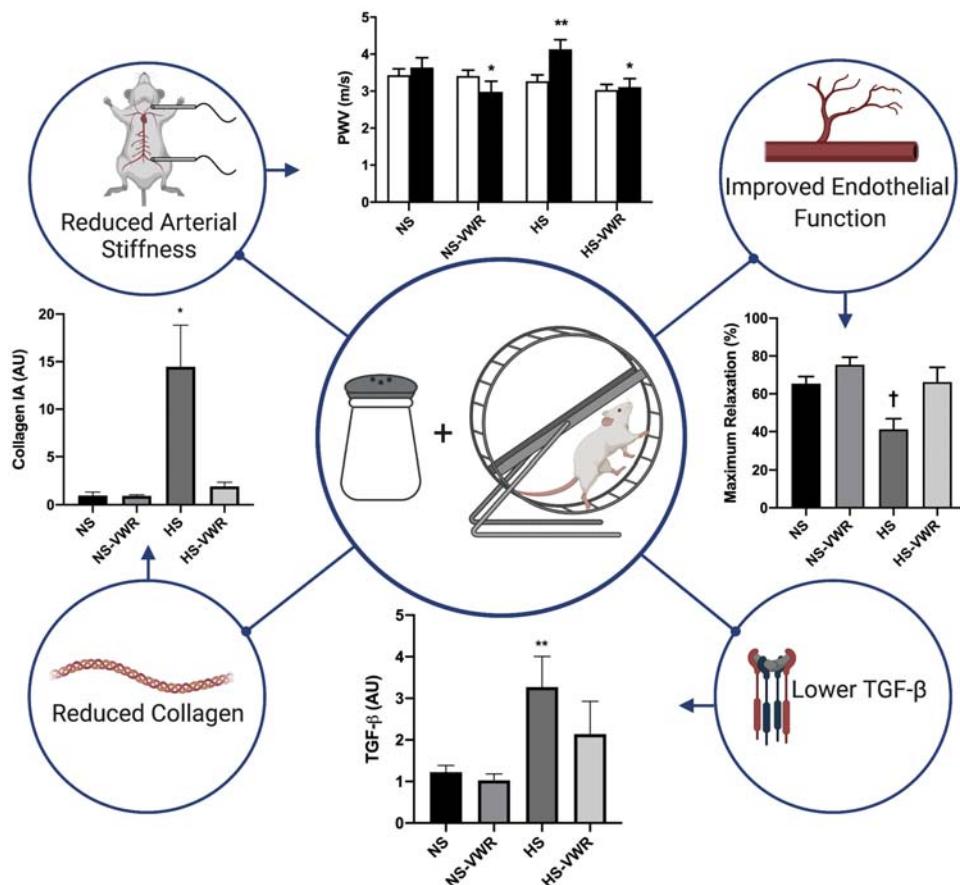
Lifestyle and dietary salt


Worldwide dietary salt intake is greater than that recommended by a number of organizations including the World Health Organization as previously mentioned. A small percentage (less than 10%) of Americans is able to abide by the dietary sodium recommendations put forth in the Dietary Guidelines for Americans.[157,158] The primary source of salt in the diet comes from processed food and meals prepared in restaurants[159] with many American exceeding the daily sodium recommendation in a single meal eaten at a restaurant (Fig. 53.4).[160,161] It is extremely difficult to get individuals to reduce their salt intake therefore other lifestyle factors may be important to consider in order to combat the deleterious effects of salt.

Sources of Salt in Diet

- Processed/restaurant food
- Added in home preparation
- Naturally occuring
- Added at the table

FIGURE 53.4 Sources of salt in the diet. The majority of salt consumed in the diet comes from processed and restaurant food. *Adapted from Harnack LJ, Cogswell ME, Shikany JM, et al. Sources of sodium in US adults from 3 geographic regions. **Circulation**. 2017; 135(19):1775−1783.*

Potassium


An individual's background diet may be important in modulating the effects of high salt. When high salt is consumed in the setting of a DASH diet that is high in fruit and vegetables and low in dairy fat, it results in lower BP compared to a standard diet that is high in salt.[17,162] The effect may be mediated, at least in part, by higher potassium intake in a DASH diet. There is evidence from large trials that a higher urinary sodium to potassium excretion ratio is associated with increased risk of cardiovascular disease[163,164] suggesting that the interaction of sodium and potassium consumption may be important. Potassium supplementation has been shown to reduce BP[165] and substituting a portion of dietary salt with potassium chloride has been shown to lower BP and reduce the incidence of hypertension.[166] However, there are limited studies of vascular function and potassium consumption. Potassium can soften endothelial cells and increase NO synthesis as demonstrated in cell studies[167] and increased dietary potassium has been shown to inhibit vascular production of TGF-β in rats fed a high salt diet.[168] Recently, endothelial function, as measured by brachial artery FMD, was not reduced on a high salt diet that was also high in potassium providing evidence that potassium may counteract the deleterious effect of salt on the vasculature.[169] Additional studies are warranted to examine the interaction of potassium and sodium on vascular function and in particular arterial stiffness.

Exercise/physical activity

Exercise and/or physical activity has many known beneficial effects including reduced cardiovascular morbidity and mortality.[170,171] The beneficial effects of exercise on arterial stiffness are reviewed elsewhere but are important to consider here in the context of a high salt diet. Exercise has the opposite effect in most instances to dietary salt when it comes to the vasculature, where salt has a deleterious effect exercise has a positive effect. There is a large body of literature that demonstrates improvements in both endothelial function and arterial stiffness from exercise. In aging there is a reduction in endothelial function and an increase in arterial stiffness whereas exercise improves or maintains vascular function.[172] It stands to reason then that exercise may counteract the deleterious effects of salt. In a recent set of studies in rats consuming a high salt diet, Guers and colleagues have demonstrated that voluntary wheel running prevented the negative effects of salt on both endothelial function and arterial stiffness[81,173](Fig. 53.5). Voluntary wheel running resulted in lower aortic TGF-β and collagen content on a high salt diet compared to high salt without voluntary running. This resulted in lower aortic pulse wave velocity. Importantly, these effects were observed without any changes in BP indicating that the positive effects of voluntary wheel running occurred independent of BP.

FIGURE 53.5 The effects of voluntary wheel running with a high salt diet. Voluntary wheel running has been shown to prevent a decline in endothelial function and increase in arterial stiffness in rats fed a high salt diet.[81,173] The lack of increase in arterial stiffness was associated with lower TGF-β and aortic collagen content.[173]

Studies in humans are needed to understand whether exercise or physical activity may be able to counteract high salt in humans.

Conclusion

Worldwide dietary salt intake is high, and excess dietary sodium is associated with increased cardiovascular disease risk and all-cause mortality. High dietary salt intake can lead to increased BP; however, there are BP independent effects of high salt on vascular function, in particular, endothelial function and arterial stiffness. The consequences of dietary salt induced alterations in endothelial function and arterial stiffness include increased pulsatile load on the LV. Endothelial dysfunction and increased arterial stiffness are predictors of cardiovascular disease and data from Framingham indicate that both are associated with incident hypertension.[102] Therefore, reducing excess dietary salt should be considered important for overall vascular health in addition to BP. Lifestyle changes, such as a diet high in potassium and/or exercise, may counteract the deleterious effects of high salt. This may be important as a reduction in salt consumption is difficult to achieve for most individuals.

Introduction

Hypertension is the most important risk factor in the global burden of disease.[1] Despite the advances in the treatment of hypertension, hypertension control remains a big challenge to every country in the world and there is substantial variation across countries in the rate of hypertension control.[2,3] Patients with hypertension are different from one another and thus may respond differently to the same treatment.[4] The well-recognized heterogeneity in the etiology and pathophysiology of hypertension defines the various hypertension phenotypes[5,6] and may provide an opportunity for the personalization of hypertension management.[4]

Increased arterial stiffness causes an increase in blood pressure pulsatility so systolic blood pressure (SBP) rises and diastolic blood pressure (DBP) falls when mean arterial blood pressure keeps unchanged.[7−9] Increased wave reflection magnitude results in an increase in central pressure augmentation in systole in the presence of increased arterial stiffness.[7−9] Therefore, progressive increase in arterial stiffness and wave reflections due to vascular aging inevitably causes the progressive rise in SBP and pulse pressure (PP), and thus the increased prevalence of hypertension with age.[9] Thus, increased arterial stiffness and adverse central pulsatile hemodynamics can be the cause as well as the consequence of hypertension.[10,11]

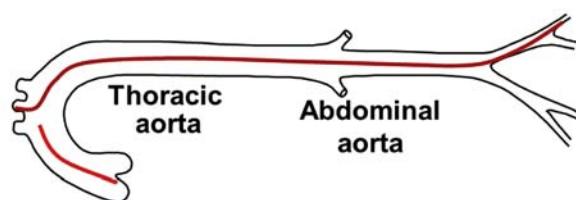
In this chapter, we attempt to review the roles of arterial stiffness and central pulsatile hemodynamics in the pathogenesis of hypertension phenotypes (Table 54.1), the effects of currently available antihypertensive medications on arterial stiffness and central pulsatile hemodynamics (Table 54.3), and the usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the diagnosis and management of the various hypertension phenotypes (Table 54.4). For the purpose of this review, measures of arterial stiffness include carotid-femoral pulse wave velocity (CFPWV),[72] brachial-ankle pulse wave velocity (BAPWV),[73] and parameters of reservoir function calculated from the carotid pressure waveform analyzed according to the reservoir-wave model[9,74]; measures of central pulsatile hemodynamics include ascending aorta pulse wave velocity (AAPWV),[75] characteristic impedance of aorta (Zc),[12,15] central SBP,[76] central PP,[77] augmentation index (cAI),[77] carotid augmented pressure (Pa),[77] amplitude of the backward wave decomposed from carotid artery pressure wave (Pb),[77] reflection magnitude (RM),[77] PP amplification,[78] and excess pressure integral (XSPI) (Fig. 54.1).[79]


TABLE 54.1 Clinical phenotypes described in the chapter.

Abbreviation	Phenotype	Definition
ISH	Isolated systolic hypertension	ISH is defined by an elevated SBP in the presence of a normal or low DBP, and is therefore always characterized by a high PP
IDH	Isolated diastolic hypertension	IDH is defined by an elevated DBP in the presence of a normal or low SBP
ICH	Isolated central hypertension	Isolated central hypertension (ICH) has been identified as central hypertension in the presence of normal brachial blood pressure (SBP<140 mmHg and DBP<90 mmHg)
IBH	Isolated brachial hypertension	Isolated brachial hypertension (IBH) as brachial hypertension in the presence of normal central blood pressure with the proposed central blood pressure threshold of 130/90 mm Hg
	White coat hypertension	White coat hypertension is referred to an untreated condition, while blood pressure is elevated in the office but normal when measured by home blood pressure monitoring or 24-h ambulatory blood pressure monitoring
	Masked hypertension	Masked hypertension is characterized by normal office blood pressure but elevated out-of-office blood pressure measures
INH	Isolated nocturnal hypertension	Isolated nocturnal hypertension is defined as a nighttime SBP>120 mm Hg or DBP>70 mm Hg and a daytime blood pressure <135/85 mm Hg through the use of 24-h ambulatory blood pressure monitoring
Exaggerated BPV	Exaggerated blood pressure variability	An abnormal increase in BPV

BPV, blood pressure variability; *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure.

Isolated systolic hypertension in the elderly

Isolated systolic hypertension (ISH) is the most common form of hypertension among both untreated and inadequately treated hypertensive individuals aged 50 years or older.[80–82] ISH is conceptually defined by an elevated SBP in the presence of a normal or low DBP, and is therefore always characterized by a high PP. ISH is strongly associated with increased cardiovascular disease morbidity and mortality,[83,84] and antihypertensive treatment in the elderly with ISH significantly reduces the risk of adverse cardiovascular events.[85–87]

Arterial stiffness and central pulsatile hemodynamics in ISH in the elderly

Patients with ISH are characterized by a marked increase in arterial stiffness[12–14,88–92] and Zc,[12,15] a moderately increase in wave reflections,[12] a marked increase in central SBP and central PP,[15] and a mildly increased total peripheral resistance (TPR) (Table 54.2).[12]

Large artery stiffening associated with vascular aging is the most important pathophysiological determinant of ISH

TABLE 54.2 Roles of arterial stiffness and central pulsatile hemodynamics in the pathogenesis of hypertension phenotypes

	Arterial stiffness	Central pulsatile hemodynamics			TPR
	CFPWV, BAPWV, total arterial compliance, five parameters from reservoir-wave analysis	AAPWV Zc	Wave reflections: XSPI cAI AP RM RI Pf Pb Reflection coefficient Amplification of SBP or PP	Central BP: cSBP cPP	
ISH in the elderly	↑↑↑[12−14]	↑↑↑[12,15]	↑↑[12]	↑↑↑[15]	↑[12]

↑, ↑↑, ↑↑↑, different degree of increase; ↓, ↓↓, ↓↓↓, different degree of decrease; ↔, no change; *BPV*, blood pressure variability; *IBH*, isolated brachial hypertension; *ICH*, isolated central hypertension; *IDH*, isolated diastolic hypertension; *INH*, isolated nocturnal hypertension; *ISH*, isolated systolic hypertension; *MKH*, masked hypertension; *N/A*, not available; *WCH*, white coat hypertension.

and the age-dependent increase in PP.[9,13,72] Invasive aortic input impedance analysis from elderly subjects with ISH demonstrated that Zc was 107% higher, the first harmonic of impedance moduli (influenced by wave reflection) was 57% higher, TPR was 44% higher, and the first impedance moduli minimum was shifted to a higher frequency, when compared to age-matched normotensive subjects.[12] The changes in impedance spectra among ISH patients indicate that the aorta and large arteries have become stiffer and facilitate an earlier return of pulse wave reflection in systole.[12]

However, other studies indicate that elevated PP in ISH is primarily attributable to elevated Zc and reduced effective diameter of the proximal aorta,[15] implying that aortic function plays an active role in the pathophysiology of ISH.[15]

An increase in TPR may indicate a decrease in the cross-sectional area of the peripheral vascular bed and a decline in endothelial function associated with vascular aging.[12,13] The marked increase in arterial stiffness in ISH offsets the increase in DBP that would have been expected from an increase in TPR.[12]

Usefulness of noninvasive measurement of arterial stiffness and central pulsatile hemodynamics in the diagnosis of ISH in the elderly

Current diagnosis of ISH is based solely on blood pressure readings taken from an upper-arm cuff blood pressure method.[5,93] Diagnostic blood pressure thresholds of ISH may vary with the current definitions of hypertension (elevated SBP and/or DBP).[5,6] Thus, in Europe, ISH is defined as SBP ≥140 mmHg and DBP <90 mmHg,[6] whereas the current cut-points for ISH are SBP ≥130 mmHg and DBP<80 mmHg in the United States.[5]

Usefulness of noninvasive measurement of arterial stiffness and central pulsatile hemodynamics in the treatment of ISH in the elderly

The relative effectiveness of antihypertensive therapies on arterial stiffness and central pulsatile hemodynamics is summarized in Table 54.3. All six classes of antihypertensive medications are variably effective in improving arterial stiffness, Zc, wave reflections, central blood pressure, and TPR (Table 54.3). However, current standard antihypertensive medications largely act through reductions in TPR or cardiac output and probably do not change the intrinsic material properties of the arterial wall.[94] A comprehensive understanding of the molecular mechanisms of large artery stiffening may help develop novel therapies to improve the material properties of the arterial wall.[94]

Patients with ISH usually have a limited response to renal denervation.[6] Measurement of CFPWV may be useful in identifying a subset of ISH patients who would respond to the renal denervation therapy.[64] It remains to be demonstrated that measurements of arterial stiffness and central pulsatile hemodynamics is useful in drug titration and monitoring of treatment efficacy for elderly ISH patients (Table 54.4).

Prognostic value of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in ISH in the elderly

CFPWV is currently considered the clinical and epidemiologic gold standard metric of large artery stiffness[95] and an increase in CFPWV (>10 m/s) in patients with hypertension is considered an indicator of hypertension-mediated cardiovascular target organ damage in some hypertension treatment guidelines.[5,6] Several studies have demonstrated the additive prognostic value of CFPWV above and beyond traditional risk factors (Table 54.4).[6,96] However, since CFPWV was more strongly related to the risk of coronary heart disease and stroke in younger subjects, it is expected that the prognostic value of CFPWV would decline in the elderly ISH patients.[96] Therefore, routine use of CFPWV measurements in elderly ISH patients is not recommended for routine practice.[6] The prognostic value of other measures of arterial stiffness and central pulsatile hemodynamics in patients ISH remains to be determined in future studies.

Isolated systolic hypertension in the young

From puberty to mid-life, SBP increases steeply during childhood, reaches a plateau phase between 20 and 40 years, and then increases subsequently,[97−99] whereas DBP displays a cubic trajectory with a plateau-like behavior followed by a decline as age increases.[97] Therefore, at the population level, PP values may be high around the age of 20 years and low in the age range between 20 and 40 years.[100−103] The transient physiological elevation of SBP and PP detected in some young adults may reach the criteria of ISH and create an innocent condition called pseudo or spurious systolic hypertension of youth whose central blood pressure is normal.[97,104] However, an increase in CFPWV has been found in about 20% of the young individuals with ISH.[17] Moreover, obesity,

metabolic disturbances, and white coat hypertension have often been documented to be associated with ISH in the young.[105,106] ISH is the most common form of hypertension in adolescents and young adults.[107] However, whether ISH in the young implies a worse outcome and requires antihypertensive treatment remains controversial and future clinical trials will elucidate if a benefit can be achieved with pharmacological treatment in some subgroups with associated risk factors and/or high central blood pressure.[97]

Arterial stiffness and central pulsatile hemodynamics in ISH in the young

Current evidence suggests two main phenotypes of ISH in the young, one is spurious systolic hypertension, the other is ISH with increased cardiovascular risk (Fig. 54.2). Young subjects with spurious systolic hypertension are characterized by normal arterial stiffness,[16] reduced wave reflections,[16−19] normal central blood pressure,[19] increased stroke volume,[17,18] and normal TPR (Table 54.2).[17,18] Young subjects with ISH and increased cardiovascular risk are characterized by increased arterial stiffness,[17,18] increased Zc,[20] normal wave reflections,[18] increased central blood pressure,[16−18] and increased TPR.[20] They are also characterized by a smaller difference between central and peripheral SBP, i.e., a reduced PP amplification, presumably from a smaller stiffness gradient between central and peripheral arteries.[97]

Usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the diagnosis of ISH in the young

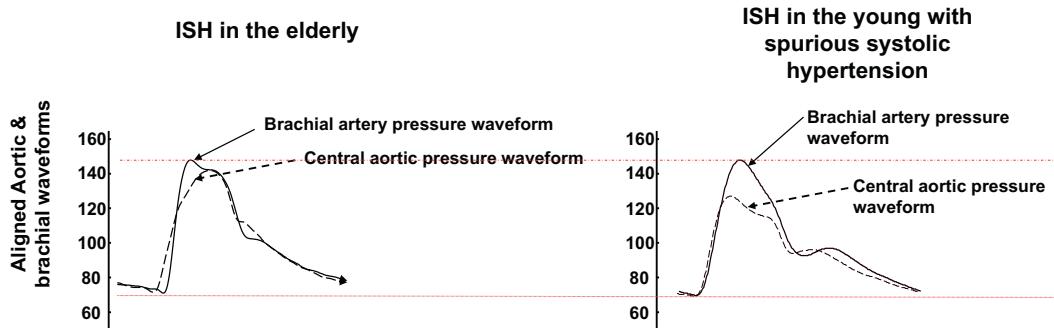
Similar to ISH in the elderly, the diagnosis of ISH in the young is based solely on blood pressure readings taken


FIGURE 54.2 Brachial and central aortic pressure waveforms of subjects with isolated systolic hypertension (ISH).

from an upper-arm cuff blood pressure method.[5,93] However, measurement of central blood pressure or CFPWV may be useful in identifying different phenotypes of ISH in the young (Table 54.4).[16−19]

Usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the treatment of ISH in the young

On the basis of currently available evidence, young individuals with ISH should receive recommendations on lifestyle modification.[6] Although measurements of arterial stiffness and central blood pressure may be useful in identifying the high risk phenotype of ISH in the young, it is unclear whether they should receive drug treatment.[6,97] There is no evidence to support the usefulness of noninvasive measurement of arterial stiffness and central hemodynamics in drug titration and monitoring of treatment efficacy in the treatment of ISH in young ISH subjects (Table 54.4). However, to the degree that measurements of arterial stiffness or central hemodynamics can identify young individuals with ISH who are at higher risk of adverse outcomes (see next section), these measurements may identify young individuals who require a more aggressive therapeutic approach; this should be the focus of further research.

Prognostic value of noninvasive measurement of arterial stiffness and central pulsatile hemodynamics in ISH in the young

According to prospective data from the Chicago Heart Association Detection Project, young men with ISH had a CV risk similar to that of individuals with high-normal blood pressure.[83] Since ISH in younger adults appears to be a heterogeneous condition, noninvasive measurements of CFPWV and/or central blood pressure may aid in discriminating high from low cardiovascular risk (Table 54.4).[17]

Isolated diastolic hypertension

Isolated diastolic hypertension (IDH) is common in young adults and may represent the early stage of hypertension development.[108,109] Increased TPR and decreased stroke volume are the major hemodynamic features for IDH[20] and obesity is one of the major risk factors.[108,110] In persons with IDH, cardiovascular disease risk is apparently being driven by DBP elevation.[111] DBP and IDH drive coronary risk in younger subjects, whereas SBP is the predominant risk indicator in older people.[112] However, whether IDH is associated with an increased cardiovascular disease risk remains inconsistent.[111,113]

Arterial stiffness and central pulsatile hemodynamics in IDH

According to the Dallas Heart Study of 2001 untreated participants 18−64 years of age, subjects with IDH had similar Zc and ascending aortic PWV (AAPWV), when compared to those with optimal blood pressure or prehypertension.[20] Subjects with IDH had decreased aortic compliance when compared to those with optimal blood pressure (Table 54.2).[20]

Usefulness of arterial stiffness and central pulsatile hemodynamics in the diagnosis of IDH

The diagnosis of IDH is based solely on blood pressure readings taken from an upper-arm cuff blood pressure method.[5,93] Diagnostic blood pressure thresholds for IDH may vary with the current definitions of hypertension (elevated SBP and/or DBP).[5,6] Thus, in Europe, IDH would be defined as SBP<140 mmHg and DBP≥90 mmHg,[6] whereas the current cut-points for IDH would be SBP<130 mmHg and DBP≥80 mmHg in the United States.[5,111]

Usefulness of arterial stiffness and central pulsatile hemodynamics in the treatment of IDH

Active treatment reduced the relative risk of major vascular events by 27% among patients with ISH, by 28% among those with IDH, and by 32% among those with systolic−diastolic hypertension.[114] Currently, there has been no evidence of differences in the magnitude of the effects of treatment among different types of hypertension. Therefore, blood pressure lowering is likely to provide a similar level of protection against major vascular events for patients with IDH as for those with ISH and systolic−diastolic hypertension (Table 54.4).[114]

Prognostic value of arterial stiffness and central pulsatile hemodynamics in IDH

Currently, there is no evidence suggesting the association of measures of arterial stiffness and central pulsatile hemodynamics with future cardiovascular events in patients with IDH.

Isolated central hypertension and isolated brachial hypertension

Central blood pressure refers to blood pressure readings measured from the central aorta or common carotid

arteries.[115,116] Hypertension is almost always diagnosed according to blood pressure measurement obtained from the brachial arteries, which highly correlates with central blood pressure.[117] Because the individual discrepancies between central and brachial blood pressure may be substantial and highly variable and may be magnified during hemodynamic changes or after pharmacological interventions,[117] brachial blood pressure readings cannot serve as direct substitutes for their central counterpart.[118] Accumulating evidence has suggested that central blood pressure may be more relevant than peripheral blood pressure in predicting target organ damage and cardiovascular outcomes.[76] Central blood pressure can now be measured noninvasively, including using convenient cuff-based central blood pressure monitors.[116] Hypertension diagnosed by central blood pressure readings and the proposed central blood pressure threshold of 130/90 mm Hg is designated as central hypertension, as opposed to the conventional brachial hypertension.[119] Central hypertension has been characterized by a greater discriminatory power for long-term events than brachial hypertension.[119] Accordingly, isolated central hypertension (ICH) has been identified as central hypertension in the presence of normal brachial blood pressure (SBP<140 mmHg and DBP<90 mmHg), and isolated brachial hypertension (IBH) as brachial hypertension in the presence of normal central blood pressure.[22,119] In a recent study from Taiwan, the national weighted prevalence rates of ICH and IBH were 7.35% and 0.30%, respectively.[22] Hypertension detection using a conventional brachial blood pressure approach may underestimate the prevalence of hypertension and result in a less effective hypertension control.[22]

Arterial stiffness and central pulsatile hemodynamics in ICH and IBH

Subjects with ICH have an elevated central blood pressure. The major determinants of central blood pressure are arterial stiffness and wave reflections, the dominant hemodynamic manifestations of vascular aging.[9] Subjects with IBH have not been characterized, except those in the subgroup of ISH in the young adults.[107,120] In the subgroup of ISH and normal central blood pressure, the high elasticity of the vascular tree may play a mechanistic role in the youth.[120] Most subjects with IBH have IDH, which is a consequence of an increase in TPR.[121]

Usefulness of arterial stiffness and central pulsatile hemodynamics in the diagnosis of ICH and IBH

Diagnosis of ICH or IBH requires measurements of brachial and central blood pressure. The various central blood pressure measuring devices can be broadly

categorized into two types. Type I device purports to give an estimate of central blood pressure relative to measured brachial blood pressure, and Type II device purports to estimate the intraarterial central blood pressure.[122] The prevalence of ICH and IBH may vary according to the central blood pressure measuring devices.[22,23]

Usefulness of arterial stiffness and central pulsatile hemodynamics in the treatment of ICH and IBH

Currently, there is no evidence suggesting the usefulness of arterial stiffness and central pulsatile hemodynamics in the treatment of ICH or IBH. Whether ICH should be treated remains an important area of future research.

Prognostic value of arterial stiffness and central pulsatile hemodynamics in ICH and IBH

Subjects with ICH may have a cardiovascular risk profile equivalent to that of those with stage 1 brachial hypertension but significantly worse than those with prehypertension.[22] Currently, there is no evidence suggesting the association of measures of arterial stiffness and central pulsatile hemodynamics with future cardiovascular events in patients with ICH or IBH.

White coat hypertension

White coat hypertension is referred to an untreated condition, while blood pressure is elevated in the office but normal when measured by home blood pressure monitoring or 24-h ambulatory blood pressure monitoring.[5,6] Although white coat hypertension is associated with less target organ damage and adverse cardiovascular events than sustained hypertension,[123] white coat hypertension should not be considered prognostically benign.[25,124] Even if the out-of-office blood pressure in white coat hypertension is normal, by definition, it is generally higher than that in normotensive subjects.[25,26] This may partly explain the associated target organ damage and increased risk of mortality in white coat hypertension.[125−127] However, whether or not patients with white coat hypertension should receive antihypertensive medications remains debatable.[6]

Arterial stiffness and central pulsatile hemodynamics in white coat hypertension

The white coat effect is positively related to arterial stiffness.[27] A metaanalysis of 20 studies has demonstrated a significant increase of arterial stiffness, indexed by CFPWV in adults with white coat hypertension, when compared to the normotensives.[28] But there was no

significant difference in CFPWV between white coat hypertension and sustained hypertension.[25,26,128] Subjects with white coat hypertension may also have higher central aortic pressure and wave reflections compared to subjects with normotension, indicating the presence of significant vascular aging and/or dysfunction.[25,26,29]

Usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the diagnosis of white coat hypertension

Out-of-office blood pressure measurements are needed to confirm the diagnosis of white coat hypertension. Arterial stiffness and central hemodynamics are probably not distinguishable between subjects with white coat hypertension and sustained hypertension.[25,26,128] Mestanik et al. proposed a potential role of corrected cardio-ankle vascular index to differentiate white coat hypertension from sustained hypertension in overweight adolescent boys.[65] However, this approach has not been independently validated.

Usefulness of noninvasive measurement of arterial stiffness and central pulsatile hemodynamics in the treatment of white coat hypertension

Although the indications of pharmacological intervention in white coat hypertension have not yet been determined, white coat hypertension does independently correlate with subclinical target organ damage, including carotid intima-media thickness, albuminuria, glomerular filtration rate, left ventricular hypertrophy, as well as incident cardiovascular events.[25,29,129] Since the white coat effect has been associated with arterial stiffness, wave reflections, and target organ damage,[25,66] noninvasive measurements of arterial stiffness and central hemodynamics may be helpful to identify subjects at risk of developing target organ damage, who may benefit from early pharmacological therapy.

Prognostic value of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in white coat hypertension

An epidemiologic study of 1257 never-been-treated individuals has shown that subjects with white coat hypertension and increased wave reflection, indexed by AIx or Pb, exhibit adverse clinical outcomes similar to those with sustained hypertension.[25] The results may encourage the clinical application of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in white coat hypertension for further risk stratification and tailored therapy.

Masked hypertension

Subjects with masked hypertension are characterized by normal office blood pressure but elevated out-of-office blood pressure measures.[5,6] Masked hypertension prevails in untreated subjects. In the Jackson Heart Study of African Americans, one-third of the study population had masked hypertension at a time when the mean office blood pressure was normal.[130] In addition, masked hypertension has been consistently accompanied by a greater degree of target organ damage and a higher risk of cardiac events and stroke than those with normotension or prehypertension.[29,130,131] Masked uncontrolled hypertension was even associated with a greater risk of death than sustained uncontrolled hypertension.[132] A specific challenge is to recognize masked hypertension early by ambulatory or home blood pressure monitoring, followed by medical therapy, especially when office blood pressure is in the high-normal range.[6]

Arterial stiffness and central pulsatile hemodynamics in masked hypertension

Although office blood pressure is normal in masked hypertension, it has been generally observed that masked hypertension is characterized by increased arterial stiffness, central blood pressure, and wave reflection, when compared with normotension.[26,29,30] A metaanalysis of seven studies and 2352 patients has further indicated that arterial stiffness in patients with masked hypertension is similar to that in white coat hypertension.[128] In addition, masked hypertension has significantly lower central blood pressure and wave reflection, when compared with white coat hypertension or sustained hypertension.[26]

Usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the diagnosis of masked hypertension

Out-of-office blood pressure measurements are needed to confirm the diagnosis of masked hypertension. Patients with masked hypertension have normal office blood pressure but increased arterial stiffness, wave refection, and central blood pressure, when compared with normotensives.[26,30] Measures of arterial stiffness and/or central pulsatile hemodynamics may indicate the presence of masked hypertension in subjects with normal office blood pressure. This may identify individuals among whom further study of out-off-office blood pressure should be implemented.

Usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the treatment of masked hypertension

The noninvasive measurement of arterial stiffness and central pulsatile hemodynamics could be helpful for the early detection of masked hypertension and to facilitate antihypertensive treatment.[26,30] Both arterial stiffness and wave reflection indices could serve as potential therapeutic targets, in addition to the home blood pressure measures. This remains to be assessed in future studies.

Prognostic value of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in masked hypertension

Currently, there is no direct evidence demonstrating an association between measures of arterial stiffness and central pulsatile hemodynamics and future cardiovascular events in patients with masked hypertension. Patients with masked hypertension are considered to have a cardiovascular risk equivalent to that of sustained hypertension. Since measures of arterial stiffness and central blood pressure have been associated with mortality or adverse cardiovascular events in patients with sustained hypertension,[117,133] similar prognostic value could be expected in patients with masked hypertension.

Isolated nocturnal hypertension

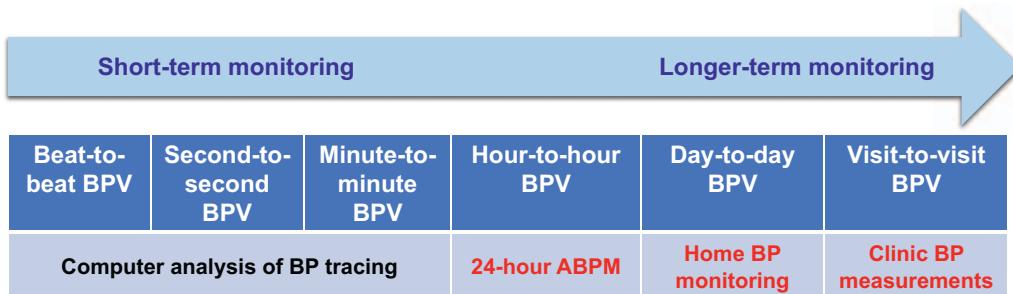
Isolated nocturnal hypertension (INH) is a relatively newly proposed hypertension phenotype (first formally described in 2007), which is defined as a nighttime SBP$\geq$120 mm Hg or DBP$\geq$70 mm Hg and a daytime blood pressure $<$135/85 mm Hg through the use of 24-h ambulatory blood pressure monitoring.[31,32,68] INH has been related to atherosclerosis and target organ damages and independently predicted cardiovascular events.[32,33,68] The incidence of INH varies slightly among different ethnic groups; Asians and blacks have less nocturnal blood pressure dipping than whites.[31]

Arterial stiffness and central pulsatile hemodynamics in INH

A systematic review summarized the evidence on the association between INH and subclinical target organ damage.[32] INH was associated with higher ambulatory arterial stiffness index, BAPWV, cAI in a Chinese study,[31] but not associated with increased arterial stiffness or left ventricular mass index in a Swedish study. The existing evidence shows that there may be a weak relationship between INH and arterial stiffness and central pulsatile hemodynamics.

The inconsistent results suggest that arterial stiffness and pulsatile hemodynamics may be involved in but not the primary mechanism responsible for development of INH.[32,34]

Usefulness of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in the diagnosis of INH

Since INH can only be diagnosed by blood pressure measurements during sleep, it is suggested that ambulatory blood pressure monitoring should be applied more widely in clinical practice. However, one recent study further investigated the reproducibility of the diagnosis of INH,[67] and concluded that INH and isolated daytime hypertension are both poorly reproducible phenotypes. They also suggested that 24-h ambulatory blood pressure monitoring should be primarily used to identify individuals with daytime hypertension and/or nocturnal hypertension, but not INH or isolated daytime hypertension. In other words, INH and isolated daytime hypertension are both poorly reproducible and not stable phenomena over the short term.


Prognostic value of noninvasive measurements of arterial stiffness and central pulsatile hemodynamics in INH

It has been repeatedly demonstrated that night-time blood pressure is superior to the daytime blood pressure in the prediction of cardiovascular outcomes.[68,134] INH has been associated with an increased risk of cardiovascular disease events and mortality.[31,135] Currently, there are no available studies assessing the association of measures of arterial stiffness and central pulsatile hemodynamics with future cardiovascular events in patients with INH. Whether these hemodynamic measures can provide prognostic value in patients with INH needs to be further explored. Future clinical studies should also address the benefit of specifically lowering the night-time blood pressure in patients with INH.

Exaggerated blood pressure variability

Blood pressure fluctuations, also coined as blood pressure variability (BPV), constitute a complex phenomenon. BPV has usually been considered a physiological indicator reflecting autonomic nerve function and arterial compliance.[136,137] It can also be used as a risk predictor for cardiovascular and cerebrovascular events in patients with hypertension and cardiovascular diseases, and an index for evaluating the efficacy of antihypertensive medications.

BPV can be classified into short-term BPV and long-term BPV according to the length of time of BP recordings (Fig. 54.3). Short-term fluctuations in blood

Short-term monitoring				Longer-term monitoring	
Beat-to-beat BPV	Second-to-second BPV	Minute-to-minute BPV	Hour-to-hour BPV	Day-to-day BPV	Visit-to-visit BPV
Computer analysis of BP tracing			24-hour ABPM	Home BP monitoring	Clinic BP measurements

FIGURE 54.3 Various measures of blood pressure variability derived from different blood pressure measuring techniques. *ABPM*, ambulatory BP monitoring; *BP*, blood pressure; *BPV*, BP variability.

pressure often occur within a 24 h period, including beat-to-beat, minute-to-minute, hour-to-hour, and day-to-night changes; long-term substantial variations in blood pressure have usually been shown to occur over more prolonged periods of time, including days, weeks, months, seasons, and even years.[138,139] A variety of methods have been utilized to measure BPV.[140] In particular, BPVs in SBP, DBP, or PP quantified by using the average real variability (ARV) index from 24-h ambulatory BP monitoring have been associated with cardiovascular outcomes independent of absolute BP levels.[141,142] ARV is calculated by the following formula:

$$ARV = |BP_{K+1} - BP_K|$$

k ranges from 1 to n − 1 and w is the time interval between BP_K and BP_{K+1}. n is the number of blood pressure readings.

Previous animal studies have demonstrated that the degree of fluctuation in blood pressure is closely related to the target organ damage.[139] Recent studies pointed out that the abnormal increase in BPV (exaggerated BPV) can add to the damage to target organs caused by blood pressure itself, and that the exaggerated BPV is an independent risk factor of target organs damages, and the prognostic value of BPV in hypertensive subjects has been extensively investigated.[141] However, the relevant mechanism of exaggerated BPV has not been fully understood.[35,36,138,139,143]

Arterial stiffness and central pulsatile hemodynamics in exaggerated BPV

It has been demonstrated that decreased arterial compliance (as measured by changes in CFPWV) is significantly related to exaggerated BPV in the American and Asian populations.[138] However, a recent study found that in the groups of normotensive and treated hypertensive patients, CFPWV was independently associated with average real variability of 24-h DBP (ARVd) but not average real variability of 24-h SBP (ARVs).[35] It has been further revealed that ARVd but not ARVs was significantly

associated with cardiovascular mortality independently of 24-h SBP in the hypertensive patients.[69] In addition, this study also uncovered that the association of amplitude of the decomposed backward pressure (Pb) with measures of the short-term BPV was stronger than that of CFPWV, cardiac output, or TPR.[35] On the other hand, TPR was not associated with ARVd or ARVs.

Usefulness of noninvasive measurement of arterial stiffness and central pulsatile hemodynamics in the diagnosis of exaggerated BP variability

Recent studies have indicated that increased arterial stiffness may be a pathological mechanism contributing to long-term BPV. The Multiethnic Study of Atherosclerosis has demonstrated that a reduction in aortic distensibility and arterial elasticity was associated with a higher visit-to-visit BPV,[139,144] but whether similar associations exist between CFPWV or other vascular measures and exaggerated visit-to-visit BPV remains to be investigated.[144,145]

Prognostic value of noninvasive measurement of arterial stiffness and central pulsatile hemodynamics in exaggerated BP variability

The definition and measurement of BPV have certain complexity, such as BPV with different time intervals and the difference in data recording methods and the analytic methods. Therefore, in patients with exaggerated BPV, whether the measures of arterial stiffness and central hemodynamics can be used to predict these patients' outcomes remains to be determined.[69] Nevertheless, short-term BPV including all indices of SBP variability with 24-h measurements has been associated with aortic stiffness as measured by CFPWV.[70] Future studies are required to demonstrate whether such associations can be used to predict outcomes of these patients with exaggerated BPV.

Summary and conclusion

In personalized medicine, understanding patients' unique personal profiles is important to inform clinical decisions. In this chapter, we present available evidence relating to several important hypertension phenotypes, including ISH, IDH, ICH, IBH, white coat hypertension, masked hypertension, INH, and exaggerated BPV. Despite using the mechanical biomarkers of arterial stiffness and central pulsatile hemodynamics might be beneficial in the detection, evaluation, treatment, and prevention of hypertension, evidence for these hypertension phenotypes is not yet widely available. However, emerging evidence has suggested the vital role of CFPWV and central pulsatile hemodynamics especially in predicting the prognosis of hypertensive patients.

In the process of vascular aging, the increase in arterial stiffness and wave reflections causes a corresponding increase in SBP and PP.[9] As the possible cause and the consequence of hypertension, it can be anticipated that arterial stiffness and adverse central pulsatile hemodynamics should play a critical role in the management of hypertension and its diverse and distinct phenotypes, including diagnosis, prognosis, and treatment monitoring. More efforts are encouraged to study the usefulness of these mechanical biomarkers in personalized medicine in hypertension.

Pulsatile hemodynamics and ventricular–arterial interactions in the pulmonary circulation: physiologic concepts

Berend E. Westerhof, Anton Vonk Noordegraaf and Masafumi Fukumitsu

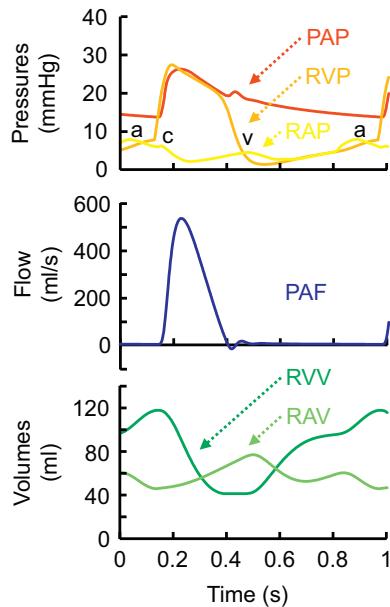
Department of Pulmonary Medicine, Amsterdam Universitair Medische Centra, Vrije Universiteit Amsterdam, Amsterdam Cardiovascular Sciences, Amsterdam, the Netherlands

Introduction

The pulmonary circulation can be described in much the same way as the systemic circulation, with static measures such as mean pressure, cardiac output (CO), and vascular resistance, and with pulsatile hemodynamics, such as systolic and diastolic pressures, pressure wave reflection, and frequency-domain analysis. That being said, many differences between the systemic and pulmonary circulations can be identified. Structure and function may differ, but similar approaches can be taken for its characterization.

Physiologically, the properties of the right ventricle (RV) and the arterial load can be described in two ways[1]: (1) by the intrinsic characteristics (for example, pulmonary vascular resistance (PVR) and pulmonary arterial compliance (PAC), and RV contractility and RV diastolic stiffness) and (2) by the system characteristics, determined by the interaction between the RV and arterial load (for example, pulmonary artery pressure (PAP), CO, and RV ejection fraction, EF). In clinical practice, the latter parameters are commonly used; however, correct interpretation of data requires an adequate understanding of the former parameters.

In this chapter, we will describe measurements in the pulmonary cardiovascular system (the system characteristics) which assess the combined effect of heart and vascular load.[2] Based on the measurements, the RV and the vasculature can be characterized (the intrinsic characteristics), from the pressure-flow relation, and the pressure-volume relation, respectively.[1]

Measurements in the pulmonary circulation


Pressures in the pulmonary system

Noninvasive measurement of pressures in the pulmonary circulation is not possible. Right heart catheterization (RHC) is highly invasive; however, it provides a wealth of data.[3] Care must be taken though to obtain reliable measurements.[4,5] RHC is the recommended method to assess pulmonary hypertension.[6]

For RHC, a pulmonary artery (PA) catheter, sometimes called a Swan-Ganz catheter eponymous of its inventors,[7] is used. After being inserted in the jugular (sometimes femoral, antecubital or brachial) vein, the balloon at the tip of the catheter allows it to "go with the flow," floating toward the heart, entering through the right atrium (RA), continuing to the RV, and finally into the PA. A Wiggers diagram of pressures and volumes in the pulmonary circulation is given in Fig. 55.1.[8] With multiple lumen catheters, it is possible to measure pressures at these sites simultaneously providing detailed information on the right side of the heart and its load.

Right atrial pressure as a function of time

In right atrial pressure (RAP) and in central venous pressure (CVP, which is similar since the connection between central veins and the RA is open), characteristic features can be distinguished, comparable to left atrial pressure (LAP).[9] With RA contraction (P-top in the ECG), an a-wave

FIGURE 55.1 Wiggers diagram of pulmonary hemodynamics, based on simulations with the Aplysia CardioVascular Lab 2020 (Aplysia Medical AB, Stockholm, Sweden).[8] Top: pulmonary artery pressure (PAP), right atrial pressure (RAP), and right ventricular pressure (RVP). Middle: pulmonary artery flow (PAF). Bottom: right atrial volume (RAV) and right ventricular volume (RVV). For detailed descriptions, see the text.

appears in RAP, which drops (the x-descent) with an interruption caused by the closing of the tricuspid valve when the RV starts to contract (just after the R-top in the ECG). Some of the RV pressure (RVP) may be transmitted to the RA by the bulging of the tricuspid valve (between the RA and the RV) into the RA, visible as the c-wave in the x-descent of RAP. The contraction of the RV stretches the RA, causing RAP decrease to its minimum value, after which the passive filling of the RA starts accompanied by an increasing RAP. When the RV relaxes further and RVP drops below RAP, the tricuspid valve opens, causing a decline of RAP, visible as the y-descent of the v-peak.[9] As long as the tricuspid valve is open, RAP and RVP are essentially equal. RAP is an important risk factor in PH.[6,10]

Right ventricular pressure as a function of time

The RVP shows a gradual increase during ventricular diastole, with a final increase in pressure at end-diastole caused by contraction of the RA. RVP systole is characterized by a steep increase, and a steep fall at the end of RV contraction. RVP is an important determinant of RV wall stress (or wall tension) together with volume (radius) and wall thickness according to Laplace's law.[11] The shape of the RV complicates the calculation of RV wall stress and tension, however, can be approximated.[12] RV wall stress and tension (see also Chapter 56 Pulmonary arterial load

and ventriculararterial coupling in pulmonary hypertension") are relevant in the understanding of progression of RV adaptation in PH.[13]

Pulmonary artery pressure as a function of time

PAP starts to increase when the pulmonary valves open, after which RVP and PAP increase and then fall together.[9] When the pulmonary valves close, RVP continues to drop quickly, while PAP falls much slower because of the Windkessel function of the pulmonary circulation. Systolic and diastolic PAP are referred to as sPAP and dPAP.

Pulmonary artery wedge pressure

By wedging the PA catheter into a branch of the PAs, or by inflating the balloon at the tip, flow in the trajectory downstream is stopped.[14] In this manner, the vasculature forms an extension of the catheter, allowing to determine the pressure at the outflow of the pulmonary system, i.e., LAP.[15] Thus, pulmonary artery wedge pressure (PAWP) or pulmonary artery occlusion pressure provides valuable information over the pressure drop over the pulmonary vasculature, called transpulmonary pressure gradient. This transpulmonary pressure gradient is usually quantified by mean PAP (mPAP) minus PAWP (determined at end-expiration when intrathoracic pressure is closest to atmospheric pressure). A historical name is pulmonary capillary wedge pressure (PCWP) which suggested that capillary pressure was measured by occlusion or catheter wedging. Now it is generally accepted that LAP is assessed[15] and PCWP is no longer used.[16] The estimation of capillary pressure is described in the next section.

Pulmonary capillary pressure

It has been suggested that pulmonary capillary pressure PCP may be estimated from the decay of the pressure after inflating the catheter-tip balloon. Several methods have been proposed, involving fitting of exponential functions, looking for an inflection point in the decay, or extrapolating part of the decay.[17–19] PCP is relevant in the pathophysiology of pulmonary edema.[20,21]

Flow measurements in the pulmonary system

Cardiac output

A Swan-Ganz catheter has a thermistor some 3 cm behind the tip, which is placed in the PA. Through a proximal port of the catheter, cold saline can be injected into the RA, where it is mixed. Downstream in the PA, the temperature change caused by the cold saline represents an indicator dilution ("thermo-dilution") curve, from which CO can be estimated[22–24] with the Stewart (1893)–Hamilton (1932) equation.[25,26]

Pulmonary artery flow

The pulsatile flow velocity (Fig. 55.1) into the PA can be measured by echocardiography or by through-plane phase-contrast MRI. With the former technique, the area of the outflow tract is needed so that flow velocity (cm/s) can be transformed to volume flow (cm^3/s, corresponding to mL/s). With through-plane phase-contrast MRI, the volume flow is obtained (usually at the main PA) by summing the flow across all pixels in a cross-sectional anatomic representation (each pixel representing a three-dimensional voxel); for each voxel, the volume flow is computed as their cross-sectional area (i.e., pixel size) times their flow velocity. Stroke volume (SV) can then be obtained by time integration of volume flow, the area under the flow curve giving volume in ml. Velocity measurement with Doppler echocardiography is sensitive to the insonation angle. Conversion of velocity to volume flow is sensitive to errors in the quantification of the outflow area, particularly when area is determined from a squared radius. For a detailed discussion regarding technical aspects of flow measurements using Doppler echocardiography and phase-contrast MRI, the reader is referred to Chapters 2 and 4.

Volume measurements of the right heart

Echocardiography

Many relevant measures can be obtained from volume measurements of the RV, such as chamber sizes, SV, and EF. Several length related quantifications can be obtained as well, like RV fractional area change, longitudinal strain, and tricuspid annular plane systolic excursion.[6] Measuring the volume of the RV with echocardiography is difficult because of its complicated shape; therefore, results should be interpreted carefully.[27] A great advantage of echocardiography is its wide availability at the bedside.

Cardiac MRI

If available, volumes of the RV are ideally measured with cardiac MRI (CMRI).[28–30] Recently it has been proposed that CMRI-derived volume measurements are not inferior to invasive pressure measurements for the risk assessment of PH patients.[31]

Conductance catheter

The conductance catheter measures changes in ventricular volume with a series of ring-shaped electrodes. A small high frequency current is injected by the outer electrodes, and the voltage that is sensed over the inner electrodes is a measure of conductance, which in turn is related to blood volume.[32]

The SV determined by the conductance catheter needs to be calibrated with separate (e.g., thermodilution) measurements. Although developed for the LV, with the assumption that the shape of the ventricle can be described by a sphere or an ellipse,[33] it has been used for the RV as well.

Right atrial volume as a function of time

With the contraction of the RA at the end of ventricular diastole, volume decreases (Fig. 55.1); after the start of ventricular systole, and closing of the tricuspid valve, volume increases again. When ventricular systole ends and the tricuspid valve opens again, the volume stored in the RA translocates to the RV.

Right ventricular volume as a function of time

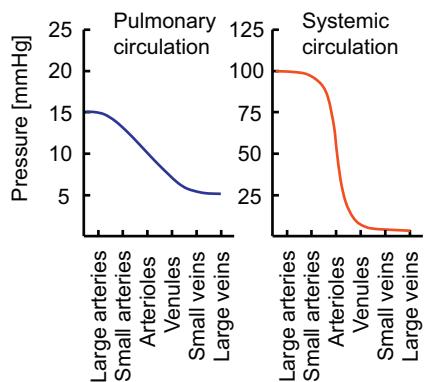
The volume of the RV is increased to its maximal value by the contraction of the RA just before ventricular systole (Fig. 55.1). With opening of the pulmonary valves and ejection, RV volume rapidly decreases. After closing of the tricuspid valve, and opening of the tricuspid valve, the volume in the RA is distributed to the RV.

The pulmonary vasculature

Anatomy and function of the pulmonary vasculature

The requirements for the geometry of the pulmonary vasculature are optimal gas exchange, thus maximum of contract area between blood and air, in a minimum of space. These requirements are met by a network with branching in rapid succession.[34,35] Typically, each mother vessel (except for the pulmonary trunk) branches into three daughter vessels. This is unlike the arrangement in the systemic circulation, that is optimized for the transport of blood, with limited loss of pressure, over relatively large distances, to the branches that supply specific tissues or organs. The arrangement of the pulmonary vasculature results in unique characteristics which will be discussed later (see "*Arterial time constant*").

The pulmonary system is connected in series with the systemic circulation. This layout allows the pulmonary circulation to operate at much lower pressures, while transporting the same flow as the systemic tree. To make this possible, the PVR is much lower than systemic vascular resistance.

mPAP is built up by the pressure resulting from PVR times CO, plus the outflow pressure of the pulmonary vasculature, i.e., LAP. LAP contributes a large proportion to mPAP when compared to the systemic counterpart. While RAP (the outflow pressure of the systemic tree) is around 2–6 mmHg, LAP is some 5–15 mmHg, quite considerable since a normal mPAP is 10–20 mmHg[36]


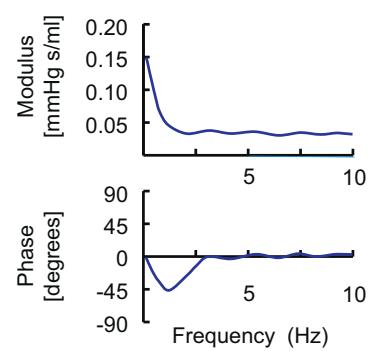
(see "Normal values in the pulmonary circulation" in this chapter). When calculating PVR from (mPAP−LAP)/CO it is clear that LAP contributes substantially and cannot be neglected in the calculation. For instance, if mPAP were 15 mmHg and LAP 5 mmHg, not taking the latter into account could result in an error of some 50%. In comparison, systemic mean arterial pressure is around 95 mmHg, thus neglecting an RAP of 2−6 mmHg in the calculation of systemic vascular resistance (SVR) results in an error close to 5%, which is negligible compared to the errors associated with the determination of CO (order of 30%).[22,37]

Resistance in the pulmonary circulation is not predominantly located in the arteries as in the systemic circulation, but is distributed over the system, resulting in a more gradual pressure drop (Fig. 55.2).[38−40]

While in the systemic circulation the pressure has decreased to approximately CVP beyond the capillaries, in the pulmonary circulation some pressure drop occurs behind the capillaries, suggesting that part of the PVR is located on the venous side.[41] Indeed, some 40% of PVR was reported to be contributed by the veins in an animal study.[39] Data reported by Chazova et al.[42] in health and PH suggest that indeed changes in the veins may increase PVR. In that sense, the term "pre-capillary PH," indicating PH related to vascular changes (as opposed to "post-capillary PH," which implicates elevated LA pressure as the cause (see Chapter 56)) could be considered confusing.

In the pulmonary circulation, compliance is more evenly spread over arteries and veins when compared to the systemic circulation. In the former the compliance in the veins is only 2 times larger compared to arterial compliance.[43] In the latter, compliance in the veins is some 20 times larger than in the arteries.[9]

Pressure and flow in the pulmonary capillaries are pulsatile,[44,45] and pulsatility was proposed to play a role in capillary recruitment[46] and in gas exchange.[47] Modeling studies confirm the pulsatility of pressure and flow,[48] and

further suggested flow pulsatility passes more or less unchanged through the microcirculation, while pressure pulsatility is reduced.[48] The effect of left atrial contraction on pressure and flow pulsatility was confirmed but considered secondary.[48] The pulsatility relative to mean capillary flow is reduced in advanced pulmonary hypertension.[49] Pulmonary endothelial dysfunction has been related to a lack of pulsatility.[50]


Descriptions of the pulmonary vascular load

Frequency domain

The vascular load can be fully described by calculating the input impedance. This is done in the frequency domain, pressure and flow as a function of time can be transformed to functions of frequency by the Fourier transform.[11] This transform yields a static term (also called DC term, from "direct current") and pulsatile terms (AC terms, from "alternating current") at the "harmonics" of the signal. The first harmonic is heart rate (HR), higher harmonics are multiples. Hemodynamic signals are adequately described by harmonics up to 10 times the heart rate. The static components of pressure and flow are mPAP and CO, respectively.

By using Ohm's law in the frequency domain, the input impedance (Fig. 55.3) is calculated by dividing the Fourier transforms of pressure and flow.[51−53]

The DC term (or zeroth harmonic) of the input impedance gives PVR. The steep drop in the modulus (magnitude) of the impedance and the negative phase after the zeroth harmonic are caused by the effect of the PAC on the pulsatile pressure−flow relation. For higher frequencies, the impedance levels out, and the phase returns to zero, indicating that the impedance behaves like a resistance. This is the characteristic impedance (Zc), which is determined by the characteristics of the proximal PA and describing the interaction of acceleration and deceleration of blood with a compliant vessel. To obtain Zc from the

FIGURE 55.2 Pressure drop in the pulmonary and systemic circulation. In the pulmonary system the decrease in pressure is more distributed over all vessels, even over the veins, while in the systemic circulation the largest pressure drop is seen in the arterioles.[11,38−40]

FIGURE 55.3 The input impedance of the pulmonary vascular load. The aspect is similar to the input impedance of the systemic vasculature, but the magnitude is lower.

input impedance spectrum (the "frequency method," see also Chapter 56), the average of the moduli of the higher frequencies (for example, 4th to 10th harmonics) is calculated. For lower harmonics, the phase is not (close to) zero, thus the impedance is not "real" (it has an "imaginary" part); for higher frequencies, the power of the signals is low, thus the signal-to-noise ratio becomes insufficient. A detailed review of the input impedance of the pulmonary circulation was written by Lammers et al.[54]

Windkessel description

The Windkessel model provides a useful simplification of the pulmonary arterial system.[55−57] The three-element Windkessel follows the frequency-domain description the input impedance well, thereby providing the values of PVR, PAC and Zc. The two-element follows the input impedance less well but can still be used for the estimation of compliance and of the arterial time constant, both discussed later.[56−58] Since the Windkessel model are "lumped" (or 0-dimensional) models, wave travel is not incorporated.

Pulmonary vascular resistance

As mentioned, PVR represents the "0th harmonic" of the input impedance; in practice it is calculated by using Ohm's law for hemodynamics

$$PVR = \frac{mPAP - PAWP}{CO} \qquad (55.1)$$

where mPAP−PAWP is the transpulmonary pressure gradient. In the field of pulmonology, often CO is expressed in l/min, together with the pressure gradient in mmHg, the units of PVR are mmHg·min/L or Wood units. When PAWP is not known or neglected, an approximation of PVR can be made which is called total pulmonary resistance (TPR):

$$TPR = \frac{mPAP}{CO} \qquad (55.2)$$

Note that in both calculations mean values are used, so oscillatory effects are not included. PVR is about a factor $10^{59−61}$ lower than the systemic vascular resistance (see sections "Differences between the systemic and pulmonary circulation" and "Normal values in the pulmonary circulation" of this chapter).

Pulmonary arterial compliance

PAC is defined as a change in volume (ΔV) for a given change in pressure (ΔP) in an experimentally isolated arterial segment filled with liquid.[59] In clinical practice, the most accurate PAC would be estimated using a 2-element Windkessel model,[58] which consists of resistance and

compliance.[60] Using measured flow waveform and resistance, arterial compliance that best predicts pulse pressure (PP) is obtained. A simpler method to estimate PAC is SV/PP,[61] assuming that there is no peripheral outflow (1-element Windkessel). In the hypothetical system to mimic an isolated arterial segment, SV is a change in volume and PP is a change in pressure. However, the end of the system is open, and therefore blood leaves the vascular bed during ejection, reducing the increase in vascular volume. SV/PP overestimates the true PAC derived from a 2-Windkessel model by 60%−80%.[56,57] Compared to the systemic circulation, accurately determining compliance in the pulmonary circulation may be even more difficult because resistive and compliant vessels overlap.[62]

PAC is 3 (or more) times higher[63−65] than systemic arterial compliance (see sections "Differences between the systemic and pulmonary circulation" and "Normal values in the pulmonary circulation" of this chapter).

Characteristic impedance

Zc is defined as input impedance in the absence of wave reflection.[59] While input impedance is represented by both moduli and phase, Zc is usually considered in terms of modulus only because the phase of Zc is close to zero. In the clinical setting, Zc can be obtained by the following two methods: (1) averaged moduli of input impedance at the higher frequencies (for example, the 4th to 10th harmonics, see the "Frequency domain" section) where fluctuations induced by reflections have settled (so-called the "frequency-domain method")[59] and 2) the slope of pressure−flow relationship in the early systole when wave reflection effects are minimal (so-called the "time-domain method")[66] (see also Chapter 56). The time-domain method avoids the complex mathematical processes such as the Fourier transform required for the frequency-domain method. On the other hand, the time-domain method needs the identification of a linear segment in the pressure−flow loops, which may carry some arbitrariness.[67] Nonetheless, if pertinently carried out, the two methods mostly show only small differences.[67]

Zc is dependent on the geometrical and mechanical properties of elastic arteries and blood viscosity,[11,59] which can be given as

$$Zc = \sqrt{\frac{\rho Eh}{2\pi^2 r^5}} \qquad (55.3)$$

where ρ: the density of blood, E: elastic modulus of proximal arteries, h: wall thickness, r: luminal radius.[11,59,68] Therefore, Zc is larger when the proximal arteries are stiffer (increasing elastic modulus), but smaller when the arteries dilate (increasing radius or cross-sectional area). The effect of Zc on the wave shape is explained in Chapter 56.

Wave reflection

In the very compliant arterial vasculature of the pulmonary circulation, wave reflection is much less pronounced than in the systemic circulation.[69] As a result, the pressure wave shape approaches a flow wave shape in appearance.[70] The differences in the pressure wave shape of the PAP and aortic pressure can be explained by wave reflection. When nitroprusside (a systemic vasodilator) is given (less wave reflection), the aortic pressure wave takes on a flowlike shape similar to PAP in the normal state, while the PAP becomes more like aortic pressure when serotonin is administered (which induces pulmonary vasoconstriction and more wave reflection) as shown in Fig. 55.4.

In Chapter 56, the increased relevance of pulse wave reflection in PH is discussed.

Relation of pressure levels

In the pulmonary circulation, sPAP and dPAP are proportional to mPAP in normal subjects and patients with several types of PH.[74–76]

$$sPAP = 1.61 \times mPAP \qquad (55.4)$$

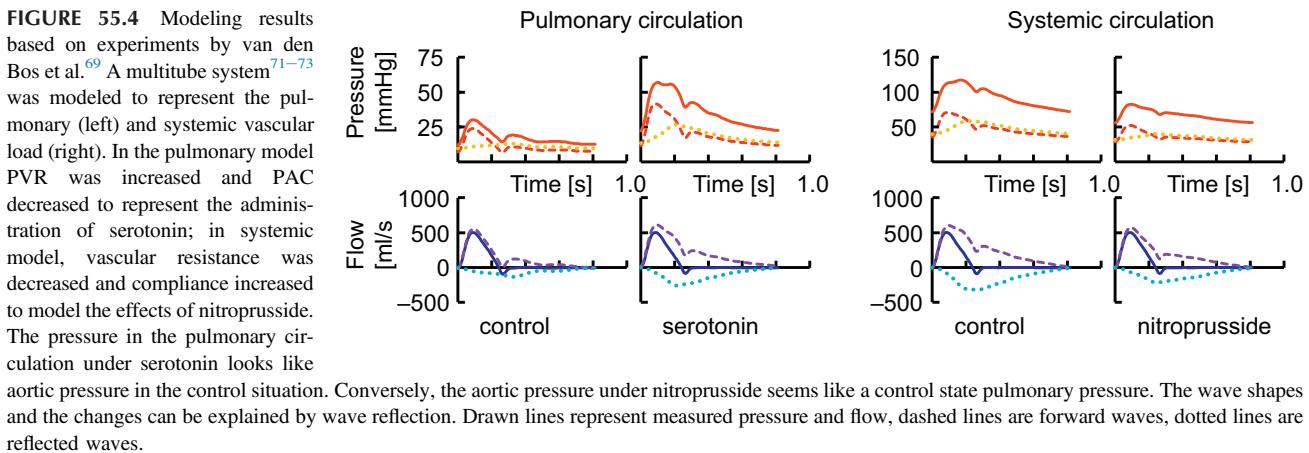
$$dPAP = 0.62 \times mPAP \qquad (55.5)$$

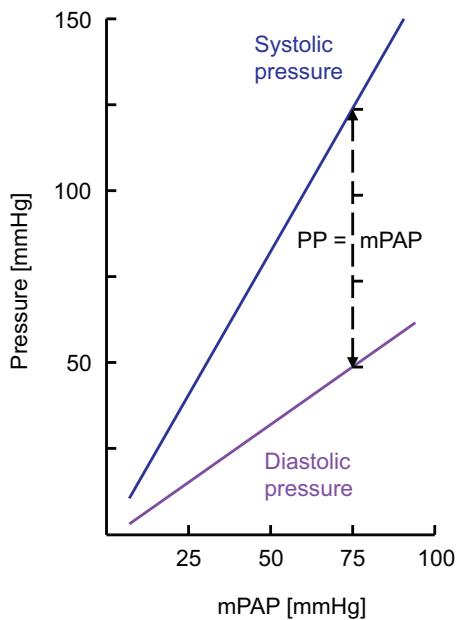
The relations are shown in Fig. 55.5.[76]

The proportionality approximates the golden ratio which could be the connecting factor.[77] If, for two numbers a and b, it holds that $(a + b)/a = a/b$, then a and b are related by the golden ratio φ. From this relation it follows that $\varphi = (1 + \sqrt{5})/2$: $\varphi \approx 1.618$, $1/\varphi \approx 0.618$. The golden ratio is found in many instances in nature, e.g., describing the arrangement of flower petals and the shape of the nautilus shell. Since antiquity the golden ratio, also called "the divine proportion," has been used in art and architecture.

From the golden ratio it follows that $PP = sPAP - dPAP = 1.618 \cdot mPAP - 0.618 \cdot mPAP = 1.0 \cdot mPAP$. The proportionality allows clinical physicians to estimate mPAP and dPAP from echocardiography measured sPAP (i.e., RV systolic pressure)[76,78] (Fig. 55.5). Since the pressure levels are closely related, in pulmonary hypertension there is no "isolated systolic hypertension" as known from the systemic circulation.

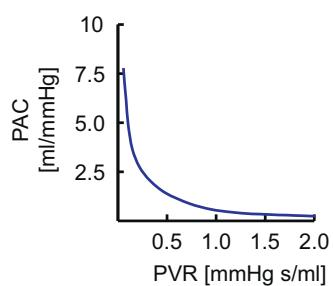
Arterial time constant

The "time constant (τ)" is a term that is perhaps more common in the fields of physics and engineering. In cardiovascular physiology, the time constant explains the elapsed time for the pressure in the vascular system to decay to 37% ($\approx 1/e$, e being the Euler's number, approximately equal to 2.718; the base of the natural logarithm) of its initial value when the arterial inflow is zero. Both a large resistance and a large compliance result in a long τ: a high compliance means a large storage of volume; a high resistance limits the outflow. Both are associated with a slow drop in pressure. The time constant in pulmonary vasculature can be determined in two ways: (1) from the diastolic PA pressure decay and (2) as the product of PVR and PAC (PVR × PAC).


Diastolic PA pressure decay can provide the time constant as follows.


$$PAP(t) = PAPes \times e^{-t/\tau} + PAWP \qquad (55.6)$$

where PAPes is PA end-systolic pressure when the pulmonary valve closes, and τ is the time constant. As time elapses after the valve closes ($t \rightarrow \infty$), PA pressure declines asymptotically to PAWP. In this method, pressure waves are required for obtaining the time constant.

Alternatively, a simpler method to derive time constant is the product of PVR and PAC (i.e., PVR × PAC). This method is based on a 2-element Windkessel model, where PVR and PAC are connected in a parallel configuration (called RC-circuit in electrical terms, in this case a first-order low pass filter system; the time constant is often called RC-time).


A remarkable finding is that the RC-time is constant in the pulmonary circulation, that was established by Lankhaar et al. in patients with pulmonary arterial hypertension as well as chronic thromboembolic pulmonary

FIGURE 55.4 Modeling results based on experiments by van den Bos et al.[69] A multitube system[71–73] was modeled to represent the pulmonary (left) and systemic vascular load (right). In the pulmonary model PVR was increased and PAC decreased to represent the administration of serotonin; in systemic model, vascular resistance was decreased and compliance increased to model the effects of nitroprusside. The pressure in the pulmonary circulation under serotonin looks like aortic pressure in the control situation. Conversely, the aortic pressure under nitroprusside seems like a control state pulmonary pressure. The wave shapes and the changes can be explained by wave reflection. Drawn lines represent measured pressure and flow, dashed lines are forward waves, dotted lines are reflected waves.

FIGURE 55.5 Systolic and diastolic pressure are proportional to mean pressure (*drawn lines*) in the pulmonary circulation.[74—76] The relation is such that the difference between systolic and diastolic pressure, PP, is approximately equal to mPAP. In the figure, the dashed line indicates a PP of 75 mmHg, at an mPAP of 75 mmHg.

hypertension (Fig. 55.6).[57,79] Reuben had already reported an inverse relation between PVR and PAC in 1971.[49] It is probably brought about by the unique structure of the pulmonary circulation, where resistance (Fig. 55.2) and compliance are evenly distributed over the vasculature.[80] Only 20% of PAC is found in the proximal PAs, while 80% distributed in the peripheral PAs.[81] In comparison, in the systemic circulation 60% located in the aorta.[58] Also, when one lung was removed, the RC-time remained the same, while R doubled but C halved.[81] Thus, PVR and PAC have a tight inverse relationship in the form of a hyperbola (Fig. 55.6).[57,79] These unique vascular properties in the pulmonary circulation have been suggested to explain the fixed pressure relations (see "Relation of pressure levels").[82]

FIGURE 55.6 In the pulmonary circulation, the product of resistance (PVR) and compliance (PAC) is constant, so that PAC as function of PVR shows a hyperbolic relation. PAC is reduced with increasing PVR.[57,79]

The right ventricle

Anatomy and function of the right ventricle

Ventricular anatomy

The RV is the most anterior part of the heart, located behind the sternum. It shares muscle layers with the LV, around which it is wrapped, giving the RV a crescent shape in transaction.[83] Seen from the side it has a triangular shape. Besides muscle layers, the RV and LV also share the pericardium and the septum. These anatomical features have as a consequence that the RV and LV continually interact (discussed in "Ventricular interaction").

Ventricular function

Although the function of the RV has been known since Harvey,[83] its relevance has been underestimated for a long time. Partly this is related to animal experiments that showed that circulation could be maintained by the LV alone. However, the left—right cooperation between the ventricles was disrupted when the pericardium was opened.[83] Moreover, the importance of the RV emerges from the astonishing way in which it is able to adapt to elevated pressure. Before birth, the RV contributes importantly to pressure and CO in the systemic circulation (while the pulmonary circulation is largely bypassed).[9,84,85] During exercise,[86,87] and also in the presence of continuously elevated afterload as in PH (see Chapter 56), the RV is able to cope with large increases in pressure.[78]

Descriptions of the right ventricular function

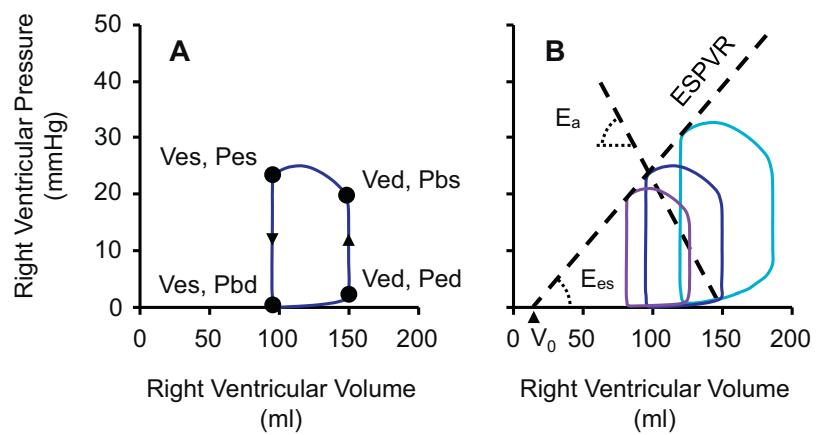
Ventricular pressure—volume relation

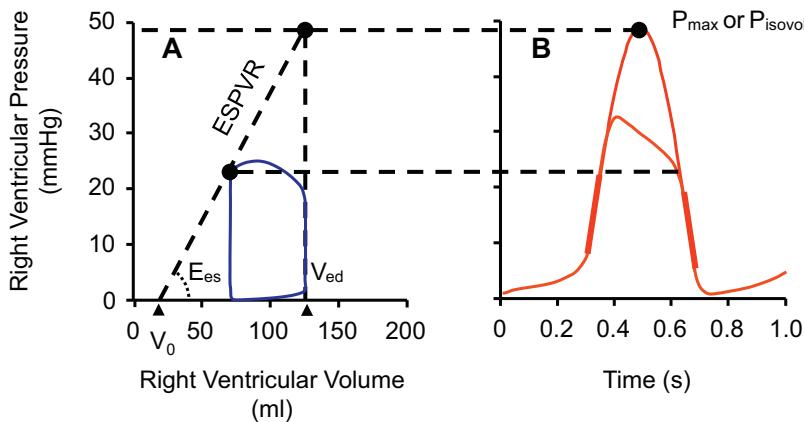
The ventricular pressure—volume relation (PV-relation, or PV-diagram/loop) has become the standard tool to describe the function of the RV,[88] and to obtain load-independent quantifications of systolic chamber function and diastolic stiffness, as well as insights about the energetic efficiency of the RV. The pump function graph gives some of the same information in a different representation, with the advantage that ventricular volume is not required, but CO or SV.[11,89—91]

To construct a PV-diagram, RVP and volume as a function of time are needed (see "Measurements in the pulmonary circulation"). When pressure is plotted against volume, time aspects are no longer evident; however, the loop runs in a counterclockwise manner, demonstrating that energy is generated by the RV (chamber volume decreases, while the RV generates pressure as a result muscle contraction, and receives volume while muscles are relaxed).

The area of the PV-loop is called stroke work and represents the external work of the ventricle. For further information on the pressure volume plane, we refer the

reader to Chapter 15; for further information regarding the work and energy consumption of the RV, we refer the reader to Chapter 56.

When looking at the PV-loop (Fig. 55.7), filling of the ventricle commences at the lowest left point, with the co-ordinates volume at the beginning of diastole (Vbd, which is the same as the end-systolic volume, Ves, when valves are competent) and pressure at the beginning of diastole (Pbd). With the increase of volume, the pressure increases slightly, until maximal volume is reached: end-diastolic volume (Ved) and end-diastolic pressure (Ped). When the RV starts to contract, pressure increases rapidly, first without a change in volume (the isovolumic contraction phase), until pressure at the beginning of systole is reached (Pbs) and the pulmo-nary valve opens. Pressure increases further and then de-clines, while the heart is ejecting, thus RV volume decreases. When RVP falls below PAP, the pulmonary valve closes: end-systolic pressure (Pes), and volume is at its lowest: end-systolic volume (Ves, which is the same as Vbd). Pressure in the RV drops rapidly (without changes in volume: the iso-volumic relaxation phase) until Pbd and the cycle repeats. The difference between maximal and minimal RV volume (Ved−Ves) equals SV.


Pressure divided by volume has the units of elastance, and several elastances can be quantified and be made visible in the PV-diagram. The elastance of the ventricle varies over the cardiac cycle, elastance is low (compliance is high) in dias-tole (allowing filling of the ventricle with little increase in pressure) and elastance is high in systole (causing a pressure increase and ventricular ejection). The changes in elastance can be represented by the slope of a line that hinges around a point on the volume axis, called V_0 (or V_d for dead volume), which is the theoretical volume of the ventricle with zero pressure. During the cardiac cycle, the slope of the line in-creases little during diastolic filling, increases steeply with systole, is maximal at end-systole, then rapidly decreases. The elastance as a function of time has been described by Senzaki et al. for the LV.[94]


End-systolic elastance

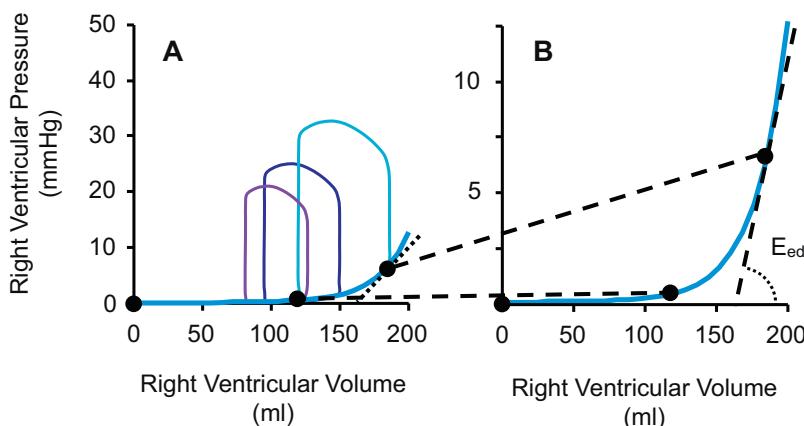
The maximal slope of the elastance line is of great interest, as it is a load-independent measure of chamber contractility. This maximal slope is called end-systolic elastance (Ees, Fig. 55.7). Since V_0 is not known in practice, other points on this line should be found so to determine its slope. This can be approached by changing the preload of the RV, e.g., by vena cava occlusion. With less preload available to the RV, Ved, and Ped will decrease (Fig. 55.7), and with that, SV will be reduced, and Ves and Pes will descend along the line that describes the contractility of the RV.[92,93] The slope of the line, however, remains the same independent of the preload changes. Several loops can be obtained during the preload reduction and connecting the end-systolic pressure−volume points allows for constructing the end-systolic pressure−volume relation (ESPVR), the slope of which is, as mentioned, Ees. The assumption that the ESPVR is a straight line is a simplification that can cause errors depending on the amount and direction of the preload changes. This has con-sequences for the determination of Ees and of V_0,[95] as was demonstrated in the systemic circulation[95] and discussed in the pulmonary circulation.[96]

The construction of the ESPVR requires simultaneous measurement of ventricular pressure and volume (e.g., with the conductance catheter), and an intervention to change preload, which is usually not feasible, although a Valsalva maneuver has been used.[97] As an alternative to the multiple-loop method, a single beat method has been proposed by Sunagawa et al.,[98] extended by Senzaki et al.[94] and validated for the RV by Brimioulle et al.[99] Nonetheless, many caveats known from studies on the systemic circulation[100] and recently discussed for the pulmonary circulation[101] should be kept in mind. The single beat method assumes that the maximal pressure that can be reached by the RV, without ejecting, can the approximated by extrapolating the iso-volumic contraction phase and isovolumic relaxation phase with a sine curve (Fig. 55.8). The maximal pressure of the sine is called Pmax, or Pisovol, since an isovolumic contraction is

FIGURE 55.7 (A) The pressure−volume diagram of the RV. Filling commences at the point labeled Ves, Pbd: end-systolic volume and pressure at the beginning of diastole. Maximal volume is reached at Ved, Ped: end-diastolic volume and end-diastolic pressure. The isovolumic contraction phase ends in Ved, Pbs: same volume, pressure at the beginning of systole. Ejection starts and continues to Ves, Pes: end-systolic volume, as mentioned, and end-systolic pressure. Pressure falls with no change in volume, the isovolumic relaxation phase. When pressure turns Pbd again, the loop is closed. (B) When the preload of the RV changes, differing loops are generated. The end-systolic pres-sure−volume relation (ESPVR) is the line that can be drawn through the end-systolic pressure−volume points. The slope of the ESPVR is called end-systolic elastance (Ees), a measure of the contractility of the RV.[92,93]

FIGURE 55.8 The single beat method (A) to determine Ees uses a fit of a sine wave to the isovolumic contraction and isovolumic relaxation phases of RVP as a function of time (B), assuming it describes the pressure in the RV when it cannot eject. The maximal pressure of the isovolumic contraction is Pmax (also called Pisovol or Piso). In the pressure—volume plane (A), the isovolumic contraction is represented by a dashed vertical line (only pressure increase, no volume change) going up to Pmax. Then, the ESPVR can be determined by from the two points Ved, Pmax, and Ves, Pes. Ees (and V_0) can now be calculated.

mimicked. An isovolumic contraction in the PV-diagram would be represented by an increase to Pmax without a change in volume (volume remains equal to Ved) (Fig. 55.8, left panel, right dashed line). Together with the end-systolic pressure—volume point of one PV-loop, the slope of the ESPVR can be determined and thus contractility:

Ees = (Pmax − Pes)/(Ved − Ves) = (Pmax − Pes)/SV. Instead of Pes, often mPAP is used since it can be more readily and reliably obtained.


Arterial elastance

A convenient heart-independent description of load that can be plotted in the PV-diagram is arterial elastance (Ea).[102] It is the slope of a line that is defined by the ratio Pes/SV (Fig. 55.7). Although Ea has the units of elastance, it has nothing to do with the elastance (or its reciprocal value PAC) of the pulmonary vasculature.[102] In fact, it is related to the heart-independent load description TPR, but without HR (which is absent in the PV-diagram). After all, TPR is mPAP/CO; since CO = SV·HR, TPR = mPAP/(SV·HR), and as we have seen that instead of Pes, mPAP can be used,[87,103−105]   Ea = Pes/SV ≈ mPAP/SV.   Thus, Ea = TPR·HR. That Ea is a nonpulsatile description of load can also be appreciated from the fact that a steady

pressure is used (Ees or mPAP) and not a ΔP such as PP which is used for the calculation of PAC from SV/PP (see section "Pulmonary arterial compliance"). Besides this theoretical demonstration that Ea is a representation of nonpulsatile load, modeling approaches[106] and cohort studies demonstrate the same.[107] From the strong dependency on heart rate it follows that it (as well as diastolic and systolic duration) is required to remain constant.[100] As discussed, the contribution of downstream pressure (PAWP) to mPAP is relatively important compared to the role of CVP in the systemic circulation. Therefore, neglecting PAWP in the calculation of Ea is a point of concern, that has not yet been resolved.

End-diastolic elastance

Like systolic function, diastolic function of the RV can be determined from the PV-diagram, by assessing the lower part of the loop (Fig. 55.9, left panel). Ideally, again preload changes are imposed, resulting in several different loops. From the end-diastolic points, an end-diastolic pressure—volume relation (EDPVR) can be constructed. The slope of the EDPVR at the end-diastolic pressure—volume point represents the stiffness, called end-diastolic elastance (Eed) of the RV. Eed the reveals much pressure is needed to fill

FIGURE 55.9 Multiple loops in the pressure—volume plane (A) give insight in the end-diastolic elastance of the RV.[93] Multiple loops however are difficult to obtain. The single beat method to determine Eed uses an exponential function (giving pressure as function of volume) to approximate the EDPVR. The following pressure—volume points are used: 0, 0; Ves, Pbd (end-systolic volume equaling begin-diastolic volume, and begin-diastolic pressure); and Ved, Ped (end-diastolic volume, and end-diastolic pressure, see also Fig. 55.7). In (B), these points and the fit are shown on an expanded scale. In the end-diastolic point, the tangent to the exponential curve is drawn (A: *dotted*; B: *dashed*). The slope in (Eed, Ped) can be calculated as measure of end-diastolic elastance Eed from the derivative of the exponential function.[103,104]

the RV to the Ved. The relation between pressure and volume of the passive RV is highly nonlinear, steeply increasing for high volumes. Eed can be affected by disease[103] (see Chapter 56).

Calculating Eed from multiple loops[93] gives the most reliable results, however, these are difficult to obtain. Therefore, also a single beat method to determine Eed is being used[103,104] (Fig. 55.9). Fitting an exponential function through the points (0,0), (Ees, Pes), and (Eed, Ped), the EDPVR can be approximated, and from the derivative of the function the slope in (Eed, Ped) can be calculated. The exponential used to describe the pressure–volume relation is $P = \alpha[\exp(\beta V) - 1]$, with P and V being pressure and volume, and α and β curve-fitting constants, β represents a diastolic stiffness constant. The derivative of the function is $dP/dV = \alpha\beta \times \exp(\beta V)$; filling in Ved gives the slope in that point, thus $Eed = \alpha\beta \times \exp(\beta Ved)$.[103,104] Both β as well as Eed are used to describe diastolic RV stiffness, Eed specifically when the RV is maximally filled.

Ventricular interaction

The interaction between the RV and the LV[108] is determined by the circuitry (being connected in series, "series interaction") and by the shared anatomy[109] ("parallel interaction," also called "direct interdependence" or "direct interaction"). In series interaction, the contribution of (elevated) LAP to PAP "passive backward transmission of left-sided filling pressures")[110] is of relevance, particularly in left-sided failure. In addition, the (reduction of) CO of the one ventricle is important since it determines the CO of the other ventricle.[111]

In normal physiology, the effect of the LV on the RV is much greater than vice versa. In PH (see Chapter 56), leftward septal bowing caused by a prolonged RV contraction time of the RV[112] hampers LV filling.[111]

Ventriculoarterial coupling

Maximal power or efficiency: energetic coupling

Ventriculoarterial coupling is a term that is often used broadly to describe interactions between the RV and its vascular load. Here we intend RV coupling to relate to the concept that the RV is working in a way such that maximal external power is produced, or in a way that efficiency is highest. These need not be identical but are close in practice.[11] Mean output power is calculated from mPAP times CO. Input power can be calculated from oxygen consumption.[113] The ratio of output power and input power is efficiency.[11]

As mentioned earlier in this chapter ("Ventricular pressure-volume relation"), the area of the PV-loop represents the external work of the ventricle. The pressure–

volume area enclosed by the ESPVR, the EDPVR, and the isovolumic contraction limb (dashed vertical line in Fig. 55.8) is related to cardiac oxygen consumption.[114] In PH, higher RV contractility and ventricular dilatation will thus increase pressure–volume area, see Chapter 56.

Ventriculoarterial coupling determined from the pressure–volume relation

For the LV it has been shown that external work to the arterial load is maximized when the ventricular and arterial elastances are equal, thus the ratio Ees/Ea = 1; while for Ees/Ea = 2, maximal efficiency is reached.[115] It has been proposed that the ventricle adapts to its load, in pulmonary hypertension Ea increases and Ees follows suit by increasing contractility and ventricular wall thickness.[78] As long as coupling is preserved, SV can be maintained. In the end stage of pulmonary hypertension, the ventricle uncouples, and SV is reduced. Uncoupling is associated with increased ventricular volumes and increased wall stress.[13]

Surrogate measures of ventriculoarterial coupling in the pressure–volume plane

Since Ees = (Pmax − Pes)/SV, and since Ea = Pes/SV, the Ees/Ea ratio is a pressure-only relation: Ees/Ea = (Pmax − Pes)/Pes. A volume-only approach would be of interest since it could be obtained noninvasively. As described earlier in this chapter, Ees can also be calculated from Pes/(Ves − V$_0$); together with Ea the ratio is then Ees/Ea = [Pes/(Ves − V$_0$)]/[Pes/SV] = SV/(Ves − V$_0$). It has been suggested to neglect V$_0$, giving Ees/Ea ≈ SV/Ves.[116,117] However, V$_0$ is not negligible, particularly not in patients with a dilated RV.[118] Moreover, SV/Ves is inversely related to RV EF. After all, EF = SV/Ved, and Ves = Ved − SV   thus,   SV/Ves = SV/(Ved − SV). Dividing numerator and denominator by Ved, we get [SV/Ved]/(Ved/Ved − SV/Ved) = EF/(1 − EF). This simplified volume-only approach gives no information over and above EF; furthermore, it has not been shown to represent coupling. See also Chapter 56.

Differences between the systemic and pulmonary circulation

Here we list some marked differences between the systemic and pulmonary circulations (Table 55.1).

Normal values in the pulmonary circulation

Normal values for pressures of pulmonary circulation and volumes and intrinsic characteristics of the pulmonary cardiovascular system are collected in Table 55.2.

TABLE 55.1 Differences between the systemic and pulmonary circulations.

Systemic	Pulmonary
Aorta forms a central reservoir: Most of the compliance is situated in the aorta	Arteries form a distributed reservoir: compliance is distributed over the arteries
Venous compliance 20 times larger than arterial compliance (much storage in veins)	Venous compliance 2 times larger than arterial compliance (little storage in veins)
One main artery with branching according to organ site and need (wide or narrow, long or short: e.g., kidneys receive 20%—25% of CO which is accommodated by short wide arteries, while the bronchial arteries are relatively long and narrow, only some 1—2% of CO needs to be transported)	From two main pulmonary arteries, branching into three daughter vessels (each of comparable diameter)
Many arteries are accompanied by 2 veins: the approximate ratio of veins:arteries = 2:1 (except for the largest vessels, where the ratio = 1:1, e.g., descending aorta and inferior vena cava)	Most of the arteries have 1 accompanying vein: overall the ratio of veins:arteries = 1:1 (except for the largest vessels, where the ratio = 2:1, e.g., two left and two right pulmonary veins and one left and one right pulmonary artery)
Little resistance in supplying arteries and collecting veins. Main pressure-drop over arterioles of organ/tissue	Resistance is more gradually increasing in the supplying arteries toward the arterioles, and more gradually decreasing in collecting veins. Little pressure-drop over arterioles
Hypoxic vasodilatation	Hypoxic vasoconstriction

TABLE 55.2 Normal values.

Pressures	Middle	Min	Max
Systolic pulmonary pressure (sPAP, mmHg)	22	16	32
Diastolic pulmonary pressure (dPAP, mmHg)	9	6	13
Mean pulmonary pressure (mPAP, mmHg)	14	10	20
Pulmonary artery wedge pressure (PAWP, mmHg)	10	5	15
Systolic right ventricular pressure (sRVP, mmHg)	22	16	32
(End) Diastolic right ventricular pressure (dRVP, mmHg)	7	2	10
Right atrial pressure (RAP, mmHg)	4	2	6
Volumes			
Right ventricular end-systolic volume (Ves, mL)	55	10	100
Right ventricular end-diastolic volume (Ved, mL)	140	60	220
Right ventricular ejection fraction (EF, %)	60	45	75
Intrinsic characteristics			
Pulmonary vascular resistance (PVR, mmHg·s/mL)	0.1	0.055	0.18
Pulmonary arterial compliance (PAC, mL/mmHg)	4	—	12
Characteristic impedance (Zc, mmHg·s/mL)	0.017	—	—
End-systolic elastance (Ees, mmHg/ml)	1.3	—	—
End-diastolic elastance (Eed, mmHg/mL)	0.2	—	—

The values in the table are based on several studies.[3,51,63,80,83,103,119—123]

Summary

In this chapter, we described physiologic concepts to understand the pulmonary circulation. Based on measurements, we looked at pulsatile and static hemodynamics, and derived descriptions of the cardiovascular system and ventricular–arterial interaction.

It is useful to distinguish between system characteristics, determined by the interaction between the RV and arterial load, which can typically be obtained by measurement of pressure, flow, or volume, e.g., PAP, CO, or EF. Intrinsic characteristics can be obtained by combining measurements, e.g., PVR and input impedance from PA pressure and flow, or Ees and Eed from RVP and volume.

Therefore, we started by describing measurements relevant to the pulmonary circulation (system characteristics). These measurements allowed us to determine intrinsic characteristics, the heart-independent vascular load, and the load-independent RV function. Finally, by combining intrinsic characteristics of the heart (Ees) and its vascular load (Ea), coupling could be defined: the condition in which ventricular–arterial interaction is optimally efficient.

Several features unique to the pulmonary circulation were discussed, such as the golden ratio relation between pressure levels and the constant RC-time and ended with a listing of differences between pulmonary and systemic circulation, and a collection of normal values of the pulmonary hemodynamics and the cardiovascular system.

Chapter 56

Pulmonary arterial load and ventricular–arterial coupling in pulmonary hypertension

Masafumi Fukumitsu, Anton Vonk Noordegraaf and Berend E. Westerhof

Department of Pulmonary Medicine, Amsterdam Universitair Medische Centra, Vrije Universiteit Amsterdam, Amsterdam Cardiovascular Sciences, Amsterdam, the Netherlands

Introduction

Definition of pulmonary hypertension

Pulmonary hypertension (PH) is a pathophysiological disorder that is characterized as increased pulmonary artery (PA) pressure. In the 2015 European Society of Cardiology (ESC)/the European Respiratory Society (ERS) guidelines for the diagnosis and treatment of PH, PH is defined by a mean pulmonary artery pressure (mPAP) ≥25 mmHg at rest, measured via right heart catheterization (RHC),[1] although a new lower threshold (mPAP >20 mmHg) has been recently proposed at the sixth World Symposium on PH.[2] Based on the "downstream" pressure (left atrial pressure, represented by pulmonary artery wedge pressure, PAWP), PH is hemodynamically classified into precapillary PH and postcapillary PH. In the current guidelines, precapillary PH describes PH with PAWP ≤15 mmHg, and postcapillary PH is PH with PAWP >15 mmHg.[1]

The pathophysiological process behind the development of PH can depend on several underlying etiologies. From the viewpoint of pathophysiological characteristics, the clinical classification distinguishes PH into the following five groups (Table 56.1), group-1: pulmonary arterial hypertension (PAH); group-2: PH due to left heart diseases (LHDs); group-3: PH due to lung diseases and/or hypoxia; group-4: chronic thromboembolic PH (CTEPH) and other PA obstruction; group-5: PH with unclear and/or multifactorial mechanisms.[1] Although these five groups have pathologically distinct etiologies, all of the groups can induce severe PH, where the right ventricle (RV) function deteriorates as a consequence of increased arterial loading.[3,4] Most importantly, right-sided heart failure is the main cause of death in patients with PH.[3–6] Consequently, it is essential to establish the pathophysiological mechanisms by which the pulmonary arterial load compromises RV function in PH.

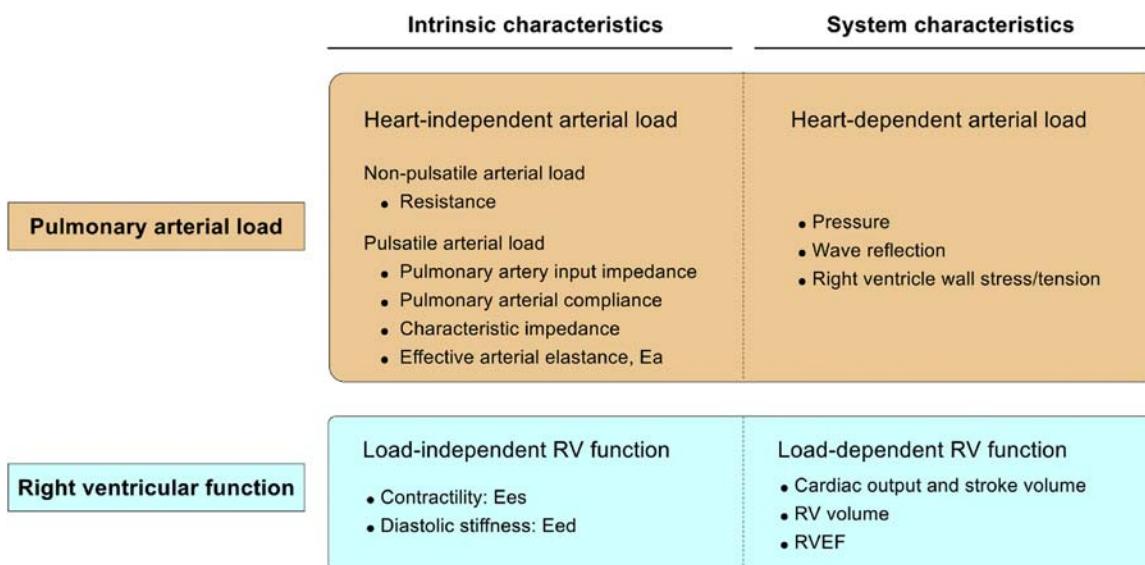
5. Pulmonary hypertension with unclear and/or multifactorial mechanisms

The properties of pulmonary arterial load and right ventricular function


To understand the pulmonary arterial load and RV function, the terms should be described correctly. The properties of arterial load and RV function can be described in two ways (Fig. 56.1), using (1) the intrinsic characteristics and (2) the system characteristics.[7] The intrinsic characteristics of the arterial load and the RV function are "independent," and insensitive to each other. The intrinsic characteristics of arterial load (vascular properties) can be determined from the PA pressure-flow relationship, and those of RV function are given by RV pressure-volume relationship. Interaction between the intrinsic characteristics of arterial load and RV function yields the system characteristics, for example, cardiac output (CO) and RV ejection fraction (RVEF) (Fig. 56.1).

The intrinsic characteristics of arterial load (vascular properties) are called "heart-independent," and the system characteristics of arterial load are called "heart-dependent" (further referred to as heart-independent or heart-dependent arterial load). The heart-independent arterial load includes pulmonary vascular resistance (PVR), total pulmonary arterial compliance (PAC), characteristic impedance of the proximal arteries (Zc), and effective arterial elastance (Ea), implicitly assuming that heart rate (a ventricular variable) is constant. On the other hand, the heart-dependent arterial load is provided by pressure (mean, systolic and diastolic pressure, and pulse pressure),

wave reflection (magnitude and timing of reflected waves), and RV wall stress/tension (Fig. 56.1).

The intrinsic characteristics of RV function are also called "load-independent," and the system characteristics are called "load-dependent" (further referred to as load-independent or load-dependent RV function). The load-independent RV function is represented by RV contractility (represented by end-systolic RV pressure-volume relationship) and diastolic stiffness (represented by end-diastolic RV pressure-volume relationship). Load-dependent RV function includes CO, stroke volume (SV), RV volumes (RV end-diastolic volume [RVEDV] and RV end-systolic volume [RVESV]), and RVEF.

In clinical practice, the heart-dependent load (PA pressure) and the load-dependent RV function (CO and RVEF) are more commonly used; however, we have to be careful when interpreting these parameters because a change in PA pressure or in CO cannot always be attributed to a change in pulmonary vasculature or the RV. For example, whereas the RV is in a hyper-contractile state, decreased RVEF and CO are present in patients with PAH.[8] The exact interpretation requires a sufficient understanding of the heart-independent load and the load-independent RV function. This chapter explains (1) properties of pulmonary arterial load and (2) properties of the RV function in terms of intrinsic and system characteristics, and describes (3) the mechanisms of how the RV adapts to increased pulmonary arterial load in PH.

FIGURE 56.1 The properties of pulmonary arterial load and right ventricular function. The pulmonary arterial load and right ventricular functions are characterized by their intrinsic characteristics. System characteristics are derived from cardiopulmonary interaction. *Ea*, pulmonary effective arterial elastance; *RV*, right ventricle; *Ees*, end-systolic right ventricular elastance; *Eed*, end-diastolic right ventricular elastance; *RVEF*, right ventricular ejection fraction.

Pulmonary arterial load in pulmonary hypertension

Heart-independent arterial load

The heart-independent load describes the intrinsic characteristic of the arterial load, represented by PVR, total PAC, characteristic impedance of the proximal arteries (Zc), and effective arterial elastance (Ea). In the human body, the ventricle ejects blood into the vascular bed beat-by-beat, which generates arterial pressure and flow waves. Since waves are the signals which vary in time, the description of vascular properties should include not only the nonpulsatile (steady) but also pulsatile (dynamic) state. Thus, the heart-independent arterial load is further classified into nonpulsatile load and pulsatile load.

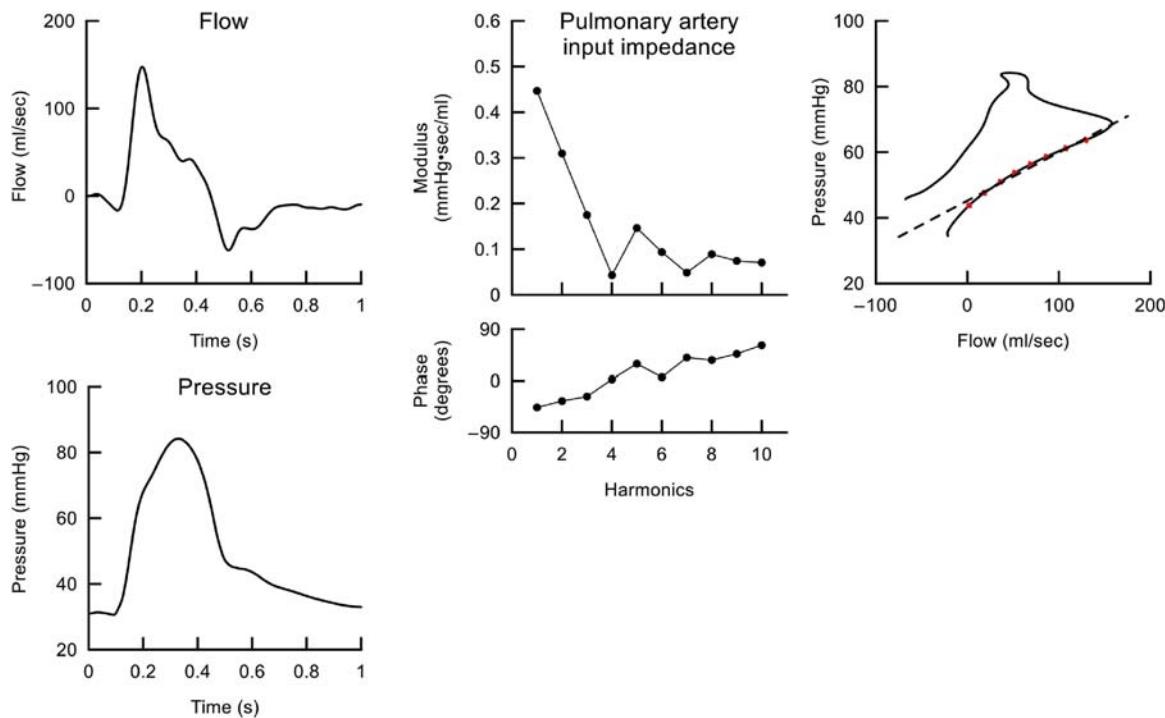
Nonpulsatile arterial load: pulmonary vascular resistance

The nonpulsatile arterial load is a vascular property in a nonpulsatile state without the emergence of waves, which is given by resistance at 0 Hz. In clinical practice, physicians can assess nonpulsatile load using PVR or total pulmonary resistance (TPR), calculated by mean values of pressure and flow. PVR is calculated as (mPAP−PAWP)/CO, where mPAP is mean pulmonary arterial pressure. CO corresponds to mean flow per one minute. TPR is calculated as mPAP/CO.

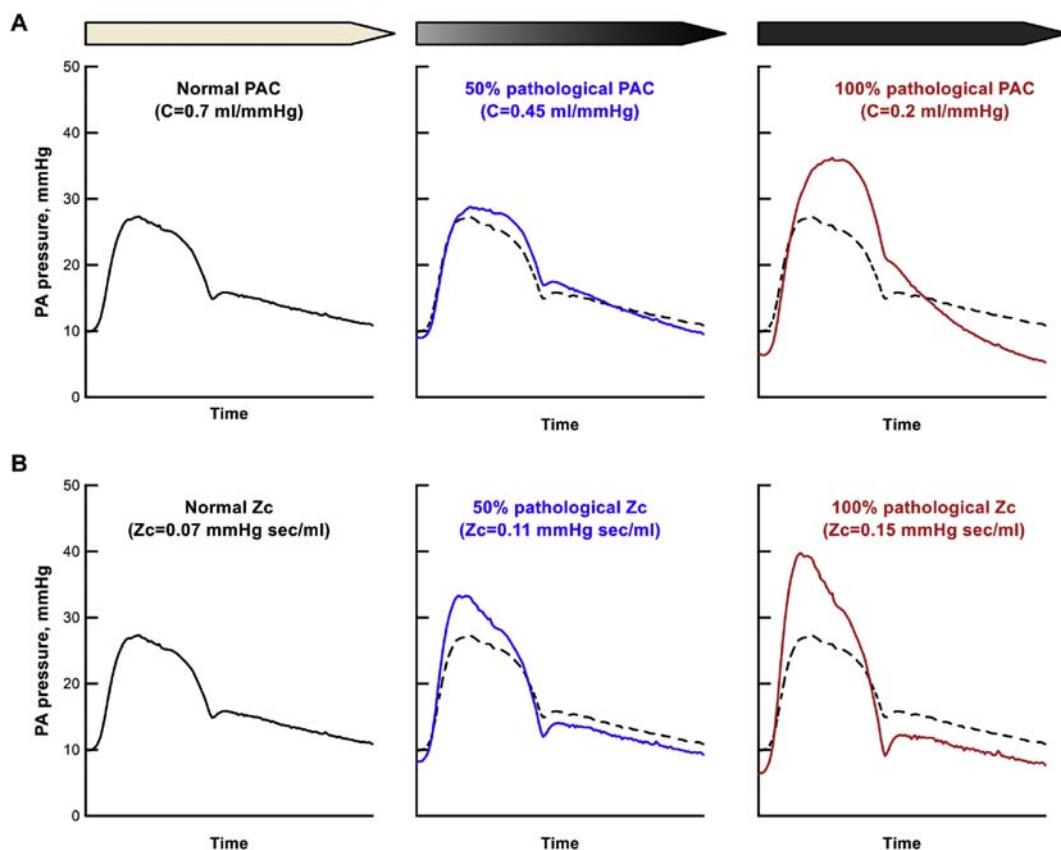
PVR represents hydraulic resistance which covers the whole pulmonary vasculature: the main trunk of pulmonary arteries, small arteries, capillaries, and veins. In PH, PVR increases as a consequence of vascular remodeling. While a 50% increase in vascular resistance in systemic hypertension is considered exceptional, PVR increases by four times or more in PH.[9] Although PVR is undoubtedly the simplest and most widely used description of arterial load, it captures only nonpulsatile load and thus ignores pulsatile load. Indeed, a reduction in PVR is not associated with improved RV function and clinical prognosis in patients with PH.[5] Thus, PVR does not provide a complete description of RV loading in PH.

Pulsatile arterial load

Pulmonary arterial input impedance

The pulsatile arterial load is nonnegligible when we treat patients with PH. Assessment of pulsatile arterial load requires an adequate understanding of pressure and flow "waves," which are generated by the heartbeat. As discussed in detail in Chapters 1 and 3, based on the magnitude and cycle length of these waves, pressure and flow waveforms can be converted to pressure and flow spectrum in the frequency domain. Physiologically, pulsatile loading can be described most completely by pulmonary arterial input impedance, which is calculated as P(f)/F(f) at each frequency, where P(f): pressure spectrum at each frequency, F(f): flow spectrum at each frequency. PA input impedance describes the vascular properties at each frequency, which consists of magnitude and phase (Fig. 56.2). Assessment of PA input impedance is feasible in clinical settings;[10,11] however, the interpretation is not straightforward for most clinicians. In this regard, the derivatives of pulmonary arterial input impedance, for example, total PAC, Ea (heart-independent load, heart rate remaining constant), and wave reflection and wall stress (heart-dependent load) may be more practical and more intuitive to understand pulsatile loading in PH. In Chapter 55, the derivation of PAC was described; here we focus on its pathological changes in PH.


Pulmonary arterial compliance

PAC is the most used parameter to evaluate pulsatile load for patients with PH. When PAC is estimated from SV/PP, PAC is 4.0 mmHg/mL in control subjects;[12] however, PAC decreases to 30−40% (1.2−1.6 mmHg/mL) in patients with precapillary PH.[13−15] While in the systemic circulation, 60% of arterial compliance resides in the proximal aorta,[16] PAC is distributed mainly to small peripheral pulmonary vessels rather than proximal large arteries. Proximal arterial compliance estimated by magnetic resonance imaging (MRI) accounts for only 20% of total PAC for the whole pulmonary vascular bed.[14]


In patients with postcapillary PH, PAC derived from SV/PP can be altered by PAWP. When PVR is given as 3.0 Wood units, PAC decreases from 3.34 mmHg/mL to 1.65 mmHg/mL (50% decrease) and to 0.82 mmHg/mL (25% decrease), if PAWP increases from 0 to 25 mmHg−50 mmHg, respectively.[17] Since PAC has an inverse relationship with PVR[18] (see Chapter 55, and the section below: "Time constant of the pulmonary circulation"), PAC is reduced with increasing PVR.[12,13] Decreased PAC changes PA pressure waveform and increases systolic PAP (sPAP) independently of PVR (Fig. 56.3). Increased PA (or RV) pressure elevates RV wall stress (see section "Right ventricle wall stress/tension"). Decreased PAC is associated with exercise intolerance and clinical adverse events in patients with PH.[19−22] PAC is the key pulsatile load for the management of patients with PH.

Time constant of the pulmonary circulation

The time constant of the pulmonary circulation (which equals PVR×PAC, as discussed in detail in Chapter 55) is similar in healthy individuals and patients with PAH and CTEPH, and even after treatment.[12,13] PVR×PAC for the single lung equals to that of both lungs together.[14]

FIGURE 56.2 Pulmonary artery flow and pressure waveforms and pulmonary arterial input impedance. Pulmonary artery input impedance represents the pulmonary pressure-flow relationship at each frequency (or harmonic). Pulmonary artery input impedance consists of modulus and phase. Characteristic impedance is obtained by (1) averaged modulus in the range of high frequencies or harmonics (for example: 4th to 10th harmonics) (frequency-method) or (2) a slope of pressure-flow relationship in the early systole (time-domain method).

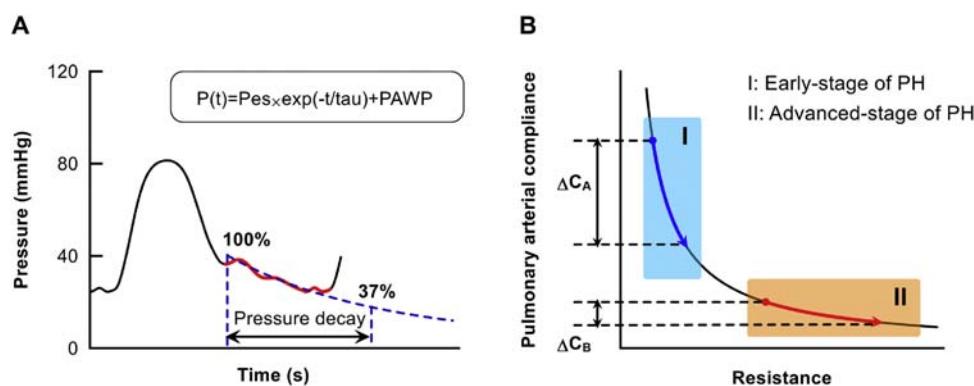
FIGURE 56.3 Effect of (A) pulmonary arterial compliance (PAC) and (B) characteristic impedance of the proximal arteries (Zc) on pulmonary artery pressure waveform. Data are simulation data using three-element Windkessel arterial model, which is constructed from a preclinical study of Fukumitsu. et al.[108] (A) When only PAC is decreased, PA pressure is increased, with its peak occurring in later systole. (B) When only Zc is increased from normal to pathological value of pulmonary hypertension, PA pressure is elevated steeply with its peak remaining in early systole. Both Zc and PAC alter PA pressure waves independently. Since resistance is unchanged, mean PA pressure remains a normal value in this simulation.

Although there is still a debate whether PVR×PAC is unchanged in patients with proximal obstruction of the pulmonary arteries,[23,24] a larger cohort study shows the inverse relationship of PVR and PAC in a wide range of severity of PH.[17] Of note, PVR×PAC is sensitive to pulmonary venous pressure (mean PAWP)[17]: in the calculation of PVR, PAWP is taken into account, but in the estimation of PAC from SV/PP, it is not (see Chapter 55, the SV/PP method to estimate PAC assumes that there is no outflow from the system). Therefore, the PVR×PAC product is influenced by PAWP. A more direct measurement of the time constant by analyses of the diastolic PA pressure decay (Fig. 56.4) would give an answer and reveal the effect of PAWP on the time constant in PH.[25]

The inverse relationship of PVR and PAC provides practically important insights to physicians. The change in PAC is more noticeable than the change in PVR in patients with early-stage of PH,[12] while in the more advanced-stage of PH, change in PVR is greater than that of PAC (Fig. 56.4). Therefore, PAC may be more suitable to detect the early stage of PH before an increase in PVR is marked.

Characteristic impedance of the proximal arteries

Characteristic impedance of the proximal arteries (an abbreviation is Zc) is not commonly used in clinical practice. However, Zc is important to describe the pulsatile arterial load, because Zc has the two relevant clinical implications: (1) Zc represents the vascular properties of the proximal PA, and (2) Zc plays a central role in wave reflection (see "wave reflection: wave separation analysis and wave intensity analysis").

Zc is defined as input impedance in the absence of wave reflection and can be determined in the frequency-domain (from the higher frequency range, see Chapter 55) or in


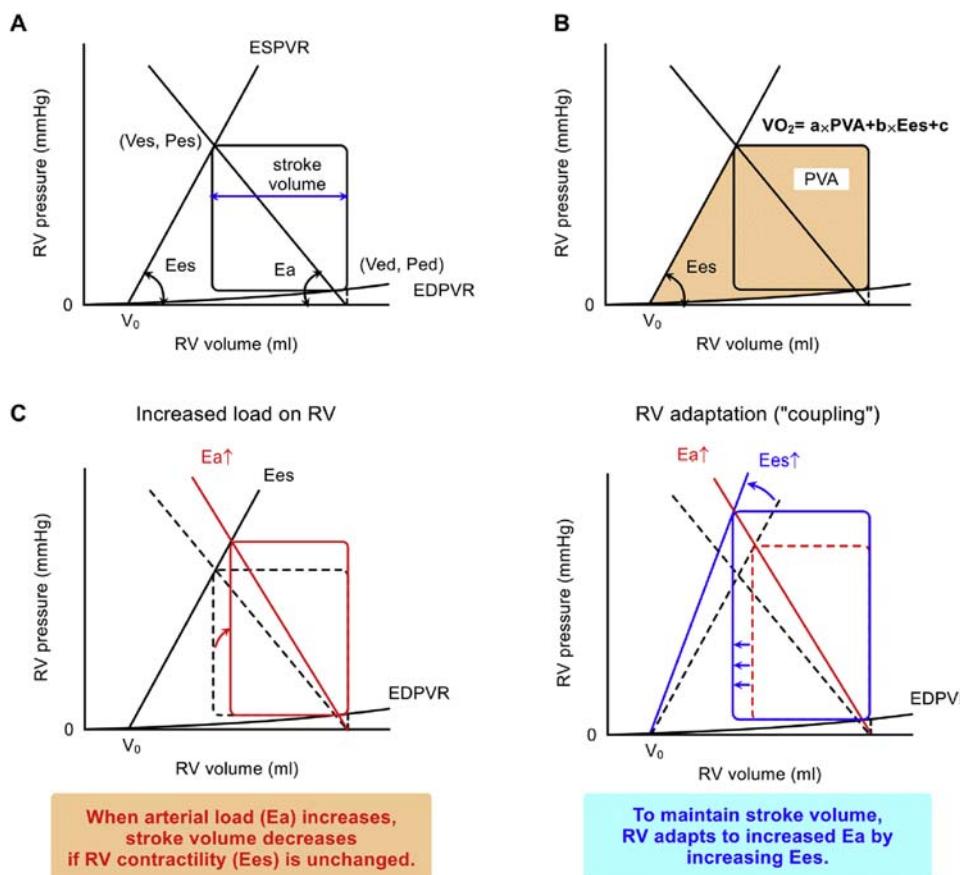
the time domain from the slope of the early systolic part of the pressure-flow relationship (Figure 56.2)[26,27]; see Chapters 1, 3 and 55. For large vessels, the Zc is a real number (whereas for smaller vessels, Zc should be described in the frequency domain with a modulus and phase).

Zc is determined by the geometry and mechanical properties of elastic arteries,[27,28] and is larger for stiffer arteries, but smaller when the arteries dilate. In clinical measurements, Zc increases 2.5- to sixfold with the development of various types of PH.[10,12,29,30]

When only Zc is increased experimentally in the systemic circulation, peak aortic pressure (systolic aortic pressure) reaches larger values and occurs earlier in the ejection period.[31] When we extrapolate this to the pulmonary circulation, increasing Zc augments pulsatile loading with an elevation in sPAP, even if PVR or PAC remains unchanged (Fig. 56.3). Given the fact that sPAP determines RV wall stress during systole (see section "Right ventricular wall stress/tension"), increased Zc would impact the RV function in PH.

Effective arterial elastance

Effective arterial elastance (an abbreviation is Ea) is a ventricle-independent measure of arterial function in the ventricular pressure-volume diagram.[32] One should bear in mind that in this pressure-volume plane description, heart rate is assumed constant. As shown in Chapter 55, heart rate is a major determinant of Ea.[33,34] Suga et al. described the ventricular contractility independent of arterial loading as the slope of the ventricular end-systolic pressure-volume relationship (ESPVR) (see section "Right ventricular contractility").[35] To understand how well the ventricle is coupled with the arterial load, the function of the arterial system is represented as "effective" arterial elastance in

FIGURE 56.4 Time constant of pulmonary circulation. (A) Calculation of time constant using diastolic pulmonary artery pressure decay. Time constant (τ) can be estimated by fitting measured pulmonary artery (PA) pressure during diastole to PAP(t) = PAPes × exp(−t/τ) + PAWP, where PAPes is end-systole PA pressure and PAWP is mean PA wedge pressure. (B) The pulmonary vascular resistance (resistance)—pulmonary arterial compliance (PAC) relationship. In early stage pulmonary hypertension (PH), the change of PAC is more readily noticed than that in resistance. In advanced-stage PH, the change of resistance is more easily detectable, while that of PAC is small.


terms of its end-systolic pressure-SV relationship as follows.[32]

$$Ea = \frac{Pes}{SV} \quad (56.1)$$

where Pes: end-systolic ventricular pressure, SV: stroke volume (Fig. 56.5A). The slope of the arterial Pes-SV relationship is neither the physical elastance nor arterial compliance, but functions as "effective" arterial elastance.[32] For the systemic circulation, it was shown by mathematical modeling[34] as well as in a large cohort[33] that Ea is insensitive to the pulsatile load, but tightly related to vascular resistance. In this Chapter 56, Ea is introduced in the section of "pulsatile load", because Ea is given using arterial input impedance approximated by a three-element Windkessel model, as follows.

$$Ea = \frac{Zc + R}{ts + \tau[1 - exp(-td/\tau)]} \quad (56.2)$$

where Zc: characteristic impedance, R: peripheral resistance, ts: duration of ejection, td: duration of diastole, τ: time constant of the diastolic pressure artery decay.[32] Thus, increased arterial compliance decreases Ea only mildly, and since Ea increases markedly with increases in peripheral resistance,[32] resistance is the major determinant of Ea. In most clinical studies on pulmonary circulation, Ea is examined as (1) mPAP/SV[8,36−38] or (2) sPAP/SV.[39] Both are based on the assumption that Pes can be approximated to mPAP or sPAP. However, these approximations should be used carefully because Pes is underestimated by mPAP in higher pressure ranges.[40]

FIGURE 56.5 The concept of the pressure-volume loop (PV-loop). (A) The slope of ventricular end-systole pressure-volume relationship (ESPVR) is Ees, and the volume axis intercept of ESPVR line is V_0. The slope of the arterial end-systole pressure-volume relationship is Ea. End-systolic ventricular volume is given by the interaction between these two lines. Stroke volume is the difference between end-diastole ventricular volume (Ved, the x-axis value of the lower right corner of the PV loop) and end-systole ventricular volume (Ves, the x-axis value of the higher left corner of the PV loop). The ventricular end-diastole pressure-volume relationship is given as EDPVR curve. (B) Pressure-volume area (PVA) is the area circumscribed by (1) the EDPVR line, (2) the PDPVR curve, and (3) the systolic segment of the pressure-volume trajectory in the PV-loop (colored pink). PVR is one of the determinants of oxygen myocardial consumption. (C) (left) When Ea increases in pulmonary hypertension (PH), the intersection of the two lines shifts upward (Ves increases and Pes is elevated). If Ees is unchanged, stroke volume decreases (right). To maintain stoke volume, the RV increases Ees so that x-axis of the intersection remains unchanged (blue line and loop).

Ea may increase by four- to fivefold in patients with precapillary PH,[8,36] and also by two- to fivefold in patients with LHD.[38,39,41] Since Ea determines SV by interacting with Ees, increased Ea reduces SV if Ees does not increase in parallel (Fig. 56.5C). Thus, the RV needs to increase Ees to maintain SV. Both Ea and Ees are given in terms of their Pes-SV relationships (with the same unit of mmHg/ml), and therefore the ratio of Ees to Ea represents how well the RV remains coupled with increased arterial load in PH (see section "the right ventricular-pulmonary artery coupling: Ees/Ea"). Increased Ea is associated with clinical adverse outcomes in patients with postcapillary PH.[39]

As described, Ea is a concept proposed initially in the systemic circulation where down-stream pressure (i.e., central venous pressure) is negligible. On the other hand, in pulmonary circulation, down-stream pressure (PAWP) is not negligible relative to Pes even in normal conditions. It is not yet established whether or not PAWP can be ignored to calculate Ea in the pulmonary circulation. A new approach to estimate Ea by subtracting PAWP was proposed by the researchers who have originally developed Ea in systemic circulation.[42] They noted that their proposal does not diminish prior findings of Ea in PH, but this approach may provide additional insight regarding the role of PAWP on the load to the RV. Further investigations would be expected.

Heart-dependent arterial load

Pulmonary artery pressure (mean, systolic, and diastolic pressure)

PA pressure is a heart-dependent description of arterial load. Owing to Ohm's law, mPAP is simply determined by the product of PVR and CO (mean flow per one minute). mPAP can increase fourfold in PH, while systemic hypertension is considered severe with a 25% increase in mean arterial pressure.[26] Just as mPAP, pressure waves are determined by not only the arterial properties (resistance, arterial compliance, and characteristic impedance) but also the ventricular function (ventricular contractility and diastolic stiffness).[43] For example, sPAP is augmented when PVR and characteristic impedance are increased, PAC is reduced, and RV contractility is enhanced. All these changes are involved in the development of PH.

As described in Chapter 55, in the pulmonary circulation, sPAP and diastolic PAP are proportional to mPAP in normal subjects and patients with several types of PH.[44–46] According to these relations, RV systolic pressure of 40 mmHg would best estimate mPAP of 25 mmHg as an indication of the presence of PH by the current guidelines.[1]

Wave reflection: wave separation analysis and wave intensity analysis

As discussed in detail in Chapters 1, 3 and 11, pressure and flow waves are generated by the cardiac ejection and are transmitted over the elastic arteries into the vasculature with a certain wave speed toward. These waves reflect at all discontinuities in the arterial trees and then return to the ventricle. The discontinuities include pathological sites; for example, where vessels are disrupted or abruptly narrowing. Physiologically (or functionally), the discontinuities can be explained by the mismatch of input impedance. Namely, wave reflections occur at the vascular sites where input impedance increases from a lower value (at normal or large vessels) to a higher value (at disrupted or narrowing vessels). Or, vice versa: when vessels widen (input impedance decreases from a higher to a lower value), negative wave reflections appear ("open reflections").

The normal pulmonary circulation is characterized by a low resistance and high compliance with little wave reflection.[47] When reflections are absent, pressure and flow waves would have the same wave shape. Indeed, PA pressure and flow are quite similar in normal physiological conditions.[47] In patients with PH, however, shapes of pressure and flow waves are different from each other. PA flow waves show a steep deceleration during systole, which coincides with pressure augmentation.[12] The deceleration of flow waves and augmentation of pressure waves is indicative of exaggerated wave reflection returning to the RV during systole.

Measured pressure and flow waves consist of forward and backward (reflected) waves. Clinically, there are two approaches to derive forward and backward waves: (1) wave separation analysis (WSA) and (2) wave intensity analysis (WIA). Both WSA and WIA methods can accomplish wave separation, using characteristic impedance. A difference is that the WSA method uses measured pressure and flow, while the WIA method is applied for time derivatives of pressure and flow.

In WSA, forward and backward pressure can be derived as:

$$Pf = \frac{Pm + Fm \times Zc}{2} \tag{56.3}$$

$$Pb = \frac{Pm - Fm \times Zc}{2} \tag{56.4}$$

where P: pressure, F: flow, and f: forward, b: backward, and m: measured, respectively.[48]

In WIA, forward and backward pressure are introduced as:

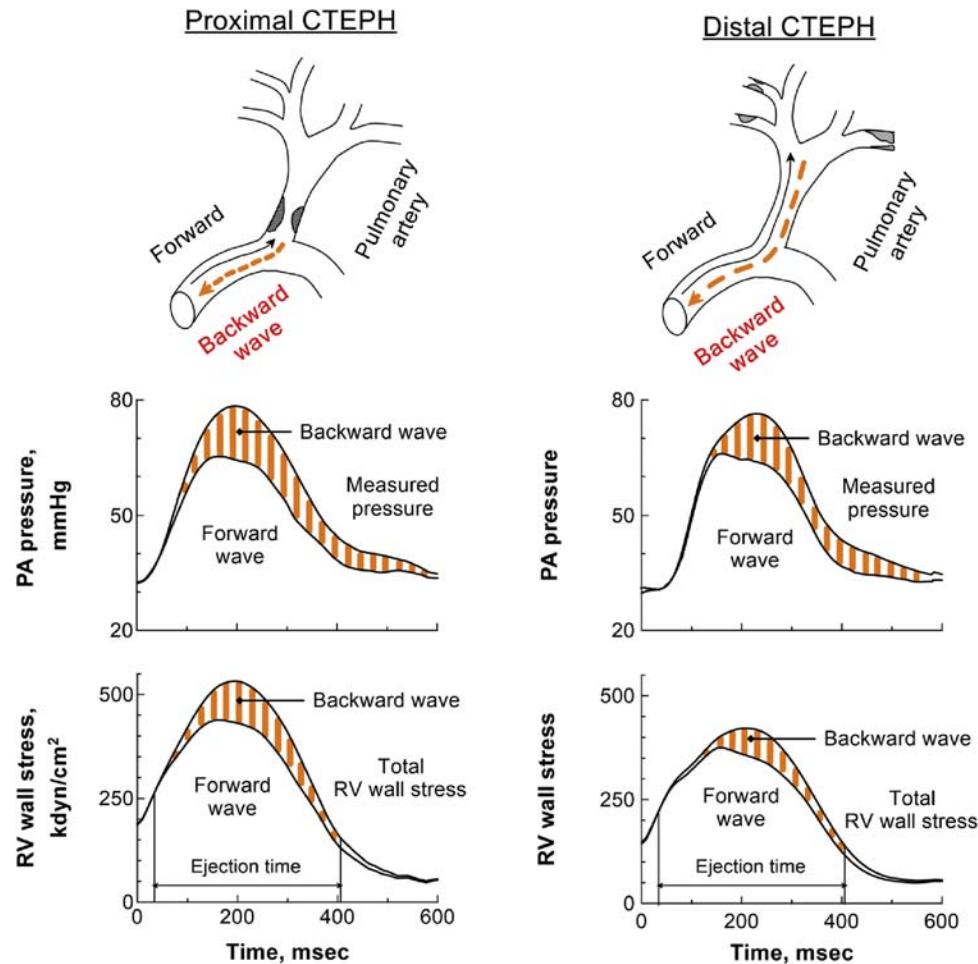
$$dPf = \frac{dPm + dFm \times Zc}{2} \tag{56.5}$$

$$dPb = \frac{dPm - dFm \times Zc}{2} \tag{56.6}$$

where dP: time derivative of pressure, dF: time derivative of flow, and f: forward, b: backward, and m: measured, respectively.[49,50] Integration of WIA-obtained forward and backward waves yields WSA-obtained waves.[51,52] With the use of the WSA or WIA, we can investigate wave reflection, in terms of (1) the magnitude and timing of backward waves, and (2) wave speed (pulse wave

velocity: PWV). The magnitude of forward and backward waves depends on both the heart and arterial load. On the other hand, the timing of backward waves and PWV are less affected by the RV function because of the relation:

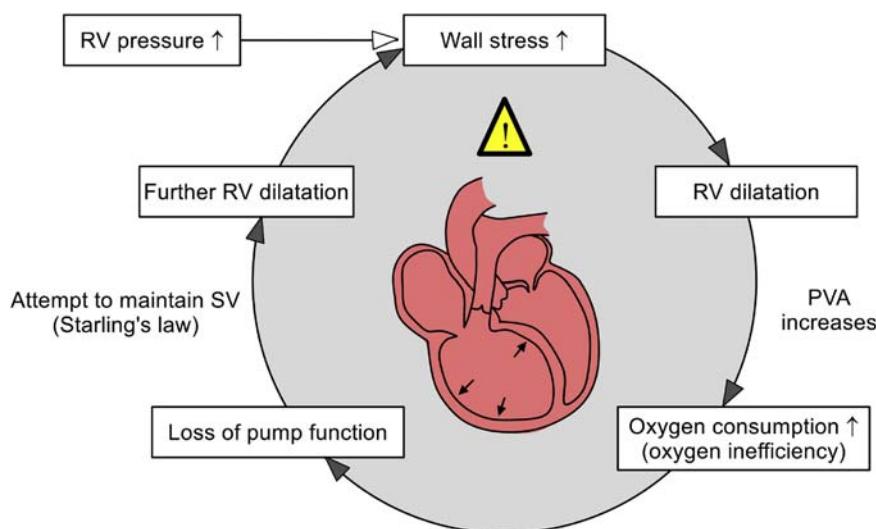
$$PWV = \frac{Zc \times A}{\rho} \tag{56.7}$$

where A: area of elastic arteries and ρ is blood density. This means that PWV depends on the properties of elastic arteries, but less on the heart. This section of heart-dependent loading includes the timing of backward waves and PWV for the convenience of explanation of wave reflection. Please be reminded that the return time of the reflected wave, which can be found by WSA or WIA, is determined by the vasculature. When looking at inflection points of measured pressure or flow, timing as well as the shapes of forward and reflected waves (which are the results of the interaction of heart and vessels) have an influence. Inflection points may thus be not directly related to timing aspects.[53,54]


In PH, backward waves five to six times larger than normal return to the RV.[55-58] A preclinical study using a PH animal model indicates that, as the peripheral pulmonary arteries are narrowed, the magnitude of backward waves becomes larger.[59]

Furthermore, backward waves return earlier in PH.[57,58] In a PH animal model, wave transmission time from the RV to the reflection point was smaller than normal animals.[59] Early return of backward waves in PH can be explained by (1) increased wave speed or (2) a location of a reflection point close to the RV.[47] Since stiffer proximal arteries can increase PWV (see Eq. 56.11), the PWV is accelerated by two to four times in patients with PH compared with controls.[55,57] In addition, proximal site of reflection is also a cause for early return of backward waves. In CTEPH patients with proximal pathological lesions, the RV is exposed to earlier backward waves than in patients with distal lesions.[60]

The early return of backward waves may increase mechanical stress on the RV (Fig. 56.6). RV wall stress/tension over the cardiac cycle depends on the RV volume (radius) and pressure, which means that wall stress is large when pressure and volume are large (see "Right ventricular wall stress/tension"). Early return of backward waves increases wall stress/tension considerably, and compromises RV function (RV dilatation and hypertrophy).[60] Since the time

FIGURE 56.6 Early return of backward waves increases right ventricular (RV) mechanical stress. Backward waves return sooner in chronic thromboembolic pulmonary hypertension (CTEPH) patients with proximal obstructive lesions, than those with distal lesions. Backward waves add pressure to the forward wave (orange, middle) and elevate RV mechanical stress (orange, bottom) according to RV volume when backward waves arrive back to the RV.


of wave transmission is not taken into account by lumped-parameter models such as a three-element Windkessel model,[61] early return of wave reflection might become a relevant addition to complement a description of arterial load in PH. Owing to the complexity of applying the WSA and WIA methods, simpler methods are used in clinical practice based on the analysis of: (1) pressure waves: increased augmentation index[62,63] and (2) flow waves: a notch of flow velocity.[64,65] Both are based on the concept that backward pressure waves add to forward pressure waves, while backward flow waves subtract from forward flow waves.[26] The shape of the pressure waves may differentiate PAH from CTEPH: CTEPH is characterized by a larger augmentation index and shorter reflection time than PAH.[62,63] An abnormal shape of flow waves is also useful to estimate an incidence of backward waves in PH.[64,65] In particular, a mid-systolic notch of flow waves is associated with poor RV function assessed by echocardiography (e.g., tricuspid annular plane systolic excursion [TAPSE] and RV fractional area change [RVFAC]).[65]

Right ventricular wall stress/tension

RV wall stress (tension) is a time-varying load imposed on the cardiac muscle.[66] RV wall stress (tension) is an important load parameter determined by an interaction of the RV and pulmonary arterial system. Increased wall stress (tension) induces oxygen inefficiency, resulting in loss of pump function.[67,68] Wall stress (tension) cannot be measured directly, but can be estimated by pressure, volume (radius), and wall thickness, based on Laplace's law:[27]

$$\text{wall stress} = \frac{(\text{pressure} \times \text{radius})}{\text{wall thickness}} \quad (56.8)$$

$$\text{wall tension} = \text{pressure} \times \text{radius} \quad (56.9)$$

which means that wall stress is directly proportional to pressure and volume, and inversely to wall thickness. In the presence of elevated pressure, the RV increases wall thickness in an attempt to attenuate increased wall stress. Ultimately, loss of pump function with a decrease in CO occurs as a consequence of increased wall stress. While the RV dilates to maintain CO, larger RV volume further increases wall stress (tension). Wall stress (tension) plays a central role in the vicious cycle of development of RV failure in PH (Fig. 56.7).[67] RV wall stress was increased by approximately fourfold in patients with precapillary PH.[69,70] Increased RV wall stress was associated with mortality in a cohort combined with pre- and postcapillary PH.[71] The foremost way to break this vicious cycle is to reduce wall stress. Lowering pressure is crucial, and also targeting volume overload by diuretics is effective in decreasing wall stress. Although wall stress might not be used for routine monitoring for PH treatment, N-terminal B-type natriuretic peptide (NT-proBNP) may become a surrogate marker to assess wall stress in clinical practice.[69,72]

The right ventricular function in pulmonary hypertension

Load-independent right ventricular function

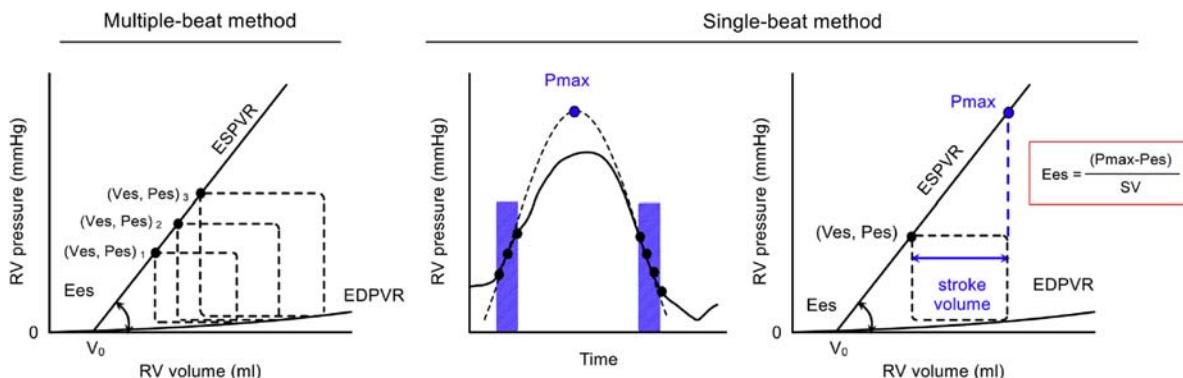
Right ventricular contractility: end-systolic elastance

Increased RV contractility is an essential adaptation of the RV to cope with increased arterial loading in PH.[25] The gold standard measure of ventricular contractility is end-systolic elastance of the ventricle (Ees), which represents the maximum elastance of the ventricle during a cardiac cycle. Ees is determined as the slope of the ESPVR in the diagram of

FIGURE 56.7 Right ventricular (RV) response to increased wall stress. Increased RV pressure elevates RV wall stress, which induces RV dilatation. RV dilatation increases pressure-volume area (PVA) (see Fig. 56.5). As a consequence, the RV results in oxygen consumption and loss of pump function. To maintain stroke volume, according to the Starling's law, the RV further dilates, however, increased RV volume (radius) further increases RV wall stress.

PV-loops,[35] requiring both ventricular pressure and volume over cardiac cycles at different loading conditions (see Chapter 55). Clinical studies of PH have applied the conductance catheter technique into the RV for investigation of PV loops.[15,73−75] Preload interventions, for example, vena cava obstruction[35,76] or a Valsalva maneuver,[15] are required for this so-called "multiple-beat method" (Fig. 56.8). In clinical studies, therefore, a simpler method (so-called "single-beat method"), not requiring PV-loops analysis or preload interventions, is applied to estimate Ees.[77] Of the measured ventricular pressure curves, the isovolumic phases are extrapolated to a hypothetical isovolumic contraction curve if the pulmonary valve would not open. This extrapolation gives the peak isovolumic pressure (Pmax), and thereby Ees can be calculated by (Pmax−Pes)/SV (Fig. 56.8). The single-beat method was originally developed for the LV, but this concept was validated into the RV by an animal model with PH,[78] and thereafter applied to the patients with PAH.[79] Although it has been discussed whether single-beat method gives a precise estimation of Pmax even in patients with severe PH,[25] it was found that the single-beat method accurately estimates an Ees-related factor (Ees/Ea) derived from the multiple-beat method in patients with moderate to severe PH.[80]

Pes/ESV was proposed as the possible simplest estimation of Ees, assuming that hypothetical volume at zero pressure (V_0) on the PV-loops diagram is negligible.[81−83] It might be a convenient measure in daily clinical practice, not requiring RV pressure curves. However, it should be noted that Pes/ESV differs from true Ees derived from the single-beat method because V_0 is not equal to zero.[84] Particularly, V_0 becomes larger as RV dilates. Thus, Pes/ESV gives much lower values than true Ees in patients with moderate to severe PH, not reflecting RV contractility.[84]

When Ea is elevated, the RV increases Ees to preserve the Ees/Ea ratio and maintain the SV (see "Cardiac output and stroke volume"). Ees is increased fourfold in precapillary PH,[8,36] and two- to threefold in PH due to LHD,[38,41] both reflecting that the RV is in a hypercontractile state in PH. Interestingly, the response of Ees may differ depending on the etiologies of PH even if these are categorized into the same group. In group-1, both idiopathic PAH and systemic sclerosis-associated PH (SSc-PH) Ees increases against the augmented Ea; however, the increase in Ees is relatively modest in SSc-PH. Ees in SSc-PH remains at only one-third of that seen in idiopathic PAH though the RV is exposed to the same loading (Ea, PVR, and PAC).[15] The insufficient increase of Ees results in poorer RV-PA coupling (given as Ees/Ea) in SSc-PH than idiopathic PAH.[15]


While the RV may properly adapt to increased load at rest in PH, the RV may have no exertional contractile reserve to deal with the further increase in arterial load.[85] Exercise increases pulmonary arterial load (Ea), but the RV cannot sufficiently augment Ees during exercise in PH, resulting in deterioration of RV-PA coupling.[85] Consequently, PH is characterized as a poor increase in SV during exercise than that in normal subjects.

Several limitations should be kept in mind when analyzing coupling in the pressure-volume plane, for which we refer to excellent reviews by, e.g., Chirinos et al.[86,87] For Ees, the crossing with the volume axis of the ESPVR, V_0 should not be neglected.[25] Moreover, the ESPVR is assumed to be a straight line which is a simplification.[88,89] When determining Ea, it is assumed that heart rate (and diastolic and systolic duration) remains constant.[86] Further, it should be remembered that Ea is a measure of non-pulsatile load and is hardly related to PAC.[33,34,86]

Right ventricular diastolic stiffness: end-diastolic elastance

RV diastolic stiffness gives an important load-independent description of RV function. The RV is stiffened with

FIGURE 56.8 Calculation of right ventricular (RV) end-systolic pressure-volume relationship (ESPVR). Multiple-beat method (left): the ESPVR line is estimated using multiple pressure-volume loops with different preload conditions. Single-beat method (right): peak isovolumic pressure is estimated by an extrapolated sine curve (dash line) from the isovolumic phase (blue zone). Using the estimated Pmax and measured end-systolic RV volume and pressure (Ves, Pes), the slope of ESPVR can be calculated.

hypertrophy, fibrosis, and specific biological alterations, such as reduced titin phosphorylation.[90] RV diastolic stiffness is determined by the end-diastolic pressure-volume relationship (EDPVR) curve in the diagram of PV-loops, so-called end-diastolic elastance, Eed[36] (Fig. 56.5A). While Ees is the maximum elastance of the ventricle (see "Right ventricular contractility"), Eed is the minimum elastance, which corresponds to the mechanical properties of a fully relaxed ventricle at end-diastole.

Eed is calculated using multiple PV-loops with preload intervention.[76] Alternatively, Eed can be estimated by fitting an exponential curve to the diastolic portion of PV-loops, with the formula $P = \alpha[\exp(\beta V) - 1]$, where P: RV pressure, α: curve-fitting constant, β: diastolic stiffness constant, V: RV volume. α and β are estimated based on the following three pressure points, (1) pressure at the beginning of diastole, (2) pressure at end-diastole, and (3) the origin (0,0).[36,37] Using α and β, Eed is given as $Eed = \alpha\beta \times \exp(\beta Ved)$, where Ved: end-diastolic volume (Fig. 56.5A).

Eed is increased two- to fourfold in several types of PH,[36,76] which means that the RV is stiffened in PH more than normal subjects. The stiffness of the RV during exercise is similar to resting values in normal subjects, but in PH due to LHD, the RV becomes stiffer during exercise.[76] Increased Eed, but not Ees or Ea, deteriorates right atrial function, which in turns contributes to backward central venous flow and systemic congestion.[91,92] Higher RV stiffness (increased Eed) is closely correlated with disease severity[90] and clinical adverse events.[36]

Load-dependent right ventricular function

Cardiac output and stroke volume

CO is determined by SV×HR. Since SV depends on the interaction of the heart and vascular systems, the diagram of PV loops may help understanding how SV or CO is determined when the RV is exposed to increased arterial load in PH. In the PV-loops diagram, SV is determined by the ratio of Ees to the sum of Ees and Ea as:

$$SV = \frac{Ees}{Ees + Ea}(Ved - V_0) \qquad (56.10)$$

where Ved is end-diastolic volume, and V_0 is volume at zero pressure determined as the volume axis intercept of the ventricular ESPVR (Fig. 56.5A).[93] This equation shows that when Ea is increased, the RV needs to enhance its contractility Ees, otherwise SV is not maintained (Fig. 56.5C). When Ees is not enhanced sufficiently, the RV needs to dilate to maintain SV (a dilated RV, with similar shortening of the muscle fibers, produces a somewhat larger output). When SV is maintained, but V_0 and EDV increase in tandem, thus the entire loop shifting to the right, EF will be lower, since the SV is a smaller

proportion of the EDV. The time course of decreasing SV with RV dilatation reflects the progress of PH since progressive PH is characterized by more dilated RV with lower RVEF and SV over time, compared with stable PH.[94]

The hemodynamic parameter which best reflects treatment efficacy is SV: an increase in SV indicates a better coupling of the RV to its load and is associated with a favorable outcome.[95–97] Note that higher CO or SV is not equal to more exaggerated RV contractility after treatment. A sufficient reduction in arterial load (Ea) can increase SV, releasing the RV from the hypercontractile status, as shown in Eq. (56.10).

Right ventricular volume and ejection fraction

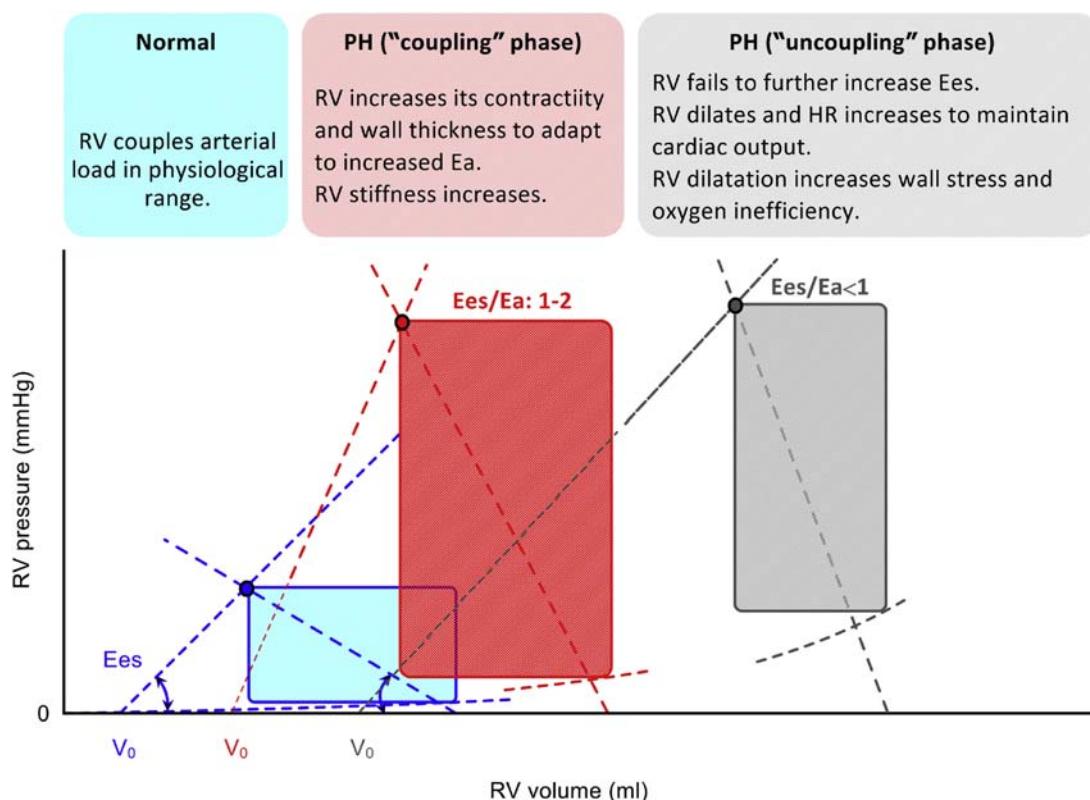
Functional imaging parameters derived by cardiac MRI or echocardiography are categorized as load-dependent function.[7] RV volume, i.e., EDV and ESV, provide anatomical information of the RV itself; however, these are determined by not only RV function but also by preload and pulmonary arterial properties (afterload). For example: when the RV contractility (Ees) does not change, increased Ea can augment ESV because ESV is determined by the point of intersection of Ea with Ees (Fig. 56.5C). Likewise, RVEF is also a load-dependent RV function, which is calculated as SV/RVEDV or (RVEDV−RVESV)/RVEDV. As already indicated in the section of "Cardiac output and stroke volume," the RV adapts to PH by dilatation such that the SV is maintained.[94] In other words, even if SV is maintained adequately, severe PH is accompanied by a larger RVEDV, resulting into lower RVEF. Lower RVEF at diagnosis is associated with adverse clinical outcomes in PH, irrespective of PVR.[5] In addition, insufficient increase in RVEF after treatment but, interestingly, not a reduction in PVR, is related to adverse clinical events.[5] Undoubtedly, RVEF is a key tool to assess the progression of PH; however, RVEF should be interpreted carefully because RVEF is neither an accurate parameter of "RV contractility" nor "RV−PA coupling." Since RVEF = SV/EDV, RVEF is determined by several parameters as follows:

$$RVEF = \frac{Pes}{ESV} \times \frac{1}{Ea} \times \frac{ESV}{EDV} \qquad (56.11)$$

where Ea is defined by Pes/SV. Since Ees should not be approximated as Pes/ESV[84] (see "Right ventricular contractility"), RVEF is not a direct measure of contractility or coupling.

Echocardiographic measures

Echocardiography is one of the most widely used tools in daily practice. Whereas the diagnosis of PH should be conducted based on RHC,[1] echocardiography is useful to assess disease severity and improvement after treatment.

The ESC/ERS guidelines proposed several echocardiographic measures; for example, RV chamber sizes, RVFAC (%FAC), the magnitude of tricuspid regurgitation, the LV eccentricity index, the RV longitudinal systolic strain/strain rate, and TAPSE.[1] Owing to the unusual and complex shape of the RV, the echocardiographic measurements are mostly angle-dependent and qualitative.[98] Both RV function and arterial load affect these echocardiographic measures.[98] In the same way as RV volume and RVEF, echocardiographic measures are improved by a reduction in arterial load after treatment.


The cardiovascular interaction in pulmonary hypertension

The right ventricle—pulmonary artery coupling: Ees/Ea

Most of the clinical parameters (for example, CO and RVEF) are determined by the interaction between the RV and the arterial load. To interpret these parameters precisely, the "intrinsic" properties of the RV and arterial loading (for example, RV contractility and diastolic stiffness and arterial elastance) should be understood correctly. We define coupling of the RV with arterial loading as the ratio of RV contractility to arterial elastance (Ees/Ea). While "coupling" is often used in a much broader sense to describe the interaction between heart and vasculature, in the context of this chapter we use coupling in the narrow sense of the Ees/Ea ratio (see also section "The properties of pulmonary arterial load and right ventricular function" where we defined intrinsic characteristics and system characteristics).[7] Cardiac performance depends on Ees/Ea, and this ratio is a measure of energy transfer from the heart to the arteries. Based on animal experiments investigating the LV,[93,99] an Ees/Ea ratio between 1 and 2 is considered to be in the normal range. This range reflects the maximum stroke work with minimizing myocardial oxygen consumption,[99] as explained in more detail in Chapters 15 and 55. Further discussions of the advantages and limitations of the use of coupling and efficiency can be found in the literature.[86]

In the relatively early stage of PH, the RV enhances its contractility by four- to fivefold to adapt to increased arterial loading. During this phase (so-called "coupling phase"), Ees/Ea is maintained above 1, and SV is preserved (Fig. 56.9). Since increased contractility is attributed to increased RV mass (hypertrophy), increased RV diastolic stiffness is also observed during the coupling phase.[36] However, when PH further advances, the hypertrophic

FIGURE 56.9 Right ventricular (RV) pressure-volume (PV) loops in control (blue), pulmonary hypertension (PH) with maintained RV-pulmonary artery (PA) coupling (early stage, red) and PH with RV-PA uncoupling (late stage, gray). *Ees*, the slope of end-systolic RV pressure-volume loop; *Ea*, arterial elastance; V_0, hypothetical RV volume at zero pressure.

process is insufficient for enhancing Ees in proportion to further increases in Ea, resulting in a decline in Ees/Ea.[36] During this phase (so-called "uncoupling phase"), the RV dilates to maintain SV (Fig. 56.9). HR also increases to compensate for the reduced SV, since CO=HR×SV. The "uncoupling" is critical for patients with PH. Decreased Ees/Ea, particularly lower than 0.7−0.8, is associated with adverse events in patients with PH.[36,80]

The framework of PV-loops provides insight not only in RV-PA coupling but also in myocardial oxygen consumption. Myocardial oxygen consumption per one heartbeat (VO_2) is described as:

$$VO_2 = a \times PVA + b \times Ees + c \qquad (56.12)$$

where PVA: systolic pressure-volume area, a, b, c: constant value.[100] PVA is the area circumscribed by the ESPVR line, the EDPVR curve, and the systolic limb of the PV-loops trajectory (Fig. 56.5B). Thus, hyper RV contractility and ventricular dilatation will increase PVA, resulting in increased myocardial oxygen consumption (Fig. 56.9). When the PH treatment decreases PA pressure and RV volume and attenuates the enhanced Ees, it contributes to an attenuation of the increased myocardial oxygen consumption and to a more effective RV function.

Right ventricle volumetric adaptation and wall stress

Wall stress/tension is a concept different from Ea to describe the ventricular loading. While Ea is an "effective" arterial elastance with a unit of mmHg/mL,[32] wall stress represents mechanical force imposed on a unit area of cardiac muscle, whose unit is dyne/cm^2 (dyne/cm for wall tension). As indicated in the section of "Right ventricular wall stress/tension," wall stress will increase when ventricular pressure and/or volume are large, both of which increase oxygen consumption. While myocardial oxygen consumption is increased as a consequence of increased wall stress in PH, oxygen supply is limited in PH.[68,101,102] Oxygen inefficiency induces loss of pump function, and ultimately RV failure. In an attempt to maintain CO, the RV needs to dilate particularly during the uncoupling phase; however, the ventricular dilatation further increases wall stress[67] (Fig. 56.7). Once wall stress augments and RV dilatation occurs, the RV is in a vicious cycle of increased wall stress (Fig. 56.7). Lowering pressure is the most reasonable approach to release the RV from the vicious cycle of wall stress, and guarantees long-term survival in PH.

Left ventricle–right ventricle interaction

The RV has little impact on the LV under normal physiological conditions; however, the interaction between the RV and the LV should not be ignored in PH. In PH, increased RV wall stress/tension prolongs RV contraction, resulting in asynchrony between the RV and LV contraction. The RV continues to contract while the LV is already in the diastolic phase. Therefore, the peak of the RV shortening occurs later than that of the LV shortening.[103] As a consequence, the ventricular septum bows leftward, impairing LV filling.[104] The importance of this hampering of LV filling is illustrated by the fact that in PH, SV does not correlate to RVEDV, but correlates positively to LVEDV.[104] Furthermore, the LV EDV provides prognostic information in addition to RV volume.[5,105] In PH, LV cardiomyocytes are atrophic, and cardiomyocyte contractile function is impaired.[106] As a result, severe LV dysfunction becomes apparent when RV afterload is largely reduced, for example, by lung transplantation.[107]

Summary

This chapter shows the adaptation of the RV to increased arterial load in PH. The pathological changes in arterial load and the RV function, and the adaptation of the RV to increased arterial load in PH are summarized as below.

- The heart-independent arterial load is increased in PH: PVR increases to fourfold, PAC decreases to 30% −40% of controls, Zc increases to 2.5- to sixfold, and Ea increases to four- to fivefold. As a result, the heart-dependent load (for example, pressure and wall stress/tension) is also elevated by the interaction of the load-independent heart function (Ees and Eed).
- Load-independent heart function is altered in PH. Ees (contractility) is increased to two- to fourfold, and Eed (diastolic stiffness) is also increased to 2 ∼ four-fold. When interpreting load-dependent heart function (for example, RV volume, RVEF, and CO), we should keep in mind that these parameters are determined by not only the RV but also the arterial load. Since the RV is under hyper-contractile state in PH, reduced RVEF and CO are not always equal to impaired contractility of the RV.
- The RV couples to increased arterial load (Ea) by increasing Ees. During the "coupling phase," the ratio of Ees to Ea is maintained between 1 and 2; here we use coupling only in this strict sense, although the term may be used in different manners. Since increased Ees largely depends on RV hypertrophy, if the hypertrophic process is not successful, Ees/Ea is below 1 ("uncoupling phase"). During the uncoupling phase, the RV needs to dilate to maintain SV. However, the dilatation increases myocardial oxygen consumption and further elevates wall stress/tension. In the advanced stage of PH, the RV is exposed to higher wall stress with oxygen inefficiency.

Pulmonary vascular stiffening and mechanobiological feedback in PH pathogenesis

Pulmonary hypertension

Pulmonary hypertension (PH), defined as an elevated mean arterial pressure in the pulmonary arterial (PA) circulation, is a serious and potentially life-threatening condition arising pathologically as a consequence of pulmonary vascular remodeling.[1] Common pathological features of this condition include endothelial dysfunction, inflammation, matrix deposition, increased smooth muscle cell (SMC) contractility, altered cellular metabolism, and amplified vascular cell proliferation, all resulting in both increased pulmonary vascular stiffening and elevated pulmonary vascular resistance (PVR).[2] Although these changes are initially spread heterogeneously throughout the pulmonary circulation and remain clinically silent, progressive disease manifests as exertional dyspnea, hypoxemia, and increased workload on the right ventricle (RV).[3] Severe disease leads to right heart failure and death. At present, treatment options are limited to pulmonary vasodilator therapies, and even these agents have not been found to be helpful for many common etiologies of PH.[4] These limitations have elicited extensive clinical research into potential targets to disrupt and reverse the vascular remodeling process.

Pulmonary vascular stiffening in clinical studies

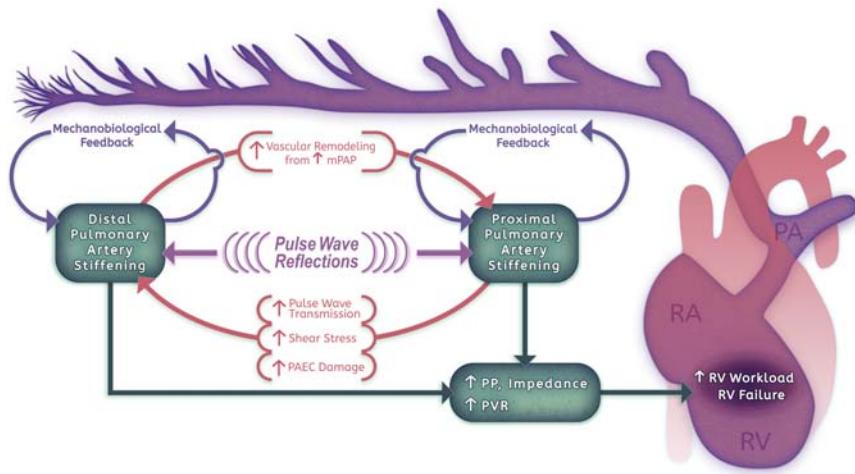
PA stiffness has become increasingly appreciated as an important disease marker that correlates with disease severity, functional status, and PH mortality.[2] Noninvasive measures of proximal pulmonary vascular stiffness or global PA capacitance have been associated with mortality in pediatric pulmonary arterial hypertension (PAH) patients, idiopathic PAH (iPAH) cohorts, scleroderma-associated PH, and PH in the setting of heart failure.[5−10] Many of these studies showed that pulmonary vascular stiffness measures were better predictors of mortality than typically measured resistance indices,[6,9,10] with particular prognostic utility in patients with normal PVR.[5,9,10]

It is not surprising that PA stiffness measures provide prognostic information, as arterial stiffening is the primary determinant of pulsatile afterload in the RV (as discussed in detail in Chapters 55 and 56), contributing approximately 23% of the RV workload.[11] In contrast with the systemic circulation, vessels throughout the pulmonary vascular tree contribute to vascular capacitance and pulsatile afterload,[12,13] with proximal large arteries contributing only 15%−25% of the total oscillatory load.[14] Global measures of vascular stiffness thus carry information about the status of vessels throughout the pulmonary tree, unlike resistance measures that are primarily impacted by changes in small arteries.

These clinical data and physiologic principles suggest that typical clinical evaluation of PH without assessment of pulmonary vascular stiffness will yield an incomplete portrait of the disease. Several investigators have therefore examined stiffness as a determinant of functional status,

---

[a] These authors contributed equally to this work.
[b] These authors contributed equally to this work.

particularly in early PH. Hunter and colleagues examined pulmonary vascular input impedance during right heart catheterization in a PAH cohort and found that increased input impedance was a better predictor of clinical worsening than PVR index alone.[15] MRI-derived measures of proximal PA stiffness have been shown to be better predictors of poor functional status on 6-minute walk test than standard resistive measures[16] and are also altered early in disease.[17] During cardiopulmonary exercise testing, decreased global PA distensibility predicts patients with known or subsequently diagnosed PH at a time when they had normal resting hemodynamics.[18] In a different cohort of patients with mixed etiologies of PH, PA distensibility was a good independent predictor of peak oxygen consumption in multivariable analysis.[19] These clinical observations offer strong supportive evidence that pulmonary vascular stiffening is an important early marker of disease activity and a clinically important contributor to PH morbidity and mortality.


Pathophysiology of pulmonary vascular stiffening in disease progression

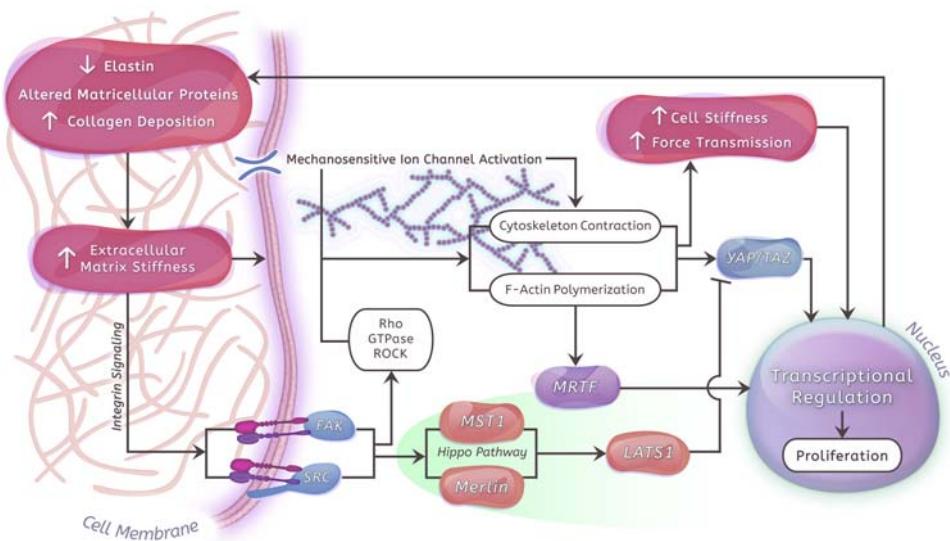
Pathophysiologic data from humans and animal PH models have steadily accumulated in favor of a critical role for PA stiffening as an early driver of disease. Stiffening of the proximal pulmonary vasculature amplifies pulse-wave transmission to the distal pulmonary arteries, and can result in inflammation, shear stress, endothelial injury, and smooth muscle remodeling.[20,21] Distal pulmonary vascular stiffening and muscularization increase the mean vascular pressures and result in large vessel remodeling including wall thickening, dilation, and alterations in extracellular matrix (ECM).[13,22] On a cellular level, changes in pulmonary vascular stiffness in either location can alter gene expression and cellular behaviors to promote proliferation and metabolic changes, increased cytoskeletal tension, and matrix alterations that reinforces local cell-matrix stiffness, a process that has been termed mechanobiological feedback.[23–25] The net result of these macroscopic and microscopic reinforcing feedback loops is pathologic progression from early pulmonary vascular stiffening toward increasingly severe vascular remodeling, increased RV afterload, and development of clinical disease.

Although often explained as a later response to changes in the resistance vessels, seminal work in PH models has demonstrated changes in the stiffness and structure of proximal pulmonary vessels at early stages of PH pathogenesis. Foundational work by Meyrick and Reid in the rat hypoxia model noted increased PA diameter and doubling of the elastic lamina thickness at 3–10 days post-exposure.[26] Further work in this model found increased collagen and hydroxyproline synthesis within 3–5 days that correlated with a doubling in stiffness throughout the

PA tree by pressure–volume loop analysis.[27,28] Ex vivo testing of mouse PAs after 1–2 weeks of hypoxia exposure also showed an increase in elastic modulus and thickening of collagen and elastin in the PA wall.[29] In the monocrotaline (MCT) rat model, the Rabinovitch laboratory found early disruption in the internal elastic lamina and high elastase activity within days after injection, weeks before hemodynamic changes.[30] Hints of distal pulmonary vascular stiffening were also seen by Meyrick and Reid, who noted muscularization of intraacinar PAs at day 3 after hypoxia or Crotolaria exposure.[31] This neomuscularization has more recently been found to arise from distal migration and proliferation of SMC progenitor cells.[32] Using atomic force microscopy to directly measure passive mechanical properties of frozen tissues, Liu et al. found a 1.5-2-fold increase in PA stiffness in the media of small vessels within 1 week of pathologic stimuli in both the MCT and sugen/hypoxia rat PH models.[24] Direct flow and pressure measurements from the main PA in vivo in the MCT model also demonstrate this early stiffening, indicating an early and linear decrease in compliance throughout the disease process before the development of a nonlinear change in resistance properties.[33]

Stiffness of the proximal pulmonary vasculature is determined in large part by the composition of the ECM proteins in the laminae of the vessel wall. The most prominent of these proteins are elastin, allowing flexibility, and collagen, providing strength.[27,28] Studies have shown that vascular remodeling occurring from PH correlates with inflammatory cell accumulation, elastin breakdown, collagen production, and vessel dilation.[34] The findings of elastin degradation and collagen accumulation correlate well with ex vivo biaxial strain testing of human PH tissue, which demonstrate collagen-predominant mechanics regardless of strain conditions.[35] Proximal pulmonary vasculature stiffening affects distal vessels by augmenting pulse wave transmission and generating high pulsatile flow distally (Fig. 57.1).[20,21,36] Studies on the effects of flow pulsatility on the endothelium and underlying smooth muscle have demonstrated alterations in nitric oxide (NO), prostaglandin-F1α, and endothelin production, increased expression of leukocyte adhesion molecules, and alterations in smooth muscle contractile proteins,[20,21,36] all of which contribute to distal remodeling. At the same time, early distal vessel stiffening and muscularization from these and other pathogenic processes will increase circumferential stress in the proximal pulmonary vessels due to pulse wave reflections and pressure-induced dilation.[13] Locally, the change in pulmonary vascular stiffness at the cellular level activates mechanotransduction pathways including integrins, cytoskeleton-associated kinases, mechanosensitive calcium channels, and nuclear transducers to increase expression of matrix proteins and cross-linking enzymes,[24,25] alter metabolism,[37] downregulate vasodilatory

FIGURE 57.1 **Pulmonary arterial stiffening in the pathogenesis of pulmonary hypertension.** Proximal and distal pulmonary arterial (PA) stiffening and stiffness-dependent mechanobiological feedback loops, which propagate pulmonary vascular remodeling, play a key role in the pathobiology of pulmonary hypertension (PH). Proximal PA stiffening may amplify pulse wave transmission to the distal pulmonary vasculature resulting in increased shear stress and injury to pulmonary artery endothelial cells (PAEC), inflammation, and vascular cell remodeling behaviors that drive distal PA stiffening. Distal PA stiffening can promote increased mean PA pressures (mPAP), leading to large PA vessel wall thickening, dilation, and extracellular matrix (ECM) alterations which drive proximal PA stiffening. Together, this crosstalk between proximal and distal PA stiffening leads to increased pulse pressure (PP) and impedance and elevated pulmonary vascular resistance (PVR) which increase right ventricular (RV) workload and ultimately may lead to RV failure in PH. *Modified from Dieffenbach PB, Maracle M, Tschumperlin DJ, Fredenburgh LE. Mechanobiological feedback in pulmonary vascular disease.* **Front Physiol**. *2018; 9:951.*

prostanoids,[24,25] and drive proliferation, all reinforcing vascular remodeling through mechanobiological feedback (Fig. 57.2).[2] In the remainder of this chapter, we will focus on these molecular pathways that drive stiffness-mediated signaling, and how targeting these pathways may offer the potential to disrupt mechanobiological feedback and pathologic pulmonary vascular remodeling in PH.


Regulation of smooth muscle contractility and tone

In the absence of disease, contractility of arterial smooth muscle regulates PA luminal diameter, thereby maintaining normal pressures and adequate blood flow throughout the pulmonary vasculature. In the setting of PH, several pathogenic stimuli, including PA stiffening, can lead to dysregulation of pulmonary artery smooth muscle cell (PASMC) contractile function, including increased tone and impaired relaxation, through a variety of mechanisms. PH leads to well-described dysregulation of the endothelial-derived mediators of arterial stiffness, NO and endothelin-1 (ET-1), which induce smooth muscle vasodilation and vasoconstriction, respectively.[38,39] Throughout the vascular tree, high pulsatility flow (HPF) increases ET-1 expression and decreases endothelial nitric oxide synthase (eNOS)-derived NO production, which enhance PA tone and lead to increased vascular resistance and stiffness. Increased proximal PA stiffness leads to further pulsatile flow and propagates the dysfunction deeper into the pulmonary

vascular tree. Additionally, HPF upregulates expression of contractile proteins such as α-smooth-muscle actin (α-SMA) and smooth muscle myosin heavy chain.[21,40,41] This may lead to hyperactive pulmonary vascular smooth muscle contractility leading to sustained abnormal vasoconstriction and thereby contributing to PH progression.[42]

During PH pathogenesis, several molecular pathways are activated to enhance vasoconstriction via increased phosphorylation of myosin light chain (MLC). Canonically, adrenergic stimulation activates myosin light chain kinase (MLCK) and induces PASMC contraction by activating calcium-dependent channels in the endoplasmic reticulum to increase cytosolic Ca^{2+} concentration ($[Ca^{2+}]$).[41] Several mechanosensitive calcium channels have been shown to play a role in enhancing MLCK activation and vasoconstriction in response to mechanical signals. In particular, the channels TRPV4, TRPM7, and TRPC6 have been shown to be significantly upregulated in iPAH PASMC compared with control cells,[43] and correlate with increased cytoplasmic calcium in response to shear stress. In animal models, hypoxia-induced TRPV4 expression correlates with increased vascular tone and TRPV4 deficiency attenuates hypoxia-induced pulmonary vascular remodeling in mice, indicating a significant role for these stiffness-dependent ion channels in PH pathobiology.[44]

An alternative regulatory mechanism that enhances SMC tone includes inhibition of MLC phosphatase (MLCP), which counteracts the effects of MLCK. The most well-studied mechanism of MLCP inhibition is the

FIGURE 57.2   Molecular mechanisms of mechanobiological feedback in pulmonary hypertension. Increased extracellular matrix stiffness activates mechanotransduction pathways, which promote vascular cell proliferation and pulmonary vascular remodeling and amplify pulmonary vascular stiffening in a mechanobiological feedback loop in pulmonary hypertension (PH). Key molecular pathways include integrins, cytoskeleton-associated kinases, mechanosensitive calcium channels, and nuclear transducers such as myocardin-related transcription factors (MRTF) and the Hippo pathway downstream effectors Yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ). Matrix stiffness regulates activation of integrin signaling and key intracellular mechanosensors, focal adhesion kinase (FAK) and steroid receptor coactivator (Src), which can activate Rho GTPase and its downstream target Rho-associated protein kinase (ROCK) and increase pulmonary artery smooth muscle cell contraction. FAK and Src also regulate the Hippo pathway and when activated may suppress Merlin, leading to inactivation of MST1/2 and LATS1/2 and promoting nuclear translocation of YAP/TAZ. When activated, nuclear YAP/TAZ bind to transcription factors to drive mechanical signaling leading to enhanced proliferation and apoptosis resistance in pulmonary vascular cells. Stiffness-induced F-actin polymerization and stress fiber formation also liberates MRTF from G-actin cytoplasmic complexes allowing it to translocate to the nucleus where it regulates smooth muscle cell contractile genes which contribute to vascular remodeling in PH. *Modified from Dieffenbach PB, Maracle M, Tschumperlin DJ, Fredenburgh LE. Mechanobiological feedback in pulmonary vascular disease.* **Front Physiol**. *2018; 9:951.*

RhoA/ROCK pathway, which plays an important role in the development of vascular diseases.[45] RhoA GTPase is activated by FAK and Src downstream of matrix stiffness-induced activation of integrin signaling (Fig. 57.2) (discussed in more detail below), as well as vasoconstriction-activated G-protein coupled receptors. RhoA GTPase then activates its downstream target RhoA-associated protein kinase (ROCK), which inhibits MLCP and leads to enhanced SMC contraction. RhoA is particularly important for sustaining enhanced tone and SMC contractility in the setting of decreasing cytosolic $[Ca^{2+}]$, and disruption of this process with Rho kinase inhibitors has been shown to be highly effective at decreasing vasoconstriction and contraction.[41,46] Treatment with the ROCK inhibitor fasudil has been found to suppress both MCT-induced PH and hypoxia-induced PH in rodents,[47,48] and has had modest success in early clinical trials in PAH.[49]

Myocardin-related transcription factors (MRTFs) are emerging as a key link between gene expression changes and stiffness-driven cellular activation in PH and fibrotic lung disease. These stiffness-dependent transcription factors are fundamental constituents of a profibrotic mechanobiological feedback loop downstream of ECM stiffness and RhoA/ROCK (Fig. 57.2).[50,51] MRTFs form complexes with monomeric soluble G-actin, sequestering them in the cytoplasm. With increased mechanical stress or migration, G-actin becomes polymerized into F-actin filaments and forms stress fibers, releasing MRTFs from cytoplasmic complexes and allowing for their nuclear translocation. There, MRTFs act as cofactors for serum response factor to modulate expression of a transcriptional program central to SMC contractile machinery[50,52,53] including α-SMA,[54] which may drive pulmonary vascular remodeling in PH. MRTFs have also been linked to activation of inflammatory responses in SMCs, endothelial cells, and myofibroblasts, and are known to be downstream effectors of profibrotic signaling.[2] Inhibition of MRTF-A using shRNA reduced collagen deposition and significantly attenuated the development of PH in hypoxia-exposed rats.[55]

Proliferation

At the cellular level, one of the most striking effects of ECM stiffness is the development of a hyperproliferative phenotype in PASMC and pulmonary artery endothelial cells (PAEC), which may contribute to the medial hypertrophy, neointimal formation, and plexiform lesions observed in PAH. This is nicely illustrated in vitro, where

human PASMC and PAEC demonstrate exaggerated proliferation and enhanced matrix production when grown on stiff matrices (mimicking remodeled PAs) compared with soft matrices mimicking physiologic PA stiffness.[24] This is accompanied by transcriptional changes in mechanosensitive genes which serve to further amplify proliferation and pulmonary vascular remodeling in a self-sustaining mechanobiological feedback loop.[24,25] The feed-forward loop initiated by stiffness-induced pulmonary vascular cell activation has led to investigation of matrix alterations and proproliferative mechanotransduction pathways as potential early contributors to PH pathogenesis.

Under homeostatic conditions, the ECM is regulated by a balance of proteolytic enzymes and their endogenous tissue inhibitors. In PAH, this balance becomes disrupted, leading to increased collagen production, deposition, and cross linkage. Increased deposition of type I, III, and IV collagen is observed in animal models of PH, and type III collagen levels correlate with severity and rapidity of disease progression in PAH.[56,57] Following increases in collagen deposition, ECM components such as tenascin-C (Tn-C), fibronectin, and serine elastases may accumulate in pulmonary arteries of PAH patients.[58,59] Tn-C is an ECM glycoprotein that is known to play a pivotal role in regulating cell adhesion, and whose expression correlates with PASMC proliferation in PAH.[58] Fibronectin, a key integrin ligand, is upregulated in intimal lesions and plays a role in medial smooth muscle remodeling in PAH.[60] These matrix alterations lead to increased stiffness in the intravascular and perivascular regions, particularly in smaller pulmonary vascular beds.[34] In proximal PAs and small arteries that contain an elastic lamina, serine elastases, which are upregulated in PAH and colocalize with pathological neointimal lesions, play a key role in vascular mechanics.[61] This accumulation of collagen and degradation of elastin by serine elastases result in lower arterial compliance and increased PA stiffness.[62] On a cellular level, elastin fragmentation promotes PASMC remodeling through liberation of matrix-bound mitogens and exposure of novel integrin binding sites.[63–65] Inhibition of serine elastases can lead to regression of progressive medial PA hypertrophy in culture ex vivo[66] and has been shown to attenuate pulmonary vascular remodeling in PH models.[67–70]

Alterations in levels of matrix metalloproteinases (MMPs) and their endogenous inhibitors, tissue inhibitors of metalloproteinases (TIMPs), can also increase extracellular stiffness in PAH.[71] MMPs are a family of zinc-dependent endopeptidases that reduce matrix stiffness by degrading ECM proteins including collagen and elastin.[72] MMPs also influence endothelial and SMC migration, proliferation, and contraction, and thus play an important role in vascular tissue remodeling in PAH. Under normal conditions, MMP levels are regulated by TIMPs, and the MMP/TIMP ratio is essential for maintaining ECM homeostasis.[73] In PAH, this normal MMP/TIMP balance becomes disrupted, leading to changes in ECM environments (Fig. 57.2). MMP-2 and MMP-9, the most efficient MMPs at degrading collagen, have been associated with vascular SMC activation and neointimal formation in arterial tissue remodeling in PAH,[74–76] and are increased in PASMC from iPAH patients.[63] MMP-9 levels have also been to found to correlate with disease severity in PAH.[14,57] In addition, MMP-3, which is likely to be a critical regulator of arterial stiffness due to its interactions with most major matrix components, is significantly reduced in human iPAH cells.[71,77] TIMP-1 and TIMP-2 are also increased in iPAH[71] and may be indicative of active vascular remodeling and reflect clinically relevant markers of disease and outcome in PAH.[57] While several animal models of PH suggest roles for MMP-2, MMP-9, and MMP-3 in disease pathogenesis,[78,79] studies of other MMP subtypes differ across animal models used, making it difficult to determine their roles in PAH from animal models alone.[14] Further work is needed to precisely delineate the roles of different MMP and TIMP subtypes in regulating ECM stiffness and PH pathogenesis.

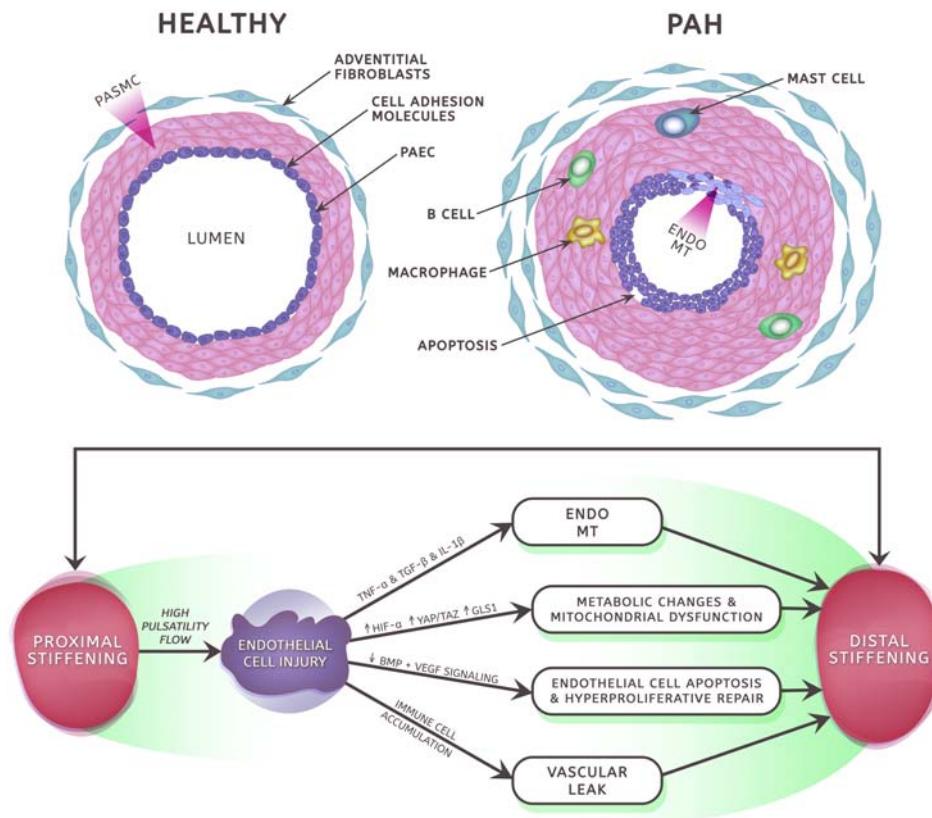
Changes in ECM stiffness are transmitted intracellularly by integrins (Fig. 57.2), which act as both signaling receptors and physically connect the ECM to the cytoskeleton.[80] Upon binding to the ECM, most notably fibronectin, integrins connect to the intracellular actomyosin system via linking proteins such as talin and vinculin, initiating downstream mechanosignaling.[81] In animal models, increased expression of α_1-, α_8-, and α_v-integrins and decreased expression of α_5- and β_1-integrins has been observed in PAs from hypoxia-exposed and MCT-treated rats.[82] Activation of MMPs also leads to accumulation of $\alpha_v\beta_3$ integrin, which interacts with many ECM ligands including fibronectin, collagen, and several MMP substrates.[63] Several studies have demonstrated that $\alpha_v\beta_3$ integrin is associated with increased SMC proliferation and migration as well as decreased SMC apoptosis,[83,84] suggesting an important role for $\alpha_v\beta_3$ integrin in mediating stiffness-induced vascular cell activation and remodeling in PH.

When integrins are activated, their cytoplasmic domains associate with focal adhesions (FAs), which directly transmit forces between the ECM and the cytoskeleton. These forces are also translated into signaling pathways via mechanotransduction. The steroid receptor coactivator (Src) family of tyrosine kinases and focal adhesion kinase (FAK) are two important proteins that are activated and recruited by ligand-bound integrins to FAs and modulate cytoskeletal proteins via mechanotransduction (Fig. 57.2).[14,85,86] Increased activation of FAK and Src has been observed in PAH PASMC and are associated with enhanced proliferation and migration.[87–90] Inhibition of

either FAK and Src activation has been shown to attenuate experimental PH in rodent models,[87,88] suggesting potential roles for FAK and Src in driving stiffness-dependent pulmonary vascular remodeling in PAH.

The Hippo pathway has emerged as playing a critical role in mediating the effects of ECM stiffness on vascular remodeling phenotypes in PAH, particularly via the homologous transcriptional coactivators, Yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ) (Fig. 57.2). Canonically, Hippo signaling suppresses cell proliferation by inactivating YAP/TAZ, which promote downstream proproliferative and antiapoptotic signaling pathways. Hippo pathway component FERM domain-containing tumor suppressor NF2 (neurofibromatosis type 2)/Merlin activates MST1/2 and serine-threonine kinases LATS1/2 which leads to sequestration of YAP/TAZ in the cytoplasm for degradation.[91−93] Increased ECM stiffness and enhanced integrin signaling through FAK and Src may downregulate the Hippo pathway by suppressing Merlin, leading to inactivation of MST1/2 and LATS1/2, and nuclear translocation of YAP/TAZ. Nuclear accumulation of YAP/TAZ activates a transcriptional program that may promote a hyperproliferative and apoptosis-resistant phenotype in PASMC and PAEC in PAH. While the Hippo pathway is the canonical YAP/TAZ regulator, there may also be relevant YAP/TAZ phosphorylation-independent modifiers of YAP/TAZ localization, including ECM rigidity, strain, and shear stress.[94]

Nuclear YAP/TAZ target a number of promoter-specific transcription factors to drive mechanical signaling, including the transcriptional enhancer activator domain (TEAD) family, which promote cellular proliferation and survival.[93] Upregulation of YAP/TAZ activity in response to matrix stiffness promotes collagen deposition and cross-linking, and is necessary for the development of stiffness-dependent vascular remodeling in PH.[23,25] This demonstrates the potential for a pathological positive feedback loop between YAP/TAZ upregulation and ECM stiffness. Promising in vivo studies have shown that pharmacological inhibition of YAP/TAZ leads to significant reductions in pulmonary vascular stiffness, RV pressures, and RVH in animal models of PH.[95]

In addition to the Hippo pathway, the transforming growth factor-β (TGF-β)/bone morphogenetic protein (BMP) pathway contributes to proliferative phenotypes in PAH. Bone morphogenetic protein type 2 receptor (BMPR2), a TGF-β receptor, is particularly relevant as mutations in the BMPR2 gene are present in 70% of heritable PAH cases and underly many cases of iPAH.[96] Loss of BMPR2 function promotes PASMC proliferation via altered TGF-β1 signaling. In addition to enhancing PASMC proliferation, exaggerated TGF-β1 signaling may regulate many cellular responses including inflammation,


angiogenesis, and migration, many of which are altered in PAH.[97] Recent studies have sought to understand the role of BMPR2 mutations in PAH development, particularly as the penetrance of PAH in families with BMPR2 mutations is only around 20%. While loss of BMP signaling induces PASMC hyperproliferation, disruption of BMPR2 increases apoptosis in PAEC in PAH.[98] PAEC transfected with mutant BMPR2 demonstrate enhanced apoptosis and release more TGF-β compared with control cells.[99] Disruption of normal TGF-β signaling is communicated via paracrine signaling from PAEC and leads to increased PASMC proliferation.[99,100] Similarly, HPF that mimics PAH environments in vitro has been found to increase PAEC apoptosis and TGF-β release (Fig. 57.3) and induce PASMC proliferation.[99]

Matrix stiffness has also been shown to alter endothelial responses to vascular endothelial growth factor (VEGF).[101,102] VEGF and its receptor 2 (VEGFR-2) regulate proper endothelial cell (EC) differentiation and function, and their signaling may be affected by ECM stiffness in PAH. Inhibition of VEGFR-2 with SU5416 initially causes PAEC apoptosis, but is followed by hyperproliferation of the remaining apoptosis-resistant PAEC in the setting of increased shear stress[103] and hypoxia leading to development of plexiform lesions in vivo.[104] Further studies are required to elucidate the effects of PA stiffness on BMP/TGF-β and VEGF signaling, as well as crosstalk between BMP/TGF-β, VEGF, and the Hippo pathway in driving stiffness-induced vascular remodeling in PAH.

Inflammation and endothelial dysfunction

Ongoing investigation into PAH pathogenesis has frequently highlighted a role for inflammatory signaling. Both innate immune cells and adaptive immune lymphocytes are found in the interstitium and tertiary lymphoid tissue around remodeled vessels in human PAH and rodent PH models.[105] Furthermore, many inflammatory cytokines, such as IL-1β, IL-2, IL-4, IL-6, IL-8, IL-10, IL-12, p70, and tumor necrosis factor-α (TNF-α), are more highly expressed in PAH patients compared to controls.[106] Not surprisingly, there is extensive crosstalk between inflammation, endothelial dysfunction, and vascular stiffness. Inflammation-induced vascular leak and edema can lead to arterial stiffening and increased tone prior to collagen deposition and fibrosis, while altered blood flow and matrix characteristics due to vessel stiffening can enhance inflammatory cell migration and inflammatory signaling.[107]

Matrix stiffness is a critical mediator of endothelial barrier characteristics due to its impact on cell−cell and cell-matrix adhesion properties. In stiff ECM environments, ECs have punctate expression of VE cadherin, a principle cell−cell junction protein, as compared to on softer matrix,

FIGURE 57.3 **Biological mechanisms and effects of pulmonary arterial stiffening in endothelial cells in pulmonary hypertension.** Proximal pulmonary arterial (PA) stiffening increases flow pulsatility in the distal vasculature which may cause endothelial injury leading to pulmonary artery endothelial cell (PAEC) apoptosis, vascular leak, and hyperproliferative repair in pulmonary hypertension (PH). Stiffness-induced endothelial barrier disruption allows for immune cell infiltration and increased expression of inflammatory cytokines including tumor necrosis factor (TNF)-α, transforming growth factor (TGF)-β, and interleukin (IL)-1β, which may promote endothelial to mesenchymal transition (EndoMT). Bone morphogenetic protein (BMP) and vascular endothelial growth factor (VEGF) signaling may modulate endothelial cell responses to PA stiffness-induced alterations in flow and endothelial injury and may promote hyperproliferative repair in PH. Metabolic reprogramming and mitochondrial dysfunction may also occur in PAEC in PH with a shift from oxidative phosphorylation to glycolysis, which is dependent on hypoxia-induced factor (HIF)-1α. Matrix stiffness activates YAP/TAZ which may promote HIF-1α stabilization as has been observed in cancer cells, although further study is necessary in PH. Stiffness-induced YAP/TAZ activation upregulates glutaminase 1 (GLS1), which promotes glutaminolysis and drives hyperproliferation in pulmonary vascular cells. Together, these stiffness-induced endothelial responses drive pulmonary vascular remodeling and propagate distal and proximal PA stiffening in a mechanobiological feedback loop.

where VE−cadherin junctions are continuous between ECs.[108] Stiffness also increases EC permeability through Rho force transmission via enhancing EC actomyosin-mediated contractility.[109] Increased intracellular contractile function leads to cell edge retraction and disruption of tight junctions, which subsequently allows for infiltration of circulating immune cells (Fig. 57.3).[110] Consequently, ECs grown on stiff matrix have enhanced leukocyte transmigration, increased expression of inflammatory cytokines, and higher induction of leukocyte adhesion molecules in response to inflammatory stimuli such as TNF-α or lipopolysaccharide.[111,112] The synergistic effects of inflammation on vascular remodeling are also demonstrated by the induction of fibronectin, collagen 1, and lysyl oxidase,[112] which contribute to progressive matrix stiffening.

Early pulmonary vascular stiffening in PH also induces inflammation through alterations in vascular flow characteristics and subsequent endothelial injury (Fig. 57.3). Like most endothelial stressors, HPF and shear-induced injury can lead to expression of endothelial adhesion molecules and induction of cytokines that enhance inflammatory cell recruitment.[105] Nuclear factor-kappa B (NF-κB) is a transcription factor known to be involved in flow-mediated inflammatory responses in endothelial cells,[113−115] and has been found to be strongly activated early and continuously by high-pulsatility flow[36] and mechanical stretch.[116] In vivo, NF-κB contributes to vascular inflammation by recruiting leukocytes to perivascular regions of PAs during vascular remodeling.[117] Inhibition of NF-κB attenuates peri-vascular inflammation, development of PH, and RVH

in rodent models.[117,118] One of the key proinflammatory cytokines regulated by NF-κB is IL-6, which has been found to be increased and associated with mortality in PAH.[106] Overexpression of IL-6 in the lung leads to spontaneous PH and RVH development in mice, which is exacerbated by hypoxia and leads to occlusive neointimal angioproliferative lesions composed of T cells and endothelial cells.[119] IL-6 and other inflammatory cytokines have also been shown to drive PASMC proliferation[120] and contribute to endothelial to mesenchymal transition (EndoMT),[121] likely further enhancing vascular stiffening in PH (Fig. 57.3). This crosstalk between inflammation and pulmonary vascular stiffening is an important contributor to PH pathophysiology that would benefit from further investigation.

Endothelial to mesenchymal transition

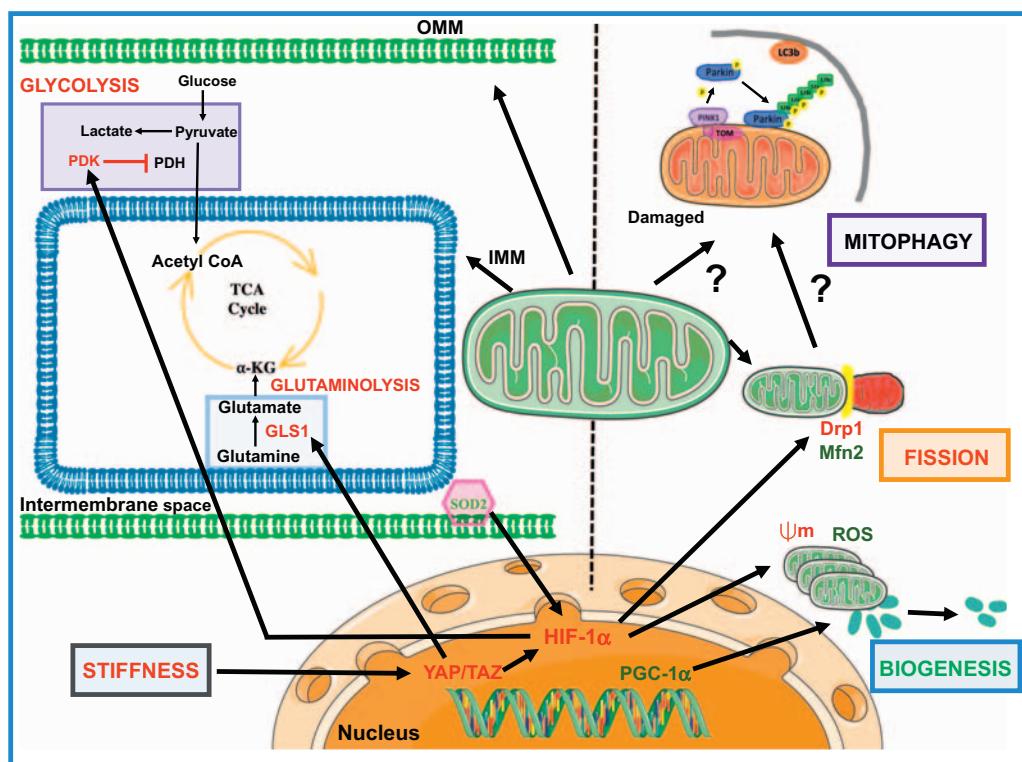
EndoMT is emerging as another phenotype which may contribute to endothelial dysfunction and vascular remodeling in PAH,[121,122] and may be dependent on ECM stiffness. ECs in the pulmonary vasculature normally act as a barrier between blood components such as inflammatory cells and tissues and remain in a monolayer comprising the vessel wall. In PAH, inflammatory processes and altered TGF-β/BMPR2 signaling have been shown to compromise this barrier and contribute to the induction of mesenchymal markers, intimal thickening, and medial migration of endothelial cells, a process known as EndoMT (Fig. 57.3).[121] In vitro, EndoMT is stimulated by increased TGF-β receptor signaling from TGF-β and cytokines leading to migration and further decreased barrier integrity in PAEC.[121,123]

During EndoMT, PAEC become elongated and lose EC-specific adhesion proteins that help maintain barrier integrity such as CD31/PECAM-1 and VE-cadherin.[124,125] These PAEC then detach from the endothelial layer and change their morphologic characteristics. They take on a more mesenchymal-like phenotype with increased collagen deposition and α-SMA expression. BMPR2 signaling has been shown to attenuate EndoMT phenotypes, and cells with BMPR2 mutations have enhanced EndoMT induction.[97,126] In animal models of PH, hypoxia has been shown to increase expression of transcriptional drivers of EndoMT.[122,127] In vitro, inflammatory cytokines IL-1β, IL-6, TNF-α, and reactive oxygen species (ROS) induce EndoMT through TGF-β pathway activation, indicating that inflammatory signaling promotes EndoMT. ET-1 has synergistic effects with TGF-β and cytokines in inducing EndoMT, which is of interest given the role of ET-1 in proximal pulmonary artery stiffening.[128] In addition, HPF has been shown to induce EndoMT and activate adventitial fibroblasts.[129]

YAP/TAZ signaling has been implicated in EndoMT in the cardiovascular system, with downregulation of YAP disrupting EndoMT in vitro and in vivo, leading to cardiac cushion defects in EC-specific YAP knockout mice.[130] EndoMT can also be induced by canonical Wnt signaling. In a myocardial infarction model and using lineage tracing, one group demonstrated that the Wnt pathway was activated in α-SMA-positive mesenchymal cells derived from ECs.[131] In vitro, activation of canonical Wnt signaling was associated with induction of mesenchymal markers and reduction in endothelial markers in endothelial cells.[131] Furthermore, TGF-β1-induced EndoMT in aortic valvular endothelial cells was enhanced in cells grown on stiff substrates and was accompanied by increased nuclear localization of β-catenin.[132] Further research is needed to determine the role of ECM stiffness and the Hippo pathway, as well as crosstalk with Wnt signaling, in driving EndoMT in PAH.

Angiogenesis

Vascular stiffness may also contribute to PH pathogenesis via upregulation of proangiogenic signaling.[108,133] Circulating levels of VEGF are elevated in PAH patients and VEGF and VEGFR-2 are both robustly expressed in pulmonary vascular neointimal lesions.[134] Leukocyte recruitment in PAH may lead to release of many proangiogenic factors that induce resident vascular cells to initiate new vessel growth.[135–137]

Several groups have demonstrated that MMPs, in addition to modulating ECM, regulate angiogenesis. MMP-9, which is increased in PAH patients, regulates the bioavailability of VEGF and has been shown to increase angiogenesis in metastatic cancer.[138,139] MMP-13 also stimulates VEGF secretion and promotes tumor angiogenesis through FAK signaling.[140] Membrane-bound MMP-14 regulates localization of VEGFR-2 on the cell surface and is required for increased angiogenesis in cancer.[108,141] MMP-2 is also localized at the cell surface during angiogenesis by interactions with integrin αvβ3, which, along with other αv integrins, are known to be overexpressed on the EC surface of newly forming vessels.[142] Studies in solid tumors have also found that increased Rho/ROCK-dependent cytoskeletal tension in ECs allow for capillary network formation.[143]


Hippo pathway mechanotransduction has also been associated with angiogenesis downstream of VEGF signaling. VEGFR activation inhibits MST1/MST2 and LATS1/LATS2, thus indirectly upregulating YAP/TAZ.[144] YAP/TAZ likely play a critical role in vascular sprouting, branching, and angiogenesis, as EC-specific YAP/TAZ knockout mice are embryonically lethal with heart and vascular malformations.[145] In addition, YAP knockdown

results in defective EC tubular network formation.[146] One of the key transcriptional regulatory targets of YAP in ECs is angiopoietin-2 (Ang-2), a vascular growth factor secreted by ECs at active remodeling sites that demonstrates context-specific regulation of angiogenesis.[144,146] The interactions between YAP/TAZ, VEGF, and Ang-2 and their in vivo consequences suggest an important role for stiffness and YAP/TAZ signaling in the regulation of angiogenesis; however, the crosstalk and effects on vascular remodeling in PAH has not yet been clearly established. While many studies demonstrate the role of stiffness-associated signaling and angiogenesis in the field of oncology, further work is needed to determine how

mechanotransduction contributes to regulation of angiogenesis in PAH pathobiology.

Metabolic reprogramming and mitochondrial dysregulation

Metabolic reprogramming, also called the Warburg effect, refers to the shift from oxidative phosphorylation to aerobic glycolysis in order to meet cellular energy requirements (Fig. 57.4).[147] Abnormalities in metabolic reprogramming have been increasingly recognized as pathologic contributors to many diseases including asthma, obesity, diabetes, chronic obstructive pulmonary disease, PAH, and

FIGURE 57.4 Vascular stiffness and mitochondrial dysfunction in pulmonary arterial hypertension. Metabolic reprogramming and mitochondrial dysfunction are increasingly recognized as contributing to the pathobiology of pulmonary arterial hypertension (PAH) with a shift from glucose oxidation to glycolysis (Warburg effect). Stabilization of the transcription factor HIF-1α leads to upregulation of PDK, PDH inactivation, and inhibition of pyruvate conversion to acetyl-CoA. Stiffness-induced YAP/TAZ activation may play a role in HIF-1α stabilization in PAH, as has been observed in malignant cells. Stiffness-mediated YAP/TAZ activation also enhances GLS1-dependent glutaminolysis, replenishing the TCA cycle metabolite α-ketoglutarate which may contribute to amino acid and nucleic acid biosynthesis in hyperproliferative pulmonary vascular cells. Other mitochondrial abnormalities in PAH include an increase in the mitochondrial membrane potential (Ψm), alteration in mitochondrial-derived ROS generation, reduced mitochondrial biogenesis (decreased PGC-1α), and enhanced mitochondrial fission/fragmentation (increased Drp1, decreased Mfn2). Much less is known about mitophagy, the process of removing damaged mitochondria, in PAH and whether it may contribute to reduced mitochondrial mass and pulmonary vascular remodeling phenotypes. While it is unknown whether vascular stiffness regulates mitochondrial dynamics in PAH, YAP has been shown to modulate expression of Drp1 and regulate mitochondrial fission and mitochondrial membrane potential during myofibroblast differentiation. Further study is needed to elucidate the effects of pulmonary vascular stiffening on mitochondrial quality control and metabolic dysfunction in PAH. *Acetyl-CoA*, acetyl coenzyme A; *α-KG*, α-ketoglutarate; *Drp1*, dynamin-related protein 1; *GLS1*, glutaminase 1; *HIF-1α*, hypoxia-induced factor-1α; *IMM*, inner mitochondrial membrane; *LC3B*, microtubule-associated protein 1 light chain-3B; *Mfn2*, mitofusin 2; *OMM*, outer mitochondrial membrane; *P*, phosphoryl group; *PDH*, pyruvate dehydrogenase; *PDK*, pyruvate dehydrogenase kinase; *PGC-1α*, Peroxisome proliferator-activated receptor-γ coactivator 1α; *PINK1*, PTEN-induced kinase 1; *ROS*, reactive oxygen species; *SOD2*, superoxide dismutase 2; *TAZ*, transcriptional co-activator with PDZ-binding motif; *TCA*, tricarboxylic acid; *TOM*, translocase of the outer membrane; *Ub*, ubiquitin; *YAP*, Yes-associated protein; *Ψm*, mitochondrial membrane potential. Red text denotes pathways that are increased in PAH, while green text indicates pathways that are downregulated in PAH.

particularly malignancies.[148,149] Given the known changes in proliferative capacity and dedifferentiation that occur during PAH pathogenesis, it is perhaps unsurprising that the Warburg effect has been consistently found in arterial vascular cells in PAH patients and rodent PH models.[150] Endothelial cells engineered to overexpress BMPR2 mutations found in patients with hereditary PAH also demonstrate increased glycolysis and the Warburg effect in culture, indicating that this reprogramming may be an important "first hit" in PAH pathogenesis.[151]

Enhanced glycolysis is well-established downstream of hypoxia-induced factor-1α (HIF-1α) activation in the setting of hypoxia, but the mechanism of Warburg activation under normoxic conditions in pulmonary vascular cells during PAH pathogenesis has been less understood until recently. An early clue was the effectiveness of the pyruvate dehydrogenase kinase (PDK) inhibitor dichloroacetate (DCA) in driving PAH-derived PASMC apoptosis and partially reversing PH in animal models.[152] PDK is a direct target of HIF-1α (Fig. 57.4), and implied likely HIF-1α stabilization during normoxic pulmonary vascular remodeling, a finding that was subsequently verified.[152] There is some evidence that superoxide dismutase 2 (SOD2) deficiency, which has been seen in human PAH and pulmonary vascular cells, may be a key underlying contributor to HIF-1α stabilization, and likely underlies spontaneous PH observed in fawn-hooded rats.[153] Although understudied in PH, TAZ forms a complex with HIF-1α in the nucleus,[154−156] and HIF-1α and TAZ act synergistically as reciprocal coactivators in breast cancer cells.[154] YAP has also been found to be essential for HIF-1α stabilization in the setting of malignancy.[157] It is therefore highly plausible that HIF-1α stabilization in the absence of hypoxia is, in some part, promoted by stiffness-dependent YAP/TAZ activation, but further study is needed to confirm this hypothesis.

Enhanced glycolysis has a profound effect on cellular metabolic activity, most directly via decreased flux through the electron transport chain, generating high membrane potentials and decreased mitochondrial ROS production that alter multiple mitochondrial functions (Fig. 57.4). Mitochondrial dynamics, including biogenesis, fission/fusion, and turnover (mitophagy), remain understudied in PH. One intriguing line of research from the Archer group has demonstrated fragmentation of mitochondria associated with an increase in one of the major proteins controlling mitochondrial fission, dynamin-related protein 1 (Drp1). Inhibition of Drp1 using a small molecule inhibitor or siDrp1 leads to antiproliferative, proapoptotic effects in vitro and partially ameliorates PH in murine models.[158] Intriguingly, the mechanism of Drp1 activation in this setting is unknown, but YAP activity at least appears to indirectly regulate Drp1 in developing myoblasts,[159] again suggesting a possible connection to stiffness-dependent

mechanotransduction. Further study on mitochondrial dynamics in the setting of pulmonary vascular stiffening and early PH pathogenesis will hopefully provide a clearer sense of how these two pathogenic phenotypes intersect.

In proliferating cells with enhanced glycolysis, mitochondrial activity via the tricarboxylic acid (TCA) cycle is still required to facilitate production of amino acids and nucleic acids. Increased TCA activity, which has been observed in human PAH lungs,[160] leads to upregulation of metabolic pathways for TCA intermediates. One such pathway is glutaminolysis, which converts glutamine into the TCA cycle metabolite α-ketoglutarate. Recent work has shown that the key enzyme in this process, glutaminase 1 (GLS1), is activated by increased vascular stiffness via a YAP/TAZ-mediated pathway in pulmonary vascular cells (Fig. 57.4).[37] Pharmacological inhibition of either YAP or GLS1 attenuates increases in right ventricular systolic pressure (RVSP) and pulmonary vascular remodeling in the MCT-induced PH model in rats.[37] Enhanced glutaminolysis has also been observed in the RV in experimental PH, and inhibition of glutaminolysis has been shown to attenuate RV cardiomyocyte hypertrophy and restore normal glucose oxidation.[161] This evidence strongly suggests that targeting mechanical signaling may have a significant impact on metabolic derangements observed in PAH. These intriguing links between mitochondrial dynamics, metabolic reprogramming, and mechanotransduction are summarized in Fig. 57.4.

Targeting PA stiffness and mechanotransduction in PH

Accumulating evidence has demonstrated that early PA stiffening is a major driver of vascular remodeling in PH by promoting mechanical signaling in pulmonary vascular cells. Inhibition of early ECM remodeling, pulmonary vascular stiffening, and mechanotransduction attenuates vascular remodeling and development of PH in preclinical models. Therapeutic targeting of ECM remodeling and mechanotransduction pathways has the potential to intercept mechanobiological feedback and arrest or reverse PA stiffness-induced vascular remodeling in PH (Table 57.1).

Inhibition of serine elastase with elafin reduces ECM accumulation and has shown promising results in preclinical PH models[69,162]; it is currently being evaluated in early-phase clinical trials. In addition to increased collagen deposition, enhanced collagen cross-linking, which contributes to ECM remodeling and pulmonary vascular stiffening, may be a potential novel mechanobiological target in PH. Lysyl oxidases (LOX) are key collagen cross-linking enzymes upregulated in PAH and experimental PH,[163] and inhibition of their activity with BAPN prevents ECM remodeling and attenuates PH in rodent models.[23,37,163] While no studies to date have evaluated LOX inhibitors in

TABLE 57.1 Potential mechanobiological therapeutic targets in pulmonary hypertension.

Mechanosensitive target	Drug/Molecular target	Preclinical	Clinical trial
ECM remodeling			
Serine elastase inhibitor	SC-39026, SC-37698, M249314, ZD0892	Attenuates/reverses hypoxia- and MCT-induced PH in rats[67,68,70]	
	Elafin	Reverses sugen/hypoxia-induced PH in rats; elafin transgenic mice protected from hypoxia-induced PH[69,162]	Phase 1 (NCT03522935)
Lysyl oxidase (LOX) inhibitor	β-aminopropionitrile (BAPN)	Prevents/rescues hypoxia-induced PH in mice[23,163]; attenuates MCT-induced PH in rats[37]	
	PXS-5505 (Pharmaxis)		Phase 2 (myelofibrosis)
Lysyl oxidase-like 2 (LOXL2) inhibitor	LOXL2 small molecule inhibitor (Pharmaxis)		Phase 2 planned (NASH, cardiac fibrosis, idiopathic pulmonary fibrosis [IPF])
	Simtuzumab (LOXL2 monoclonal antibody)		Negative phase 2 in IPF[164]
Transglutaminase-2 (TG2)	ERW1041E (TG2 inhibitor)	Attenuates ECM remodeling and RVSP but not RVH in mouse sugen/hypoxia model[165,166]; hypoxia-induced PH attenuated in VSMC-specific TG2 knockout mice[a]	
	ZED1227		Phase 2 (celiac disease)
TGF-β signaling	TGF-β receptor I (ALK5) inhibitor SD-208, TGF-β antibody T9429	Attenuates MCT-induced PH in rats[167,168]	
	TGFBRII-Fc (TGF-β1/3 ligand trap)	Attenuates MCT-induced PH and sugen/hypoxia- induced PH in rats and sugen/hypoxia-induced PH in mice, improves established PH in rats induced by MCT and sugen/hypoxia[169]	
	ACTRIIA-Fc (GDF8/11 and activin ligand trap)	Attenuates PH development and improves established PH induced by MCT and sugen/hypoxia in rats[170]	
	Sotatercept (GDF8/11 and activin ligand trap)		Phase 2 trial showed improvement in PVR and 6-minute walk distance at 24 weeks in PAH patients (NCT03496207, NCT03738150)[171,172]; phase 3 in PAH (NCT04576988)
Mechanosensors			
FAK	PF-573228, FAK siRNA	Inhibits MCT-induced PH in rats[88]	
	GSK-2256098		Phase 2 in pancreatic cancer (NCT02428270)
	Defactinib (VS-6063)		Phase 1 in advanced pancreatic cancer (NCT02546531), phase 1/2a in advanced solid malignancies (NCT02758587)

TABLE 57.1 Potential mechanobiological therapeutic targets in pulmonary hypertension.—cont'd

Mechanosensitive target	Drug/Molecular target	Preclinical	Clinical trial
Rho/ROCK	Fasudil	Attenuates MCT-induced PH in rats and hypoxia-induced PH in mice[47,48]; reduced hypoxia-induced PH in VSMC-specific ROCK2[+/−] mice[b]	Short-term IV use reduces PVR and mPAP, may improve outcomes in right heart failure and severe PH[49]; improves hemodynamics in PH-HFpEF[173]; oral extended formulation (AT-877ER) use for 12 wks improved cardiac index from baseline, no difference in 6-minute walk distance[174]
Transcriptional mechanotransducers			
YAP/TAZ	Verteporfin	Attenuates MCT-induced PH in rats[37]	FDA-approved for IV use in photo-dynamic therapy of age-related macular degeneration
MRTF-A	MRTF-A shRNA	Attenuates hypoxia-induced PH in rats[55]	
miRNA-130/301	miR-130/301 inhibition (Short-130)	Reduces ECM expression, YAP activity, RVSP, and RVH in MCT-treated rats; attenuates vascular stiffening in sugen/hypoxia model in mice[23]	
Metabolism mediators			
Glutaminase inhibitors	C968, CB-839	Prevents/reverses MCT-induced PH in rats[37]	Telaglenastat (CB-839) in phase 1/2 clinical trials in advanced lung cancer (NCT03831932, NCT04250545, NCT04265534) and other solid malignancies (NCT02071862)

patients with PH, a Phase 2 trial of simtuzumab, a monoclonal antibody against lysyl oxidase-like 2 (LOXL2), showed no significant improvement in progression-free survival in patients with idiopathic pulmonary fibrosis (IPF).[164] A LOX inhibitor PXS-5505 is in Phase 2 trials for myelofibrosis and a small molecule inhibitor of LOXL2 is currently being developed for study in nonalcoholic steatohepatitis (NASH), cardiac fibrosis, and IPF. Tissue transglutaminase (TG2), which promotes cross-linking of ECM proteins with serotonin and leads to increased ECM stability and tissue rigidity,[175] is emerging as another potential mechanobiological target in PH. TG2 expression and activity are upregulated in rodent models of PH[165,176] and TG2 inhibition with ERW1041E reduces ECM production and attenuates RVSP in the sugen hypoxia model in mice.[165,166] While a Phase 2 trial of the oral TG2 inhibitor ZED1227 is underway in celiac disease, TG2 inhibitors have yet to be studied in PH or fibrotic diseases.

Integrins relay critical mechanical information from the ECM to key intracellular mechanosensors such as FAK, Src, and Rho/ROCK, and downstream transcriptional mechanotransducers such as YAP/TAZ and MRTF-A, all of which may be potential mechanobiological targets in PH. Integrin signaling also activates latent TGF-β,[177] which drives EndoMT and leads to further matrix stiffening and amplification of pulmonary vascular remodeling in PH. Small molecule inhibitors of different integrins are under investigation in fibrotic diseases with an ongoing Phase 2a trial of a dual selective αvβ6/αvβ1 integrin inhibitor, PLN-74809, in IPF (NCT04072315). While integrins have been less well-studied in PH, small molecular inhibitors of TGF-β signaling have been shown to be beneficial in animal PH models.[167,168] Most recently, a selective TGF-β 1/3 ligand trap has been shown to attenuate and reverse established PH in experimental models.[169] Furthermore, treatment with a ligand trap targeting ACTRIIA ligands activin and GDF8/11 attenuated established PH and inhibited pulmonary vascular cell proliferation via inhibition of Smad 2/3 activation.[170] Preliminary results from a Phase 2 trial (PULSAR) of the human ACTRIIA-Fc analog sotatercept

in PAH were recently reported,[171,172] showing improvement in PVR and 6-minute walk distance at 24 weeks. A Phase 3 trial of sotatercept in PAH (NCT04576988) is planned.

Inhibition of the downstream mechanosensor FAK with pharmacological inhibitors or siRNA has been shown to attenuate MCT-induced PH[88] and preclinical lung fibrosis.[178] While no clinical studies have evaluated FAK inhibition in PAH, several Phase 2 trials evaluating small molecule inhibitors of FAK are underway in pancreatic cancer and other advanced solid malignancies. Inhibition of the Rho/ROCK pathway with fasudil has also shown promise in experimental PH models[47,48] and clinical trials evaluating its short-term use.[49,173,174] Intravenous (IV) fasudil has been shown to acutely reduce PVR and mean pulmonary arterial pressures (mPAP) in patients with PAH[49] and PH due to left ventricular heart failure with preserved ejection fraction (PH-HFpEF),[173] although the effects of long-term fasudil use remain understudied. A small trial of an oral extended release formulation of fasudil (AT-877ER) in PAH patients for 12 weeks showed modest improvement in cardiac index, although did not significantly improve 6-minute walk distance.[174]

Stiffness-dependent activation of transcriptional regulators, such as YAP/TAZ and MRTF, play a key role in driving transcriptional programs that promote vascular cellular remodeling and have therefore emerged as potential mechanobiological targets in PAH. Knockdown of MRTF-A has been shown to attenuate hypoxia-induced increases in RVSP, pulmonary vascular remodeling, ECM expression, and RVH in rats.[55] MRTFs are also of interest as potential targets in fibrosis and pancreatic cancer; however, studies remain preclinical to date. YAP/TAZ are powerful effectors of mechanical signaling in pulmonary vascular cells and have recently shown promise in experimental PH. Pharmacological inhibition of YAP with verteporfin, an FDA-approved photosensitizer for treatment of age-related macular degeneration, reduced PA stiffening, RVSP, and RVH in MCT-treated rats.[37] In addition, inhibition of miRNA 130/301 reduced ECM deposition, YAP activation, and attenuated PH in MCT-treated rats in a YAP/TAZ-miRNA 130/301-ECM feedback loop.[23] Furthermore, treatment with a GLS1 inhibitor prevented YAP/TAZ-dependent activation of GLS1 and in doing so, both attenuated PH development and reversed established PH in MCT-treated rats.[37] The glutaminase inhibitor telaglenastat is currently being studied in Phase 1/2 trials in advanced lung cancer and other solid malignancies, and may be a promising therapeutic in human PAH. In addition to agents which inhibit YAP/TAZ-TEAD interactions such as verteporfin, a number of small molecules have been found to inhibit upstream activation of YAP/TAZ, including statins,[179] and dopamine receptor D1 agonists such as dihydrexidine, which selectively inhibits YAP/TAZ activation

in fibroblasts and reverses experimental lung and liver fibrosis.[180] Development of small molecule inhibitors of YAP/TAZ activity is an active area of research, particularly in the oncology field,[181] with significant potential for therapeutic applications in fibrosis and PAH.

Conclusion

Accumulating evidence demonstrates that early PA stiffening drives vascular cell activation via upregulation of mechanosensitive molecular pathways that promote further vascular remodeling, matrix stiffening, and progression of disease in PAH. Recent studies have begun to elucidate the mechanisms by which pulmonary vascular cells sense and transduce signals from the micromechanical environment to drive transcriptional responses which promote pathologic vascular remodeling in PAH. Therapeutics that intercept this mechanobiological feedback loop, whether directed at ECM remodeling or the downstream signaling pathways that are activated in response to alterations in the matrix microenvironment, may have potential to halt or reverse vascular remodeling in PAH (Table 57.1). Further research is needed to more thoroughly delineate the key mechanotransduction pathways activated in pulmonary vascular cells in response to PA stiffening in order to identify optimal targets for mechanotherapeutic targeting in PAH.

Chapter 58

Therapeutic approaches to improve pulmonary arterial load and right ventricular–pulmonary arterial coupling

Michael J. Bashline[1] and Marc A. Simon[2]

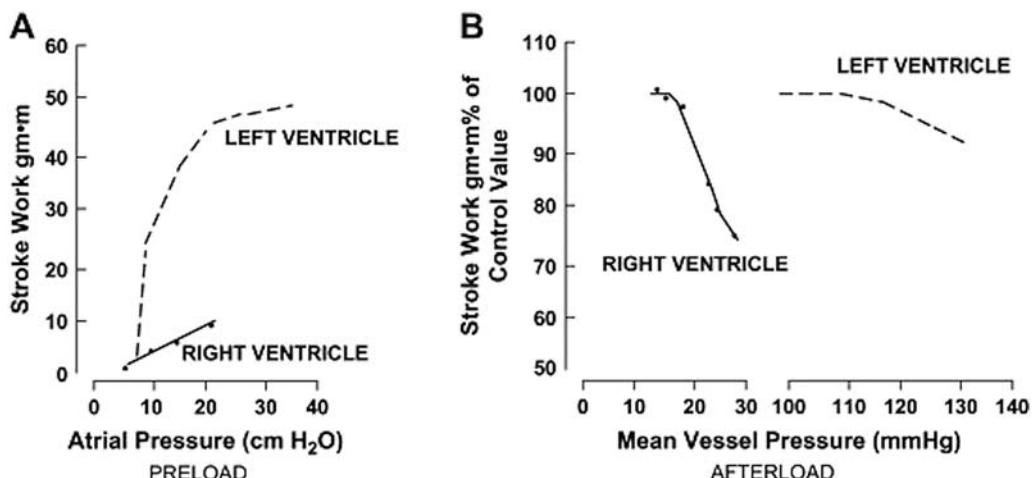
Introduction

The prevalence of heart failure continues to remain an epidemic on a global scale, especially throughout the United States, contributing to an elevated mortality and morbidity within the healthcare system. Significant advancements have been made that resulted in an improvement in mortality and reduction of hospitalizations for patients with heart failure with reduced ejection fraction (HFrEF) since the implementation of guideline directed medical therapy (GDMT).[1] Furthermore, research has continued to produce trials that support the use of newer agents that provide incremental benefit in this specific patient population, including SGLT-2 inhibitors and oral guanylate cyclase stimulators.[2,3] However, less success has been made with right ventricular (RV) failure, despite the increasing recognition of importance as the presence of RV dysfunction or failure is among the strongest predictors of outcome for patients with precapillary pulmonary hypertension (PH) as well as in left-sided heart failure.[4,5] While several explanations are possible including numerous etiologies with different pathophysiologic mechanisms, another reason is likely due to the physiology of the pulmonary circulation and the unique loading forces that the RV encounters.

This chapter will first review the pathophysiology of RV dysfunction and eventual failure, and then will briefly expand upon RV afterload. A current approach to managing RV dysfunction and failure will be presented, focusing on strategies to improve RV performance by reducing afterload. The most common conditions that contribute to an increase in RV afterload will be reviewed, including PH due to pulmonary arterial hypertension (PAH) and heart failure with preserved ejection fraction (HFpEF) while emphasizing the available treatment options and novel therapies under current investigation.

Right ventricular dysfunction and failure


Response to normal loading conditions

Due to the inherent differences between the structure and anatomy of the RV and left ventricle (LV), the response to alterations in preload and afterload are dramatically dissimilar. The LV can tolerate abrupt increases in afterload, but has difficulty handling abrupt increases in preload. In contrast, the thin-walled, highly compliant nature of the RV can accommodate changes in preload but cannot tolerate abrupt increases in afterload.[6] Therefore, the highly compliant RV allows for significant increases in end-diastolic volume (EDV) without significant increases in the end-diastolic pressure (EDP) (Fig. 58.1).[6–8]

According to the law of LaPlace, wall tension (σ) is proportional to the pressure (P) times the radius (r), divided by the wall thickness (h).

$$\sigma \propto \frac{P * r}{h}$$

Thus, wall tension is greater in the RV during conditions that raise afterload or preload given that the RV has a thinner wall (h) and dilates easily, resulting in an increased cavity radius (r) during contraction.[9]

FIGURE 58.1 *Left panel*: Effects of an increase in preload on the left ventricle (LV) compared with the right ventricle (RV). RV is more compliant as demonstrated by large changes in stroke work with little changes in atrial pressure. *Right panel*: Effect of an increase in afterload on the LV compared with the RV. A small increase in afterload results in a large reduction RV stroke work which is in contrast to smaller reductions in LV stroke work. *Reproduced from Chan CM.* **Clin Chest Med**. *2008; 29:661−76. Pathophysiology of acute right heart failure

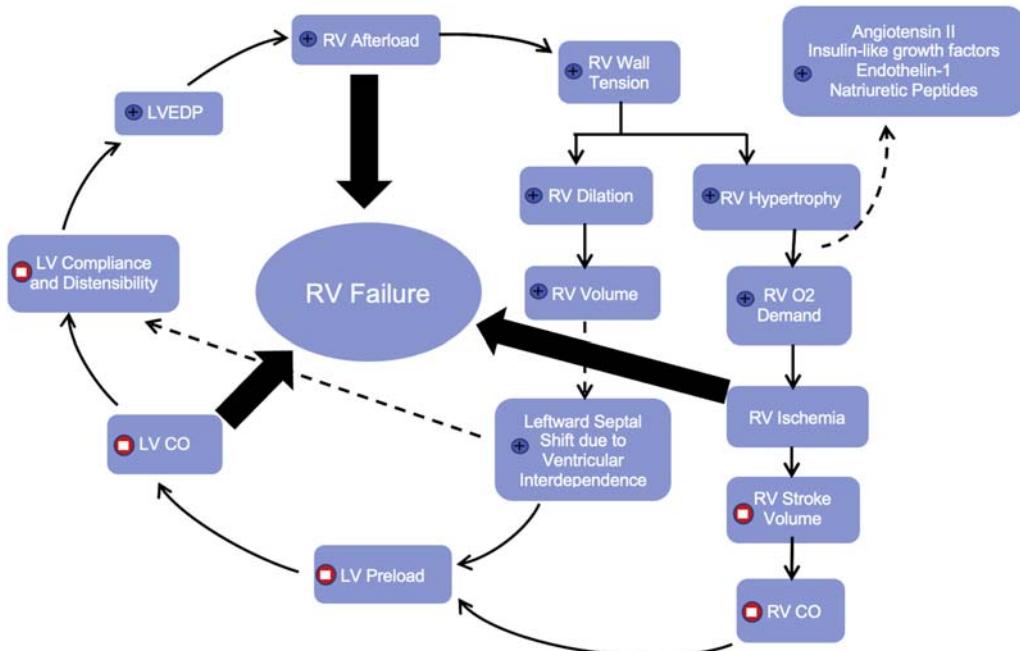
Acute failure of the RV is either due to the result of an abrupt increase in afterload, or a sudden decrease in contractility/RV performance. A common cause of an abrupt increase in afterload is pulmonary embolism (PE), while RV infarction or acute, fulminant myocarditis of the RV are the common etiologies of reduced contractility.[10] As mentioned above, the RV is less equipped to tolerate an abrupt rise in afterload and results in a decline in RV stroke volume (SV) without a corresponding increase in RV systolic pressure. Without adequate contractility, the RV will not be able to generate a sufficient SV to maintain cardiac output (CO) to the LV, which ultimately leads to cardiogenic shock.

Pathophysiology of chronic right heart failure


There are a variety of clinical conditions, including myocardial ischemia, PH, left-sided heart failure, valvular heart disease, cardiomyopathies, and congenital heart disease, that can lead to RV dysfunction over time. Regardless of the underlying etiology, RV dysfunction often starts with myocyte hypertrophy and chamber dilation in response to an increased wall stress which permits the RV to generate a higher RV systolic pressure and EDV. RV hypertrophy involves an increase in size via sarcomere synthesis and extracellular matrix expansion via fibrosis that is mediated by an overexpression of growth factors including angiotensin II, insulin-like growth factor I, natriuretic peptides, and endothelin 1 that seem to be uniquely expressed in the RV.[11,12] Furthermore, there is growing evidence that these biochemical signaling pathways that lead to RV remodeling are unique when compared to the remodeling pathways

present in the LV. This is likely due to the unique physiology of the RV and pulmonary vascular circulation, as well as a distinct embryological origin in comparison to the LV.[13,14] While these pathways are initially a compensatory adaptation of the RV in response to increase in wall stress, continued tension will eventually lead to a decompensated state in which RV contractility becomes uncoupled from the pulmonary vascular circulation. In this phase, the RV is unable to generate a high enough RV systolic pressure to maintain CO.[6,15–17]

Interventricular interdependence also may contribute to RV dysfunction. Normally, LV EDP is greater than the RV EDP, and thus the septum shifts toward the RV during diastole. However, in situations that cause an elevation in RV afterload, the RV EDP can exceed the LV EDP and the interventricular septum shifts toward the LV during diastole, which results in a reduction in LV filling and a subsequent decrease in CO.[7,18,19] Fig. 58.2 is a diagram that illustrates the complex pathways and mechanisms that intersect to lead to RV failure.

The components of right ventricular afterload

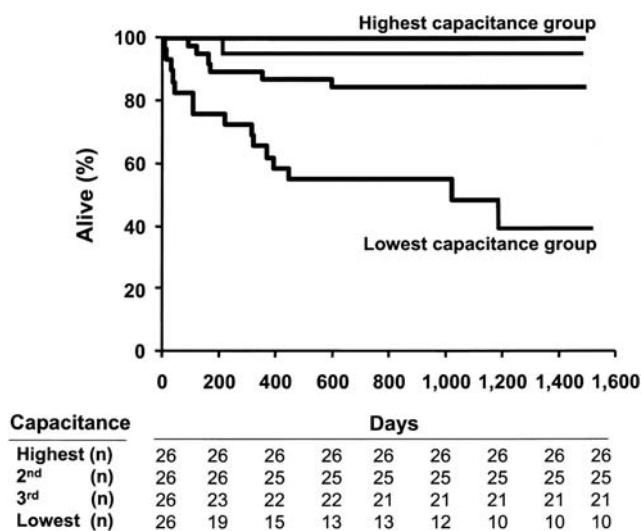
In order to understand the various treatment options available to reduce RV afterload and improve RV myocardial performance, a brief understanding of the components that represent afterload must be described. Afterload by definition represents the impedance to blood flow that the ventricle encounters during systole. There are two components to RV afterload: resistance which is the steady-state opposition to flow, and forces related to the pulsatile nature of blood flow. Pulmonary vascular

FIGURE 58.2   Schematic illustrating the complex pathophysiology that results in a negative feedback loop and eventual RV failure. *CO*, cardiac output; *LVEDP*, left ventricular end-diastolic pressure.

resistance (PVR), which can be obtained invasively via right heart catheterization (RHC), is defined as the change in pressure from entry to exit of the pulmonary vasculature (also known as the transpulmonary gradient [TPG]), and is defined as the difference between the mean pulmonary artery pressure [mPAP] and the pulmonary artery wedge pressure [PAWP] divided by to CO:

$$PVR = \frac{TPG}{CO} = \frac{(mPAP - PAWP)}{CO}$$

However, PVR is a steady-state measurement, rather than representing the time-varying load during ventricular systole, and thus ignores the pulsatile components of load. The pulsatile component of RV afterload is substantial, representing up to one-third to one-half of the total hydraulic load encountered by the RV.[20]

While PVR can be obtained via RHC, it is more difficult to accurately measure the pulsatile components that contribute to RV afterload. Several studies have shown a correlation between the pulsatile load and pulmonary arterial compliance (C_{PA}) which is estimated as the RV SV divided by the PA pulse pressure (PP), defined as the difference between systolic pulmonary artery pressure (sPAP) and diastolic pulmonary artery pressure (dPAP). However, this method does not take into account the presence of wave reflections.[21–23]


$$C_{PA} = \frac{SV}{PP} = \frac{SV}{sPAP - dPAP}$$

Considering PVR in isolation as a measure of load not only neglects approximately one-third to one-half of the RV afterload but also several recent trials that have found an association between C_{PA} and mortality or cardiac hospitalizations in patients with PH due to heart failure with preserved ejection fraction (PH-HFpEF). C_{PA} has also been shown to be an independent risk factor for mortality in patients with idiopathic PAH (Fig. 58.3).[22,24,25]

The gold standard for assessing RV afterload is the pulmonary vascular impedance (PVZ) which incorporates the steady-state load and pulsatile load, including the wave reflections that the RV encounters.[20,26,27] PVZ is technically challenging to measure, which explains its limited use clinically, as it represents the ratio of pressure to flow waves in the frequency domain, and thus requires performing a fast Fourier transform to obtain the sinusoidal components of the pressure and flow waves via a method that has been validated by several prior studies.[28,29] Chapters 1 and 7 include detailed discussion regarding the derivation and interpretation of input impedance spectra.

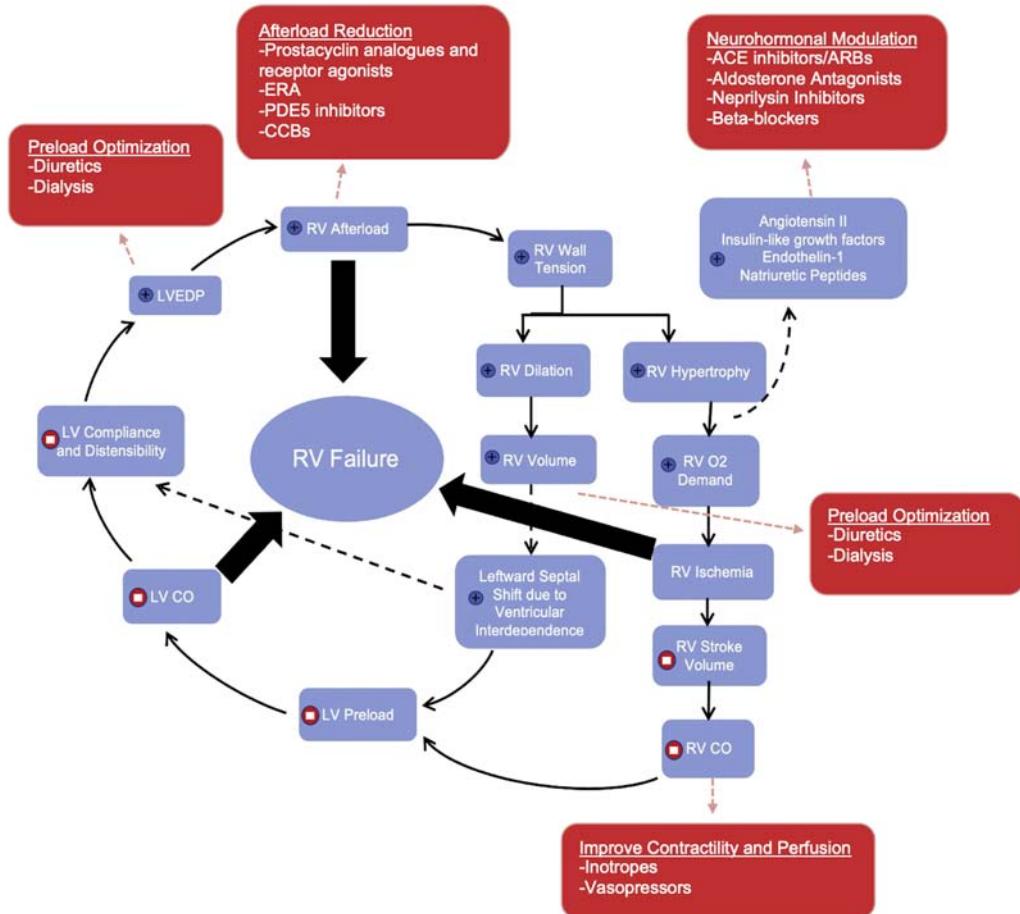
Approach to the management of right ventricular failure

The approach to RV dysfunction and failure continues to represent a challenging dilemma for physicians as management depends on the underlying etiology, yet the presence of RV failure is an independent risk factor for

FIGURE 58.3   Kaplan–Meier survival curve in a population with idiopathic pulmonary arterial hypertension depicting higher percent survival with time in the highest capacitance group, and the lowest percent survival with time in the lowest capacitance group. *Reproduced from Mahapatra S. J Am Coll Cardiol. 2006; 47:793–803. Copyright 2006, with permission from Elsevier.*

mortality regardless of etiology. Despite this, several broad themes exist that are common to management, including optimization of preload and volume status, maintenance of perfusion, improvement of contractility, and neurohormonal modulation. An additional approach revolves around therapeutic agents that target reducing the afterload, which will be the focus of the next section. While each of these approaches to management will be presented separately, it is important to remember that a combination of strategies is often required for the optimal treatment of RV dysfunction/failure, and applying one of these management strategies will often impact the others. Fig. 58.4 illustrates each of these themes in the pathway of RV failure and the corresponding therapies that will be discussed.

Optimization of preload and volume status

The importance of optimizing volume status, or preload, was illustrated in the CHAMPION trial which showed a 37% reduction in heart failure–related hospitalizations using CardioMEMS, an implantable hemodynamic monitor placed in the distal pulmonary artery, to guide volume management.[30] However, this trial included patients with HFrEF, and did not report on the degree of RV dysfunction/failure present. Physiologically, this principle is illustrated by the Frank–Starling curve which depicts how changes in preload affect SV. The Frank–Starling curve for the RV tends to be much flatter in comparison to the LV, owing to the highly compliant nature of the RV, implying that RV contractility changes less over a wide range of right atrial filling pressures.[6–8]


RV afterload is usually increased in the vast majority of cases where RV dysfunction/failure is present, and in the presence of RV dysfunction is frequently accompanied by volume overload (increased preload). Therefore, reducing preload is important to reduce RV dilatation, free wall tension, and septal shifting that can impair LV filling.[31] Presentation of volume overload due to RV failure is often an insidious process that eventually results in lower extremity and scrotal edema, hepatic congestion, and ascites. Furthermore, an elevated right atrial pressure can lead to renal congestion resulting in acute kidney injury and activation of the sympathetic nervous system and the renin-angiotensin-aldosterone axis, with the degree of severity linked to poorer outcomes.[32–34]

Given the consideration above, diuretics remain one of the hallmark treatment options, with an estimated 75% of patients with chronic RV dysfunction/failure requiring a daily dosing regimen.[35] While guidelines do not recommend a specific diuretic, most clinicians use bumetanide over furosemide, due its higher oral bioavailability, which is often advantageous due to the presence of bowel wall edema in these patients.[36,37] Patients admitted to the hospital often require large doses of intravenous diuretics, and often require combination therapy with thiazide diuretics for sequential nephron blockage of sodium reabsorption.[38] Among patients that fail to respond to diuretic doses, renal replacement therapies including intermittent hemodialysis or continuous veno-venous ultrafiltration may be considered to remove intravascular volume. While there have not been any trials examining the role of these therapies in isolated RV failure, the CARRESS-HF trial included patients with left-sided or biventricular failure and compared a stepwise approach of a diuretic regimen to ultrafiltration. Ultrafiltration was associated with more adverse events, worsening renal function, and no change in weight.[39] However, a more recent meta-analysis suggested that ultrafiltration was safe and effective at reducing body weight without increase risk of renal injury and may even reduce admissions.[40] Due to the conflicting evidence, early use of renal-replacement is often not recommended at this time.

A concurrent strategy used to maintain an optimal preload state is fluid and salt restriction. Current guidelines recommend limiting sodium intake to <2 g/day and a fluid restriction of 1.5–2 L/day.[1]

Maintaining myocardial perfusion

Decreased myocardial perfusion in RV failure is often due to two separate mechanisms: RV myocardial oxygen supply-demand mismatch causing an increase in oxygen extraction or decreased systemic CO resulting from hypotension. As discussed previously, wall tension increases in response to either a decrease in contractility due to RV infarction or increase in afterload which initially results in

FIGURE 58.4   Schematic revealing where available therapeutic agents act in the pathway that leads to right ventricular (RV) failure. *ACE*, angiotensin converting enzyme; *ARBs*, angiotensin receptor blockers; *CCBs*, calcium-channel blockers; *CO*, cardiac output; *ERA*, endothelin-1 receptor antagonists; *LVEDP*, left ventricular end-diastolic pressure; *PDE5*, phosphodiesterase-5.

adaptive changes to the RV including dilation and eventual hypertrophy. These changes require an increase in myocardial oxygen delivery.[6,41,42] While reperfusion with percutaneous coronary interventions is the mainstay treatment for restoring perfusion in patients with RV ischemia or infarction, optimizing preload, afterload, and contractility will help reduce myocardial oxygen demand.

Systemic hypotension resulting from impaired RV CO can be seen in severe cases of RV failure, which often necessitates the use of inotropic support with addition of vasopressor agents if hypotensive. The use of inotropes to improve contractility will be discussed in the next section. Norepinephrine, an alpha and beta receptor agonist, tends to be the preferred vasopressor agent in patients with cardiogenic shock, when compared to dopamine and epinephrine.[43,44] In a small analysis of patients with septic shock, norepinephrine was associated with an improvement in RV myocardial oxygen delivery, as well as an increase in PVR, although there was no adverse effect on RV contractility.[45] Epinephrine was shown to improve RV

contractility in a different small analysis in patients with septic shock, but its use was limited by arrhythmias.[46] Therefore, norepinephrine seems to be the vasopressor agent of choice, although some clinicians still favor the use of epinephrine or dopamine due to their mild inotropic properties. It is important to recognize that the major drawback of all these vasopressor agents is that they will further increase ventricular afterload. Therefore, these agents should be used with the sole goal of maintaining a mean arterial pressure to ensure adequate CO to vital organs.[6,10,17] Vasopressin, which binds to V1 receptors on vascular smooth muscle cells, at low doses (0.01−0.03 U/ min) can cause pulmonary vasodilation via endothelial nitric oxide stimulation, but its use clinically for this is limited by a frequent need for higher doses.[47,48]

Improving contractility

Contractility is a measure of the strength of ventricular contraction, or inotropy, and represents an intrinsic

property of the ventricular myofibers. The gold standard measurement of ventricular function is end-systolic elastance (E_{es}) which is derived from the end-systolic pressure-volume relationship on the pressure-volume (PV) loop. E_{es} is a load-independent measure of myocardial contractility, but clinically it is often interchanged with CO, although they should not be equated as CO is a load dependent measure of ejection.[18,49] As mentioned in the prior section, inotropic therapy should be considered for known or suspected low CO states which manifests clinically as signs of worsening end-organ perfusion and inadequate response to diuretics. The ultimate goal is to augment myocardial contractility and RV SV while optimizing EDV and EDP.

Milrinone, a phosphodiesterase 3 inhibitor, and dobutamine, a beta-receptor agonist, represent the two most common inotropic agents used clinically. As a class, they both have inotropic and vasodilator properties and thus can worsen or precipitate hypotension which may necessitate use of a vasopressor agent in conjunction, and direct comparisons of these two drugs have shown similar outcomes with a potential to induce arrhythmias.[50,51] Milrinone is generally not recommended in isolated RV failure as the vasodilator properties may result in cardiovascular collapse. In such cases, vasopressors with inotropic properties, such as norepinephrine, are preferred.[6,52,53] Regardless of the agent selected, the goal should strictly be for short-term administration as chronic use is associated with increased mortality.[54,55]

Levosimendan is a myocardial calcium sensitizer and vasodilator agent that is currently unavailable in the United States. Several smaller studies in patients with decompensated right-sided heart failure have shown favorable improvements in hemodynamics via a dose-dependent increase in CO and SV that is associated with a reduction in PAWP. In addition, it appears to have some effect on the pulmonary vascular circulation by reducing PVR and TPG and is currently being investigated in patients with right-sided heart failure due to PH-HFpEF (NCT03541603).[56-59]

Neurohormonal modulation

Dysregulated neurohormonal pathways are one of the main mechanisms of heart failure that pharmacologic agents have had success targeting. These agents include the use of β-blockers, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), mineralocorticoid receptor antagonists (MRAs), and neprilysin inhibitors. While these agents have been shown to reduce the incidence of heart failure hospitalizations and improve mortality with the administration of these agents in patients with left-sided heart failure (HFrEF), the role of these agents in right-sided heart failure is less clear.

β-blockers, such as metoprolol succinate, carvedilol, and bisoprolol, remain the cornerstone in treatment of patients with HFrEF by improving LV ejection fraction and mortality.[1] In brief, the mechanisms are thought to be secondary to inhibition of altered sympathetic stimulation mediated by the renin-angiotensin-aldosterone system (RAAS), decrease in preload, and decrease in myocardial oxygen demand. There are preclinical data from several studies that demonstrated direct benefit in RV function, exercise capacity, mortality, and reduction in fibrosis in rat models that had RV failure secondary to PH mediated by monocrotaline and Sugen-hypoxia.[60-62] However, these results have yet to translate into human clinical trials with most reporting no benefit or even potential harm including one small RCT in PAH patients treated with bisoprolol which demonstrated significant reductions in heart rate, cardiac index, and 6-minute walk time.[63] Not all β-blockers are equivalent, however. For example, nebivolol was shown to reduce PA smooth muscle cell proliferation and proinflammatory cytokines while increasing nitric oxide release in comparison to metoprolol.[64] Currently, β-blockers are not recommended for use in RV failure unless indicated for a concurrent comorbidity, such as left-sided HFrEF.

Similar to β-blockers, the use of ACE inhibitors and ARBs for treatment of RV failure is controversial. By suppressing the RAAS, these agents reduce sympathetic stimulation and reduce the progression of myocardial hypertrophy and fibrosis.[65] To date, trials have shown that ACE inhibitors increase RV filling time in patients with concurrent HFrEF, ARBs have been shown to attenuate RV dysfunction after myocardial infarction in animal models and improve RV-arterial coupling in animals with PAH. However, these trials were small and other trials have shown no clear hemodynamic benefits and an increased risk of hypotension.[17,66-68] Therefore, ACE inhibitors and ARBs are not recommended for use in RV failure unless indicated for a concurrent comorbidity. MRAs such as aldosterone have been shown to improve pulmonary vascular remodeling and reduce PA pressure, but no effect has been shown on RV function, which may suggest that its beneficial effects are secondary to afterload reduction.[69] Interestingly, retrospective analyses of the ARIES-1 and ARIES-2 trials suggest that patients treated with combination of ambrisentan, an endothelin type-A receptor inhibitor, and spironolactone had improved 6-minute walk times and a greater reduction in brain natriuretic peptide levels when compared to ambrisentan alone.[70] Thus, current trials with spironolactone are being conducted in patients with PAH (NCT01712620) and with chronic right heart failure (NCT03344159).

Sacubitril/valsartan is one of the newer agents available for the treatment of left-sided heart failure. It acts by combining the ARB mechanism of action of valsartan with

sacubitril, which is a neprilysin inhibitor that prevents the breakdown of natriuretic peptides. It was studied in patients with HFrEF and shown to have a reduction in all-cause mortality, cardiovascular mortality, and heart failure hospitalizations when compared to the ACE inhibitor, enalapril.[71] While there are limited data for patients with RV failure, a recently published trial suggests that this agent may prevent maladaptive RV remodeling via reduction of hypertrophy, afterload, prevention of RV-PA uncoupling, and prevention of myocardial stiffness in Sprague−Dawley rat model that had main PA banded.[72] Another preclinical trial demonstrated a significant reduction in RV pressure, RV hypertrophy, collagen content, PA pressures, and decreased pulmonary vascular wall thickness compared to valsartan alone and placebo in mice with PH.[73] Therefore, sacubitril/valsartan remains a promising agent for the treatment of RV failure.

Therapies targeting right ventricular afterload

This section will provide an overview of the different therapeutic approaches that reduce RV afterload. To accomplish this, a brief review of the relationship between resistance and compliance in the pulmonary vascular system (including resistance-compliance curves and ventricular−vascular coupling) will be provided, in order to fully understand the mechanisms of action and some of the current limitations of available therapeutic options. Other chapters in this textbook provide a more detailed discussion of pulsatile hemodynamics and ventricular−arterial interactions in the pulmonary circulation in general (Chapter 55), and in PH in particular (Chapter 56).

The most common cause of an increase in RV afterload is PH, which includes a wide spectrum of disorders with a common end result being an elevated PVR. PH is defined by a mean PA pressure >20 mmHg with a PVR ≥3 Wood units on RHC.[74] Table 58.1 lists an updated clinical classification of PH accordingly.

The majority of this section will focus on the various treatment agents available for Group 1 PAH, while the rest will explore the challenges associated with managing Group 2 PH.

Relationship between resistance and compliance

We earlier outlined the two components of afterload as PVR, which represents the steady-state load, and C_{PA}, which represents the pulsatile load. While these two components are conceptually two separate entities, they are dependent upon each other and changes in one factor will impact the other; this is particularly true in the pulmonary circulation. A dynamic, inverse relationship is present between these two factors that explains the treatment responses to pharmacologic agents that reduce afterload. The product of resistance (R) and compliance (C) is closely related to time constant (τ), or RC time, of diastolic pressure decay.[75] An inverse, hyperbolic relationship between the two has been shown to be relatively constant in patients with PH regardless of etiology and treatment.[76,77] The hyperbolic resistance−compliance relationship explains why patients with severe PH will require a much larger reduction in resistance when compared to patients with mild PH to achieve the same reduction in RV afterload. These patients with severe PH are on the right side of the RC curve, and thus reducing PVR has minimal impact on compliance. In contrast, patients with mild PH are located on the left side of the RC curve, and the same net reduction in PVR will have a more profound improvement in compliance (Fig. 58.5).

It also follows from this curve that a reduction in resistance will only affect the steady-state load in severe PH, whereas the same reduction will affect the steady-state and pulsatile load in mild PH.[76,78]

Ventricular−vascular coupling

The RV and the pulmonary vascular system work together as a cohesive unit rather than two separate entities, and the combination together is known as ventricular−vascular (RV−PA) coupling.[79] The most widely used approach to assess RV−PA coupling has been via the PV plane. For the application of this paradigm, the gold standard method of obtaining key parameters is via measurements of PV loops under varying loading conditions. In the PV plane, RV contractility is best represented by the slope of the end-systolic pressure volume relationship, and its slope is known as the end-systolic elastance (E_{es}), while RV afterload is best represented by the ratio of end-systolic pressure to SV, which is also known as E_a. The heart and pulmonary vascular system attempt to work under a state of maximal efficiency, and thus tries to maintain a ratio of 1.5−2. Normally, as the afterload in the pulmonary vasculature increases, the RV will first increase the contractility to match the corresponding increase in afterload. Initially, the RV will be able to compensate and maintain the ratio of 1.5−2 via adaptative mechanisms such as RV hypertrophy, but after a prolonged period of time, RV dilation occurs leading to an uncoupled state of the RV-PA unit with a ratio below 1.5.[80,81] Fig. 58.6 provides an example of the RV in a normal state, a normal, but compensated state, and an uncoupled state.

TABLE 58.1 Updated clinical classification of pulmonary hypertension.

Group 1: Pulmonary arterial hypertension (PAH)

(1) Idiopathic PAH
(2) Heritable PAH
(3) Drug-or-toxin-induced PAH
(4) PAH associated with:
   - Connective tissue disease
   - HIV infection
   - Portal hypertension
   - Congenital heart disease
   - Schistosomiasis
(5) PAH long-term responders to calcium channel blockers
(6) PAH with overt features of venous/capillaries (PVOD/PCH) involvement
(7) Persistent PH of the newborn syndrome

Group 2: PH due to left heart disease

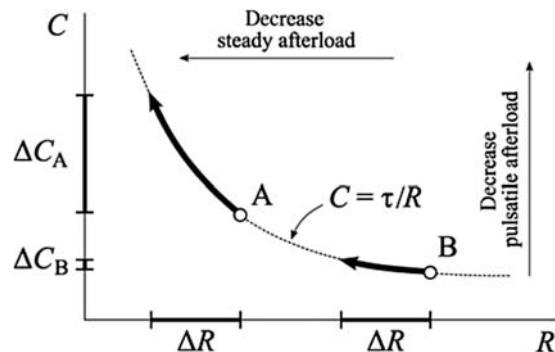
(1) PH due to heart failure with preserved LVEF
(2) PH due to heart failure with reduced LVEF
(3) Valvular heart disease
(4) Congenital/acquired cardiovascular conditions leading to postcapillary pH

Group 3: PH due to lung disease and/or hypoxia

(1) Obstructive lung disease
(2) Restrictive lung disease
(3) Other lung disease with mixed restrictive/obstructive pattern
(4) Hypoxia without lung disease
(5) Developmental lung disorders

Group 4: PH due to pulmonary artery obstructions

(1) Chronic thromboembolic PH
(2) Other pulmonary artery obstructions

Group 5: PH with unclear and/or multifactorial mechanisms


(1) Hematological disorders
(2) Systemic and metabolic disorders
(3) Others
(4) Complex congenital heart disease

Clinically, this is useful as it could be used to monitor the response of pulmonary vasodilator therapy on RV function or provide clinicians with a more accurate way of assessing RV dysfunction compared to conventional noninvasive methods. However, the acquisition of PV loops requires an invasive procedure and specialized costly equipment, limiting its performance to a few research centers. To overcome this limitation, several noninvasively derived parameters have been proposed as surrogates to E_{es}/E_a. The ratio of SV/ESV has been shown to be related to E_{es}/E_a and highly predictive of outcomes in PH.[82–84] SV/ESV can be measured with cardiac MRI or 3D echocardiography. The ratio of tricuspid annular plane systolic excursion to pulmonary artery systolic pressure as measured from echocardiography has also been shown to be a surrogate for E_{es}/E_a that also correlates with clinical outcomes in PH.[85] Such noninvasive estimates of RV−PA coupling may be useful for following treatment for PH and RV failure.

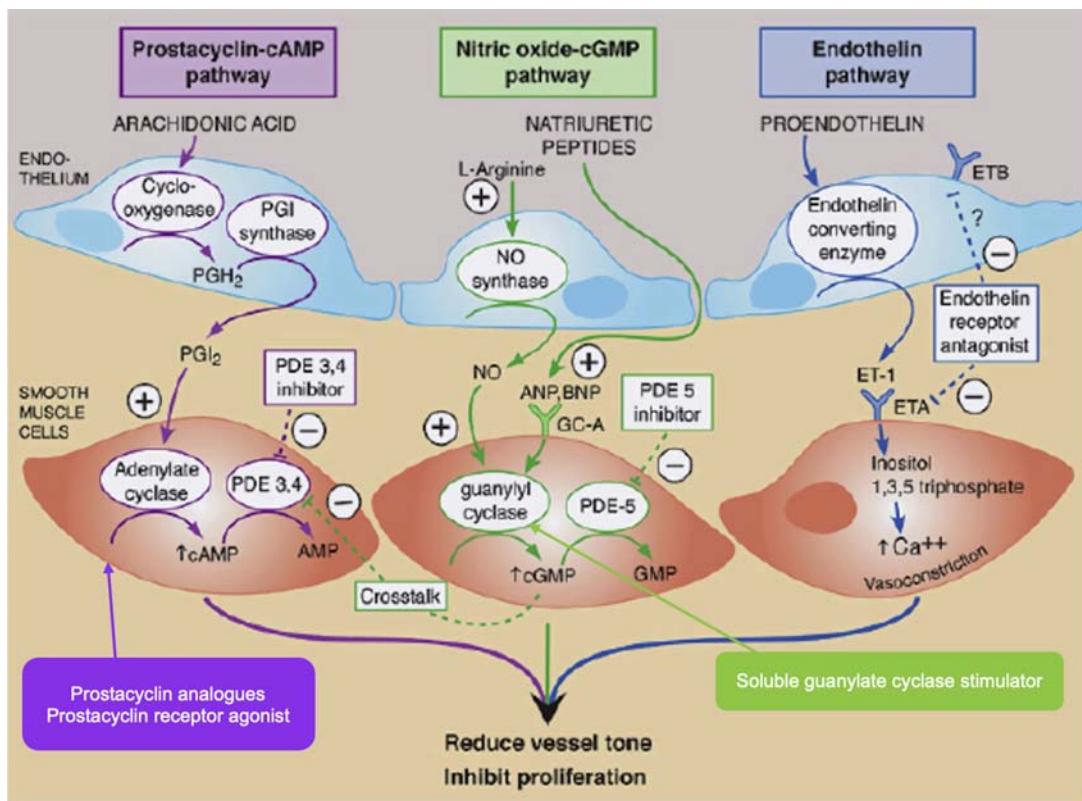
Therapeutic agents for treatment of pulmonary arterial hypertension


Group 1 PH, also referred to as PAH, is defined by a mean PA pressure >20 mmHg, PCWP ≤15 mmHg, and PVR ≥3 Wood units and due to a wide spectrum of disorders including idiopathic, familial, connective tissue disorders, HIV infection, and congenital heart disease.[74] While the exact pathophysiology has yet to be fully described, vasoconstriction, vascular remodeling of the pulmonary vessel wall, endothelial cell dysfunction, inflammation, and thrombosis in situ are all thought to be implicated, resulting in an elevated PVR.[86] Chronic alterations in these parameters lead to dysregulation of key vascular mediators such as nitric oxide, prostacyclin, and endothelin-1 which are the targets of the available therapeutic agents for the treatment of Group 1 PAH. Fig. 58.7 illustrates the key pathways of these hormones and the corresponding therapeutic agents that target them.

Prostacyclin analogues and prostacyclin receptor agonists are some of the most effective therapeutic agents currently available. Prostacyclin is a potent vasodilator that is produced by endothelial cells that works by stimulating the production of cyclic adenosine monophosphate (cAMP), inhibits growth of vascular smooth muscle cells, and is a powerful platelet aggregation inhibitor.[87,88] Epoprostenol is a synthetic prostacyclin with a half-life on an order of minutes which requires continuous intravenous administration. This agent has been extensively studied in patients with idiopathic PAH (IPAH) and PAH due to connective tissue disease revealing an improvement in WHO functional class, exercise capacity, and improvement in hemodynamics by causing a reduction in mean PA pressure and PVR, with an improvement in CO, and is the

FIGURE 58.6 Representative PV loops of the RV under different loading conditions. *Box A* (gray), shows an RV PV loop under optimal loading conditions with E_{es}/E_a ratio = 2. In *box B* (blue), RV afterload increased, but the RV contractility was able to compensate to maintain a normal E_{es}/E_a ratio. *Box C* (red) shows uncoupling of the RV-PA unit after further increases in RV afterload. *Reproduced from Vonk Noordegraaf A.* **J Am Coll Cardiol**. *2017; 69:236−243. only treatment available that has been shown to reduce mortality in IPAH.[89,90] For example, when compared to administration of conventional oral therapy at that time for patients with IPAH which included diuretics, supplemental oxygen, and oral vasodilators such as calcium channel blockers (CCBs), administration of epoprostenol was associated with improvement in quality of life metrics, average increase in 6 minute walk distance (6MWD) by 32 m, reduced mPAP by average of 8%, and reduced PVR by average of 21% when compared to baseline values. These hemodynamic benefits resulted in improvement in RV function, which was assessed by an average increase in SV of 6.2 ± 2.2 mL, and average increase in cardiac index of 0.3 ± 0.1 L/min/m^2 in the epoprostenol group.[90] Epoprostenol is often initiated at a low dose (2−4 ng/kg/min), and in an intensive care unit setting, can be titrated upwards by 2 ng/kg/min every few hours to achieve the optimal dose which is patient dependent and ultimately limited due to such as systemic hypotension, high output heart failure, flushing, headache, diarrhea, and muscle/joint aches. The main drawback with this agent is the need for permanent central venous access which greatly increases the risk of infection, pump malfunction, or drug interruption which can lead to a rebound increase in afterload if stopped abruptly and withheld for a long enough period of time.[91] Epoprostenol has been associated with worse outcomes in left-sided heart failure, and is therefore not indicated in this patient population.[92]

Iloprost and treprostinil are prostacyclin analogues that have the benefit of having a longer half-life. Iloprost is delivered via inhalation, while treprostinil is approved in formulations for IV, SQ, inhaled, and PO administration. Both iloprost and treprostinil have similar hemodynamic benefits when compared to epoprostenol. Administration of iloprost resulted in significant improvements in 6MWD of 36.4 m and an average reduction in mPAP of 4.6 ± 9.3 mmHg, and average reduction in PVR of

239 ± 279 dynes*sec*cm^{-5} from baseline values when compared to a placebo.[93] The benefits of continuous subcutaneous treprostinil was first illustrated in an RCT in 2002 that showed an improvement in median 6MWD of 16 m, and an average reduction in mPAP of 2.3 ± 0.5 mmHg, and average reduction in pulmonary vascular index (PVRI) of 3.5 ± 0.6 Wood units/m^2 from baseline values. An improvement in RV function was demonstrated by an average increase in CI of 0.12 ± 0.04 L/min/m2.[94] Inhaled treprostinil was associated with a median improvement in 6MWD of 18 m, while administration of the oral formulation was recently shown to delay clinical progression (defined as death form any cause, hospitalization for worsening PAH, disease progression, initiation of inhaled or infused prostacyclin therapy, or unsatisfactory clinical response) in patients already on oral monotherapy.[95–97] The IV formulation was shown to increase mean 6MWD by 125 m and result in a reduction in mPAP by 17% and PVRI by 50%, while increasing CI by 56% that was sustained up to 48 weeks in a multicenter, prospective trial.[98]

The most recent agent in the prostacyclin class is selexipag which is an oral prostacyclin IP receptor agonist, which is chemically distinct from prostacyclin. Selexipag has been reported to reduce PVR by 30.3% after 17 weeks in a phase 2 proof-of-concept study, improve WHO functional class, and reduce the composite endpoint of death from any cause or complication related to PAH according to the GRIPHON trial.[99,100] However, it should be noted that there was a significant increase in rates of medication discontinuation in patients on selexipag due to adverse effects including headache, diarrhea, nausea, and jaw pain.[99]

Phosphodiesterase type 5 (PDE5) inhibitors (sildenafil and tadalafil) reduce the enzymatic breakdown of cyclic guanosine monophosphate (cGMP), and thus increase NO levels leading to pulmonary vasodilation. Both agents have been shown to improve exercise capacity, quality of life, improve pulmonary hemodynamics by causing a reduction in mPAP and PVR, and reduce time to clinical worsening.[101–104] The SUPER trial was a double-blind, RCT that compared administration of sildenafil to a placebo and demonstrated significantly increased mean 6MWD of 45, 46, and 50 m from to baseline for 20 mg, 40 mg, and 80 mg doses of sildenafil, respectively. All sildenafil doses yielded significant hemodynamic benefits in a dose-dependent manner with a reduction in mPAP (4.7 mmHg, for 80 mg dose), PVR (261 dynes*sec*cm^{-5}), and increase in CI (0.37 L/min/m^2).[105] The SUPER-2 trial showed that the improvements in 6MWD were sustained for up to three years.[103] In addition to targeting the increased afterload, a smaller study has shown that sildenafil can improve RV

contractility in heart preparations and in individual cardiomyocytes.[106] Systemic vasodilation is the main side effect of this class of drugs which can cause systemic hypotension, headache, gastrointestinal disturbances, and muscle/joint aches. Sildenafil has been associated with worse outcomes in left-sided valvular heart disease, and thus its use is not indicated in this population.[107]

Riociguat is an oral soluble guanylate cyclase stimulant that enhances cGMP production, rather than inhibit its breakdown like the PDE5 inhibitors. Riociguat has shown beneficial effects in the PAH population in the PATENT-1 and PATENT-2 trials.[108,109] After 12 weeks when riociguat was compared to placebo, patients had a significant improvement in 6MWD as demonstrated by a mean increase in 30 m from baseline, reduction in mPAP of 4 ± 8 mmHg and PVR of 223 ± 260 dynes*sec*cm^{-5}, improvement in CO of 1 ± 1 L/min, and improvement in time to clinical worsening. This agent is also FDA approved for treatment of inoperable or persistent chronic thromboembolic pulmonary hypertension (CTEPH) and was shown to improve 6MWD by a mean of 39 m, reduce PVR by 226 dynes*sec*cm^{-5}, and improve functional class in this patient population.[110]

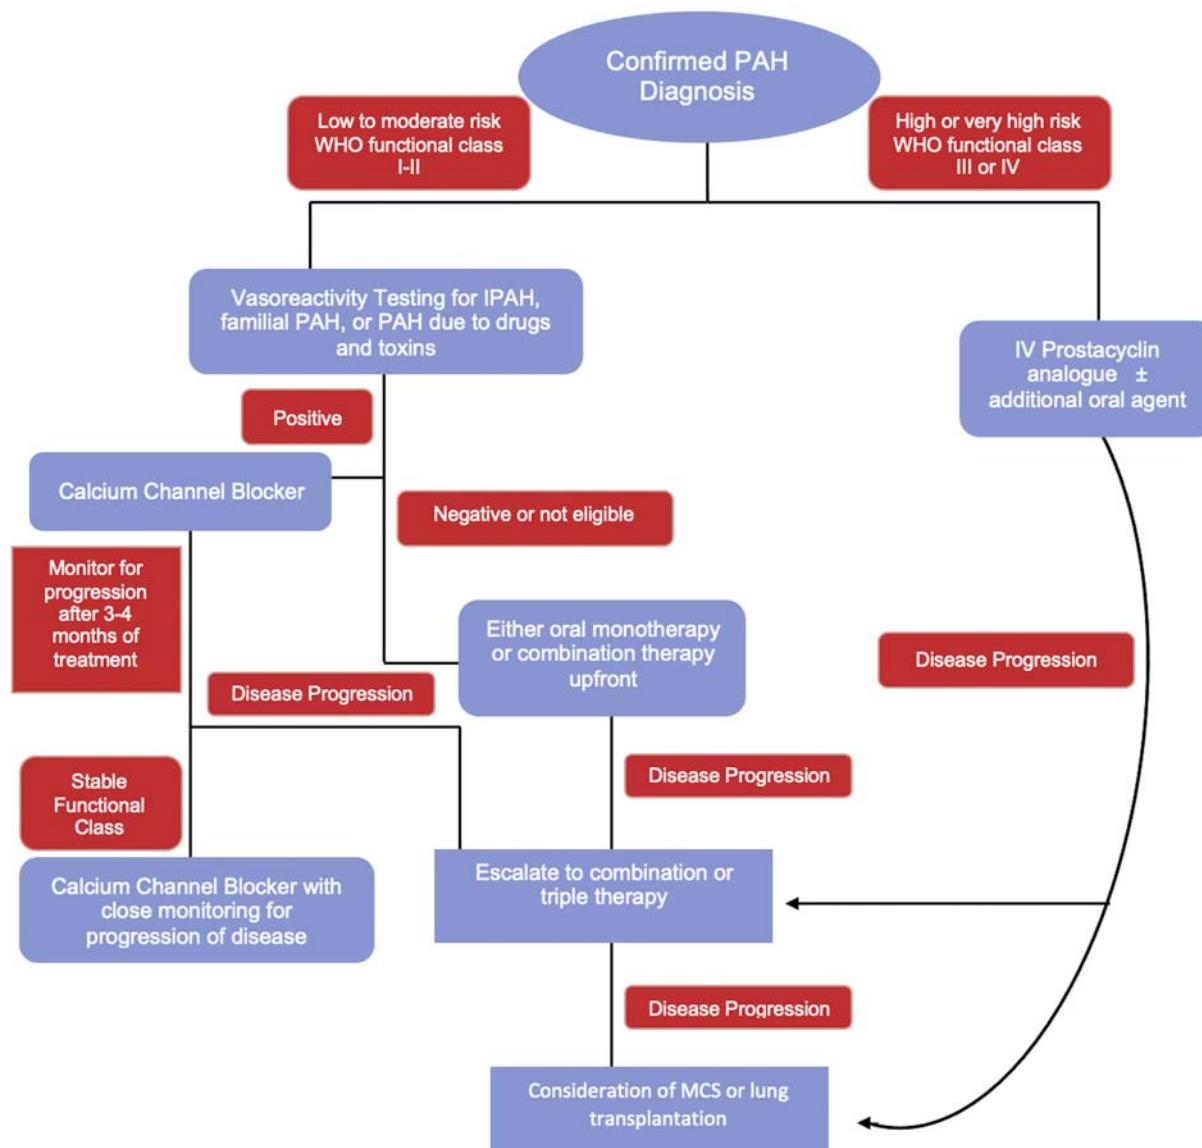
Endothelin-1 not only has a direct vasoconstrictor effect on the pulmonary vasculature but also can cause vascular smooth muscle cell proliferation leading to fibrosis, via endothelin receptor type A while endothelin receptor type B mediates endothelin-1 clearance.[111] Thus, therapeutic agents that modulate these receptors are attractive options, and include the nonselective receptor blockers macitentan and bosentan, while ambrisentan is a selective receptor A blocker. Ambrisentan has been analyzed in two RCTs (AIRES-1 and AIRES-2) in patients with moderate-severe IPAH and PAH due to connective tissue disorders (WHO functional class II–III) and found that ambrisentan delayed disease progression and clinical worsening, while improving exercise tolerance as demonstrated by a mean increase in 6MWD of 59 m, Borg dyspnea scale, WHO functional class, and quality of life compared to placebo.[112,113] Other trials have shown similar benefits with bosentan and macitentan, but due to the selective endothelin receptor type A effects of ambrisentan, this agent is often the initial choice. Endothelin receptor antagonists (ERAs) have also been shown to improve RV function as assessed by cardiac MRI in one study that demonstrated an increase in RV EF of $4.6 \pm 10.7\%$, LV EF of $3.6 \pm 9.8\%$, RV SV index 4.9 ± 10.5 mL/m^2, and improvement in CI of 0.33 ± 0.72 L/min/m^2 compared to placebo.[114] Furthermore, COMPASS 3 trial, which studied the use of bosentan $\pm$ sildenafil, found that cardiac MRI correlated strongly with RHC parameters at baseline, including a strong correlation between RVEDV: LVEDV, and a strong inverse

correlation between RVEDV:LVEDV to SVR:PVR.[115] The main adverse effects of this class include peripheral edema as well as hepatotoxicity causing elevated transaminase levels. However, the actual risk of hepatotoxicity for these agents, especially for ambrisentan, is quite small as this concern stemmed from the use of sitaxsentan which was withdrawn from the market following cases of severe hepatotoxicity. Bosentan has also been associated with worse outcomes in left-sided heart failure, so the use of ERAs as a class is not currently approved.[116]

CCBs currently have a limited role in the treatment of PAH since the development of newer, more effective therapeutic agents, but it still does have a niche for patients with a positive vasoreactivity test. CCBs cause smooth muscle relaxation leading to vasodilation in the pulmonary vascular circulation, but also causes systemic vasodilation and can lead to hypotension. In a vasoreactivity test, patients are administered a short acting pulmonary vasodilator, usually nitric oxide, epoprostenol, or adenosine, with a positive test defined as a reduction in mean PA pressure ≥ 10 mmHg to a value ≤ 40 mmHg without a significant reduction in MAP and unchanged CO. These patients potentially benefit from a short trial of three to four months of a high dose nifedipine, amlodipine, or diltiazem. Similar to the use of oral anticoagulation, vasoreactivity testing should not be performed in all patients with PAH, as it seems to have its greatest benefit in patients with IPAH, familial PAH, or PAH due to drugs or toxins, and little to no benefit in PAH due to connective tissue disorders, HIV, or portopulmonary hypertension.[117] Its increasingly recognized that among those patients that undergo vasoreactivity testing, only about 10%–20% of them will test positive, and out of those patients, an even smaller percentage will be able to tolerate the CCBs due to side effects and/or not require an additional agent due to progression of disease.[118]

Traditionally, anticoagulation was considered an essential therapy for all patients with PAH due to the increased risk of intrapulmonary vascular thrombosis, high prevalence of vascular thrombotic lesions in postmortem studies, and risk of hemodynamic collapse in this patient population with early studies suggesting possible benefit.[119–121] However, the overall data are inconclusive with recent trials suggesting no benefit of anticoagulation and even potential harm in patients with PAH secondary to connective tissue diseases.[122] There is a strong consensus that anticoagulation should therefore be avoided in patients with PAH secondary to connective tissue diseases, and the general trend is shifting toward avoiding anticoagulation unless there is a separate indication. If anticoagulation is to be used without a separate indication, it is recommended that it only be added for patients with idiopathic PAH (IPAH), familial PAH, or PAH due to anorexigens because the data show the most potential benefit in these groups.

Approach to the treatment of pulmonary arterial hypertension

While there is a number of different therapeutic agents available for the treatment of PAH as noted above, the approach to management of PAH can be quite nuanced and dependent on a number of different factors, with which a PAH specialist or center is able to assist. Once a diagnosis of PAH has been made by RHC, the patient should be classified into a low-risk, intermediate-risk, or high-risk category. There are several risk scoring systems with considerable data, including French Pulmonary Hypertension Network, 2015 ESC/ERS guidelines risk classification table, and REVEAL 2.0 which is shown in Fig. 58.8.[123–125]


These systems have highlighted the need to treat patients more aggressively to a goal of attaining the low-risk category in order to preserve RV function and improve clinical outcomes. The scores all include a measure of RV function and/or afterload. Fig. 58.9 depicts a proposed algorithm in the management of PAH based off of patient's baseline risk as well as WHO functional class.

In general, it is reasonable to consider vasoreactivity testing in patients whom are classified as low-to-moderate risk with WHO functional class I–III symptoms, only if they have IPAH, familial PAH or PAH due to drugs or toxins.[117] If positive, CCB monotherapy can be initiated for a short trial of 3–4 months to monitor for therapeutic response, which is defined as a same or improved hemodynamic response than what was seen on initial vasoreactivity testing, and usually a mean PA pressure <30 mmHg. As mentioned before, only about 5% of patients will fall into this category, so vasoreactivity testing is becoming less common.[118]

Patients typically present with functional limitation and intermediate or high-risk features since PH can be a challenging diagnosis with an average delay of two years to diagnosis.[74] This has underscored the need for early diagnosis. Patients are commonly considered either average or moderate-risk with either WHO functional class II or III symptoms. The main approach to management in this patient population involves upfront combination therapy, rather than monotherapy. The two classes of drugs that are often selected include an ERA along with a PDE5 inhibitor. The combination of ambrisentan and tadalafil was shown in the AMBITION trial to be associated with a 50% reduction in rate of clinical failure (mainly driven by decreased hospitalizations) as well improved exercise capacity.[126] Other drug combinations studied include tadalafil + bosentan, macitentan + sildenafil, selexipag + ERA.[99,127] Interestingly, there are data suggesting that the combination of sildenafil + bosentan is not beneficial which may be related to drug interactions.[128] Some clinicians argue for a staggered initiation with one agent added at a time in short succession,

FIGURE 58.8 REVEAL 2.0 risk calculator. A score 0−7 is considered low risk and is associated with a predicted one-year survival of ≥95%, 8 is considered average risk and is associated with a predicted one-year survival of 90% to <95%, 9 is considered moderate risk and is associated with a predicted one-year survival of 85% to <90%, 10−11 is considered high risk and is associated with a predicted one-year survival of 70% to <85%, and ≥12 is considered very high risk and is associated with a predicted one-year survival <70%. *Reproduced from Benza, RL. **Chest**. 2019; 2:323−337. FIGURE 58.9 A simplified algorithm for management of pulmonary arterial hypertension (PAH) based off of REVEAL 2.0 risk score and WHO functional class symptoms. *MCS*, Mechanical circulatory support.

which provides clinicians with the benefit of being able to accurately monitor response to adverse reactions of a specific agent while assessing treatment response, while data from the large RCTs seem to suggest that upfront, low-dose combination therapy is equally safe and effective.[126]

Patients considered high or very high-risk with WHO functional class III or IV symptoms are often treated initially with monotherapy in the parenteral prostacyclin analogue class with eventual goal of getting patient on combination therapy or even triple therapy.[123] Parenteral prostacyclin analogues are the most potent vasodilators available with immediate benefits often appreciated, which makes these agents useful in the ICU setting in patients with cardiogenic shock due to RV failure from PAH.

Intravenous epoprostenol was shown to improve mortality in patients with IPAH.[90]

With the exception of one trial of intravenous epoprostenol in IPAH and a few meta-analyses involving the parenteral prostacyclin analogues, these PH agents improve hemodynamics and exercise capacity while reducing progression of clinical worsening, but data on mortality are lacking. There have been few outcome-driven trials due to the number of patients required in a rare disease. More recent trials involving clinical outcomes such as GRIPHON and SERAPHIN utilized composite endpoints of clinical worsening.[99,127] Despite being some of the largest trials in PAH ever performed, it was not feasible to power these trials for mortality. It is also unknown if these therapeutic

agents would improve mortality in asymptomatic patients, or in patients with mild PH. The EDITA trial was a double-blinded, placebo-controlled RCT that studied the effect of initiating ambrisentan in patients with PAH due to systemic sclerosis with a mildly elevated mean PA pressure between 21 and 24 mmHg at rest or >30 mmHg with exercise. At six months, there was no significant different in mean PA pressures; however, patients treated with ambrisentan had a significant improvement in CI at rest of 0.36 ± 0.66 L/min/m^2 and with exercise of 0.7 ± 0.81 L/min/m^2, and reduction in PVR at rest of 0.70 ± 0.78 Wood units and with exercise of 0.84 ± 0.48 Wood units.[129]

More recently, upfront triple therapy has been studied. A small, retrospective pilot study of PAH patients looked at initiation of the combination of intravenous epoprostenol, bosentan, and sildenafil. Out of 19 patients, 17 (89%) were WHO functional class I or II, and 100% of the patients were alive at 3 years.[130] More recently, the TRITON study compared triple therapy with selexipag, macitentan, and tadalafil versus macitentan and tadalafil. While there was no difference in primary outcome of PVR, 6MWD, or N-terminal pro-brain natriuretic peptide levels, at 26 weeks, there was a nonsignificant 41% reduction in risk of disease progression in the triple therapy group suggesting a signal for improved long-term outcomes.[131] This treatment approach requires further study.

Of note, one of the ways to determine success of treatment is through monitoring change in PVR, which as mentioned before, ignores the pulsatile load that affects the RV. PA compliance has been shown to a more accurate predictor of mortality than PVR and often declines early in the disease process prior to any change in PVR.[132,133] For example, pulmonary vascular compliance has been shown to be a better predictor for long-term response to CCBs in patients with IPAH with positive vasoreactivity testing compared to PVR.[134] Thus, measuring the pulsatile load either invasively or via PA compliance might allow us to detect PH earlier and more accurately monitor treatment response.

Creation of palliative right-to-left shunts

The idea of creating a right-to-left shunt for treatment of PH and/or RV failure stems from anecdotal evidence demonstrating that patients with severe PAH whom had a patent foramen ovale (PFO) lived longer compared to those patients without a PFO, as well as in patients with Eisenmenger physiology having a lower right atrial pressure and higher CO compared to patients without Eisenmenger physiology.[135,136] Mechanistically, this occurs as blood is able to bypass the lungs and instead travel through a shunt at the interatrial level, thus increasing systemic CO while

also reducing RV pressure and unloading the RV. Blood is able to travel right-to-left due to the increased right-sided pressures that are greater than the left-sided pressures. However, this comes at a cost of worsening systemic arterial oxygen saturation as blood is shunted away from the lungs into the systemic circulation.

Balloon atrial septostomy is the most common procedure that utilizes this technique and involves perforating the septum at the interatrial level, and using balloons of increasing sizes in a "step-by-step" manner while measuring hemodynamic variables to ensure reduction in right-sided pressures and improvement in CO. The size of the shunt is ultimately limited by a drop in systemic arterial saturation of >10% from baseline or increased in LVEDP >18 mmHg.[137] An alternative procedure is called a Potts anastomosis which creates a surgical anastomosis between the left PA and the aorta, and thus mimics a patent ductus arteriosus. The main benefit of this method is that it does not lead to arterial oxygen desaturation in the upper part of the body and thus would have more oxygen to supply the brain and coronary arteries. Despite these theoretic benefits, this procedure is technically challenging to perform non-invasively and has almost exclusively been studied in small trials in children, and thus lacks the long-term data of balloon atrial septostomy.[137,138] An interatrial shunt device that is implanted transcutaneously via a catheter-based approach is being investigated for the treatment of PAH (NCT03838445).

Current guidelines recommend balloon atrial septostomy in patients with severe PAH who have refractory right-sided failure despite maximally tolerated medical therapy either for palliative purposes or as a bridge to transplantation. Contraindications to performing this procedure include patients with baseline arterial oxygen saturation <85%, patients with LV dysfunction or Group 2 PH, or patients with baseline right atrial pressure >20 mmHg since this will likely lead to acute pulmonary edema upon creation of the shunt.[123]

Approach to treatment of group 2 pulmonary hypertension

Group 2 PH, which is due to left-sided heart disease including HFrEF, HFpEF, valvular disease, etc., may be isolated postcapillary PH or combined pre- and post-capillary PH. Isolated postcapillary PH is defined as a mPAP >20 mmHg with PAWP >15 mmHg, and a PVR <3 Wood units. Combined pre- and postcapillary PH is defined as a mPAP >20 mmHg with PAWP >15 mmHg, but a PVR ≥3 Wood units. This is an important distinction, as this population exhibits an increased mortality and a phenotype that is more similar to PAH.[74,139,140]

Management of Group 2 PH focuses on treating the underlying etiology. For example, in patients with HFrEF, this often means diuretics to reduce the wedge pressure along with GDMT medications that have been shown to improve mortality. Agents that target a reduction in afterload via pulmonary vasodilation have yielded no benefit until recently. However, recently the VICTORIA trial demonstrated that vericiguat, an oral guanylate cyclase inhibitor, significantly reduced the composite endpoint of cardiovascular death and time to first heart failure hospitalization compared to placebo in patients with HFrEF, without an impact on mortality.[2] Vericiguat likely has multiple effects on the systemic vasculature, pulmonary vasculature, myocardium, and other organs, such that the extent to which pulmonary vascular effects are responsible for the improved outcomes seen in this trial is unclear.

Patients with PH associated with HFpEF (PH-HFpEF) represent a unique population that is much more challenging to manage as there are currently no approved therapeutic agents that have been shown to improve mortality in patients with HFpEF. Several possible explanations for a lack of benefit include different pathophysiologic mechanisms that lead to develop of HFpEF, rather than neurohormonal dysfunction that is prominent in HFrEF, and belief that HFpEF compromises a wide range of different phenotypes that might require a more personalized treatment strategy.[141] PH is not only a common complication of patients with HFpEF, but it is also an independent predictor of hospitalization and mortality.[25] Impairment in nitric oxide bioavailability is thought to play a role in the development of LV diastolic dysfunction and increased PA pressure, but trials using isosorbide mononitrate and inhaled sodium nitrite have not yielded positive results.[142,143] One possible reason is that the study population included patients with HFpEF rather than patients with PH-HFpEF. This may also have been associated with the neutral findings of the INDIE trial of inhaled sodium nitrite despite multiple earlier single center studies showing improvements in hemodynamics including PA compliance and impedance spectra, as well as functional capacity.[142,144−146] However, the very short half-life of inhaled sodium nitrite ($\sim$35 min) combined with the administration regimen (three times/day) in the INDIE trial may have been related to the failure of this preparation. Ongoing studies with orally administered inorganic nitrate (which has a half-life of several hours) are ongoing. A detailed discussion of agents that target the nitrate-nitrite-NO pathway can be found in Chapter 51; a detailed discussion of the role of these agents in HFpEF

can be found in Chapter 36. Finally, there are ongoing clinical trials that are examining the role of riociguat (NCT02744339) and tadalafil in patients with PH-HFpEF (2017-003688-37).

Advanced therapeutic options for treatment of right venrticular failure

Up to this point, various pharmacologic therapies have been presented with the goal of optimizing RV performance by modifying preload, contractility, perfusion, and afterload. However, there are occasions when the RV will continue to fail despite exhaustion of all possible medical and pharmacologic therapies, such as RV infarct, postcardiotomy ventricular failure, or RV failure after placement of a left ventricular assist device (LVAD). It is at this point, that advanced therapeutic options should be discussed, which include the use of mechanical circulatory support (MCS) devices and heart transplantation. Two major barriers to the use of the various MCS devices are the lack of durable, long-term options and, in the case of biventricular failure, the need for concurrent LV support. RV MCS devices work by reducing right-sided filling pressures while improving RV CO and therefore increasing LV preload. If the patient has concurrent LV failure, increasing the preload to the left side of the heart will result in acute pulmonary edema and the patient will continue to have low systemic perfusion.

One of the most commonly used MCS devices for RV failure is the RP Impella (Abiomed Inc, Danvers, MA), which is a percutaneous microaxial-flow device that sits in the RA and delivers blood to the PA, thus bypassing the RV. It can provide up to 4 L/min of additional flow while decreasing RA pressure, increasing right-sided CO, and increases preload to the left-side of the heart, thus improving systemic perfusion.[147] It does not have an oxygenator present, so is not effective for patients with severe PH who also have concurrent hypoxia. The RECOVER RIGHT trial demonstrated an improvement in RA pressure and cardiac index while also permitting weaning of inotropes and vasopressors in patients with acute RV infarct or postcardiotomy.[148] Common adverse effects include vascular access complications, including hematoma or dissection, as well as hemolysis.

Right ventricular assist devices (RVADs) have a similar mechanism to the RP Impella and include the TandemHeart RVAD (TandemLife, Pittsburgh, PA) and the Protek Duo cannula. These devices are an extracorporeal centrifugal-flow pump that has an inflow cannula in the RA that

bypasses blood externally before returning to the outflow cannula that is located in the PA. The RVADs are not only capable of providing RV support up to 4.5 L/min but are also able to have an oxygenator added to the circuit, and thus can be used for patients with an acute PE or decompensated, severe PH.[17,147] Studies have shown an improvement in RA and PA pressures, improvement in CO and RV stroke work, and improvement in oxygenation.[147] Common adverse effects include vascular access complications, bleeding, and thrombosis.

Venoarterial extracorporeal membrane oxygenation (VA-ECMO) displaces venous blood from the RA across an oxygenator and returns it to the arterial circulation. Unlike the RVADs, VA-ECMO will increase LV afterload due to the increase in blood return to the arterial circulation and can cause worsening cardiogenic shock and acute pulmonary edema if the patient also has LV dysfunction. In these instances, it is often necessary to implant an additional MCS device, such as an Impella device or intra-aortic balloon pump to help unload the LV and reduce left-sided filling pressures. Adverse events associated with ECMO include bleeding, thromboembolism, and vessel injury.[10,147]

As briefly mentioned above, MCS for RV failure is currently only designed for short-term use unlike the LVADs which have been approved for destination therapy. Thus, careful consideration must be taken among a multidisciplinary heart team, including heart failure specialists, interventional cardiologists, and cardiothoracic surgeons, prior to implantation as they are typically reserved for either a short-term bridge to recovery or bridge to transplantation. Currently, the CentriMag pump (St. Jude, Minneapolis, MN), an extracorporeal centrifugal-flow pump, is the longest duration support device available and is approved for use up to 30 days. Future studies are examining the feasibility of more durable RV support devices and include the HeartWare MVAD, the Circulite Synergy device, and the Syncardia total artificial heart (Syncardia Systems, LLC, Tucson, AZ).[149−151]

Emerging therapeutic options

Given the high morbidity and mortality associated with RV failure, there remains a strong need for novel therapeutic agents that target unique pathways contributing to RV dysfunction. As the severity of PH worsens, the RV will begin to dilate leading to left-to-right asynchrony, which can be visualized by septal bowing in early LV diastole on echocardiography. The RV volume will shift toward the relaxed LV leading to septal bowing, but this allows the pulmonary valve to close while the RV is still contracting

leading to increase in oxygen consumption and a decrease in early LV diastolic filling.[152,153] Therefore, it has been postulated that cardiac right-to-left resynchronization therapy by pacing the RV earlier might be beneficial for patients with severe PH and evidence of RV dilation and septal bowing. While cardiac resynchronization therapy is currently approved for patients with HFrEF and a wide QRS morphology in an effort to improve LV systolic dysfunction, data are limited in this patient population, mainly occurring in experimental animal models and one small trial in patients with CTEPH in which RV pacing reduced asynchrony, increased RV contractility, and improved LV diastolic filling time and SV.[154,155]

One of the mechanisms that is thought to contribute to RV dysfunction is activation of the RAAS and excess sympathetic tone. As discussed previously, while this pathway is important in the pathophysiology of HFrEF and inhibition of this pathway via ACE inhibitors or ARBs have resulted in an improvement in LVEF and mortality, these agents have had mixed results in isolated RV failure. Nevertheless, an emerging therapeutic option consists of directly blocking the excess sympathetic tone and bypassing the RAAS, via performing PA denervation. This is a minimally invasive catheter-based procedure that utilizes radiofrequency ablation to eliminate the PA baroreceptors located between the distal main trunk and ostial left branch, thus reducing sympathetic tone.[156,157] The benefits of PA denervation were studied in the PADN-5 trial which compared PA denervation to sildenafil plus a sham procedure in patients with combined pre- and postcapillary PH and found that PA denervation group had a higher 6MWD and lower PVR at 6 months.[158] Similar hemodynamic findings were shown in animal models with Group 1 PAH, and a clinical trial is planned (NCT02835950).[159]

Several other pharmacologic agents that are currently being investigated include antioxidant agents that target reactive oxygen species (ROS), fatty acid oxidation inhibitors, and antiinflammatory agents.[69,160] Studies to date with these agents have been limited to animal models or small clinical trials with the only randomized controlled trial being the use of trimetazidine, a fatty acid oxidation inhibitor, for patients post percutaneous coronary intervention which did not show any benefit, although this trial did not examine the benefits in isolated RV infarct.[161] Thus, further clinical trials are needed studying patients with RV failure and/or PH before widespread use will be adopted. Table 58.2 reviews the different therapeutic options along with brief description of mechanism of action and supporting trial data that has been discussed in this chapter.

TABLE 58.2 Overview of main therapeutic agents along with mechanism of action discussed throughout chapter.

Therapeutic agents	Mechanism of action	Trials
Diuretics		
• Furosemide • Torsemide • Bumetanide • Dialysis	Optimization of preload to improve RV stroke volume, reduce RV dilatation, reduce RV free wall tension	CARRESS-HF: Diuretics versus dialysis[39]
Vasopressors		
• Norepinephrine • Epinephrine • Dopamine • Vasopressin • Phenylephrine	- Increase perfusion by increasing blood pressure but may increase RV afterload - Epinephrine has some inotropic effect at low-dose - Vasopressin can cause pulmonary vasodilation via endothelial nitric oxide stimulation at low doses	Norepinephrine[45] Epinephrine[46] Vasopressin[47]
Inotropes		
• Dobutamine • Milrinone • Levosimendan	- Dobutamine: beta 1 and 2 receptor agonist - Milrinone: phosphodiesterase 3 inhibitor and often preferred agent due to mild pulmonary vasodilation properties - Levosimendan: myocardial calcium sensitizer	Levosimendan[56–59] Dobutamine and milrinone[6]
Neurohormonal modulation		
Beta-blockers (metoprolol succinate, carvedilol, bisoprolol, and nebivolol)	- Either selectively block beta-1 or 2 receptors, or nonselective blockade of both - Decrease in altered stimulation mediated by RAAS - Decrease in preload and decrease myocardial oxygen demand - Nebivolol may reduce PA smooth muscle proliferation	60,62 Bisoprolol[61,63] Nebivolol[64]
ACE inhibitors and ARBs	Blocks RAAS by either blocking angiotensin receptors or by inhibiting angiotensin converting enzyme	17,66–68
Mineralocorticoid receptor antagonist (aldosterone)	- Blocks aldosterone receptors to suppress RAAS stimulation - May also reduce afterload when combined with ambrisentan (AIRES trial)	ARIES trial[70] Use in PAH (NCT01712620) Use in RV failure (NCT03344159)
Sacubitril/valsartan	- ARB with a neprilysin inhibitor that inhibits breakdown of natriuretic peptides - May prevent maladaptive remodeling	72,73
Prostacyclin analogues and prostacyclin receptor agonists		
• Epoprostenol (IV) • Iloprost (Inhaled) • Treprostinil (IV, SQ, inhaled, PO) • Selexipag (PO)	- Either mimic prostacyclin or acts on receptor to increase production of prostacyclin which then increases production of cAMP and leads to vasodilation - Reduces mPAP and PVR; improves 6MWD and CO/CI - Epoprostenol improves mortality in IPAH	Epoprostenol[89,90,92] Iloprost[93] Treprostinil[94–98] Selexipag in GRIPHON trial[99,100]
Phosphodiesterase 5 inhibitors		
• Sildenafil • Tadalafil	- Reduces enzymatic breakdown of cGMP and increase levels of NO leading to pulmonary vasodilation - Reduces mPAP and PVR; improves 6MWD and CO/CI	Tadalafil[101] Sildenafil[102–107]
Oral soluble guanylate cyclase		
Riociguat	- Enhances cGMP production Also has benefit in Group 4 PH - Reduces mPAP and PVR; improves 6MWD and CO/CI	PAH[108,109] Group 4 PH[110]
Endothelin receptor antagonists		
• Ambrisentan • Bosentan • Macitentan	- Ambrisentan: receptor A blocker → blocks production of endothelin-1 - Bosentan and macitentan: receptor A and B blockers → blocks of production of endothelin-1 but also blocks clearance of endothelin-1 - Reduces mPAP and PVR; improves 6MWD and CO/CI	Ambrisentan[70,112,113] Bosentan in COMPASS 3[115]

TABLE 58.2 Overview of main therapeutic agents along with mechanism of action discussed throughout chapter.—cont'd

Therapeutic agents	Mechanism of action	Trials
Calcium channel blockers		
• Nifedipine, amlodipine, or diltiazem	- Blocks calcium channels leading to vasodilation - Need to be vasoreactivity testing positive to get benefit	117,118
Palliative right-to-left shunts		
• Balloon atrial septostomy • Potts anastomosis	- Creates a shunt at atrial level to improve CO while reducing RV pressure - Will cause hypoxia as a result so generally reserved for palliative cases - Potts anastomosis creates a shunt between left PA and aorta; does not cause hypoxia	Balloon atrial septostomy[135–137] Potts anastomosis[138] Transcutaneous interatrial shunt (NCT03838445)
RV resynchronization therapy		
	Paces RV earlier in order to reduce RV oxygen consumption and promote cardiac synchrony	154,155
PA nerve denervation		
	Eliminate the PA baroreceptors located between the distal main trunk and ostial left branch to reduce sympathetic tone that contributes to altered RV remodelling	PADN-5 Trial[158] 159 NCT02835950
Fatty acid oxidation inhibitors and antiinflammatory agents		
	- Reduce inflammation and inhibit production of fatty acid metabolism to reduce myocardial oxygen consumption	69,160 Trimetazidine[161]

6MWD, 6 minute walk distance; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *CI*, cardiac index; *CO*, cardiac output; *IPAH*, idiopathic pulmonary arterial hypertension; *mPAP*, mean pulmonary artery pressure; *NO*, nitric oxide; *PA*, pulmonary artery; *PVR*, pulmonary vascular resistance; *RAAS*, renin-angiotensin aldosterone system.

Conclusion

In conclusion, it is important to recognize and treat RV failure as it remains a strong predictor of mortality in patients with heart failure due to left-sided dysfunction and PH. Management requires optimization of several different parameters, including preload, contractility, myocardial perfusion, and afterload. As our understanding of the RV continues to grow, there is a push to better incorporate our understanding of the components of RV afterload that contribute to RV dysfunction (including pulsatile components, including wave reflections) into the design of agents that target these mechanisms in effort to improve outcomes.

TEXTBOOK OF
ARTERIAL STIFFNESS AND PULSATILE HEMODYNAMICS IN HEALTH AND DISEASE

VOLUME 2

Edited by

Julio A. Chirinos, MD, PhD, FAHA, FESC

Associate Professor of Medicine; Director, Arterial Hemodynamics and Cardiac Imaging Quantification Core Laboratory; Co-Director, Training Program in Cardiovascular Biology and Medicine, Clinical/Translational Science; Adjunct Faculty, Center for Magnetic Resonance and Optical Imaging. University of Pennsylvania Perelman School of Medicine, USA

Most biology-oriented books misinterpret or lack an in-depth discussion of key biophysical aspects of arterial stiffness and pulsatile arterial hemodynamics. A proper understanding of the field requires both biologic/clinical and biophysical/bioengineering knowledge which *Textbook of Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease* provides in a comprehensive yet simplified manner. The resource is organized into five parts covering principles, physiology, biologic pathways, clinical implications, and therapeutics and provides a thorough overview of the field, presenting complex engineering concepts in a way that those in life science and medicine can more easily understand.

Textbook of Arterial Stiffness and Pulsatile Hemodynamics in Health and Disease includes detailed illustrations and advanced bioengineering concepts presented in boxes for the reader who wants more in-depth biophysical knowledge. This is a must-have reference for students, researchers, and clinicians interested in learning more about this rapidly growing field.

Key features

- Provides a comprehensive review of the clinical implications of arterial stiffness and pulsatile hemodynamics and its role in human disease
- Incorporates mathematical principles explained in a conceptual manner without complicated formulas
- Features chapter contributions from leading international researchers and clinicians
